Consider now a family of one dimensional sources in the region $z>0$, locally described by[11]

$$\mathbf{X} = \mathbf{X}(\eta, n), \tag{10}$$

where n denotes the source and η labels the points on that source. From Eqs. (9) and (10), the images that the observer sees on the lens plane $z=0$, given by all the

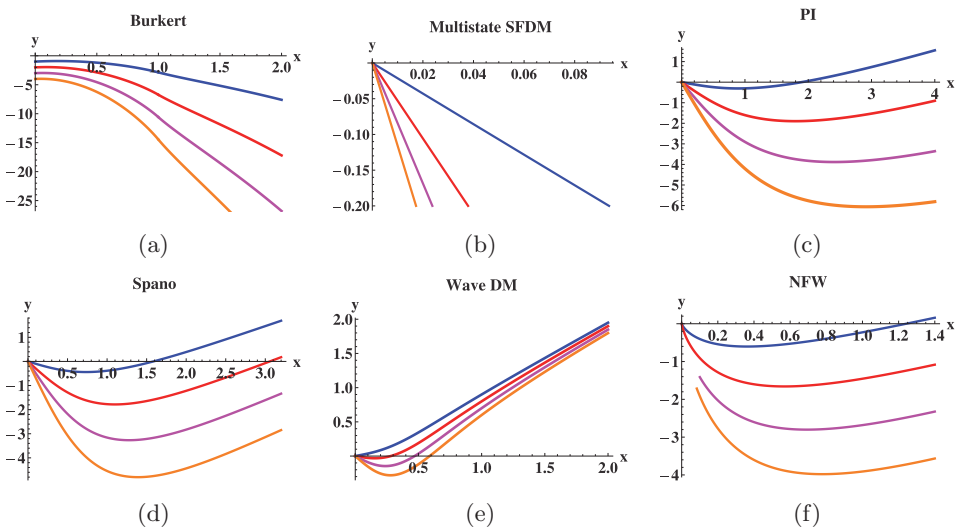

Fig. 1. Plots of the mapping $y = x - z_0\alpha$ for $z_0 = 1, 2, 3, 4$ and $n = 0$. The solutions for $x = 0$ in each profile denote the possible Einstein rings produced in each case. Notice that because in the Burkert and the multistate profiles, the curves does not intersect the horizontal axis, these profiles don't have Einstein rings.

points $(x\cos\phi, x\sin\phi, 0)$, where x and ϕ are solutions to[11]

$$\begin{aligned} X_s(\eta, n) &= [x - Z_s(\eta, n)\alpha(x)]\cos\phi, \\ Y_s(\eta, n) &= [x - Z_s(\eta, n)\alpha(x)]\sin\phi. \end{aligned} \tag{11}$$

Taking the simplest case for line sources that coincide with the x axis, the equations for obtaining the image for each fringe is determined by all the points in the lens plane such that[11]

$$X_s = [x - z_0\alpha(x)]\cos\phi, \tag{12}$$

$$n = [x - z_0\alpha(x)]\sin\phi, \tag{13}$$

with $-L \leq X_s \leq L$.

Now, Eq. (7) encodes the information related with the imaging formation process of the optical system, because describes how is the mapping of points from the lens plane to the source plane; the $\mathbf{X}$ is related with the usual lens mapping.

Because of the axial symmetry of the optical system, the caustic generated by the vector field (7), has a central branch (along the observation axis z). If this branch has contact with the source plane, the observed image is a ring; these are the *Einstein rings*.

In fact, for $n = 0$ (a source aligned exactly with the observation axis), these rings correspond to the roots of Eq. (13), and this is illustrated in Figs. 1. For example,

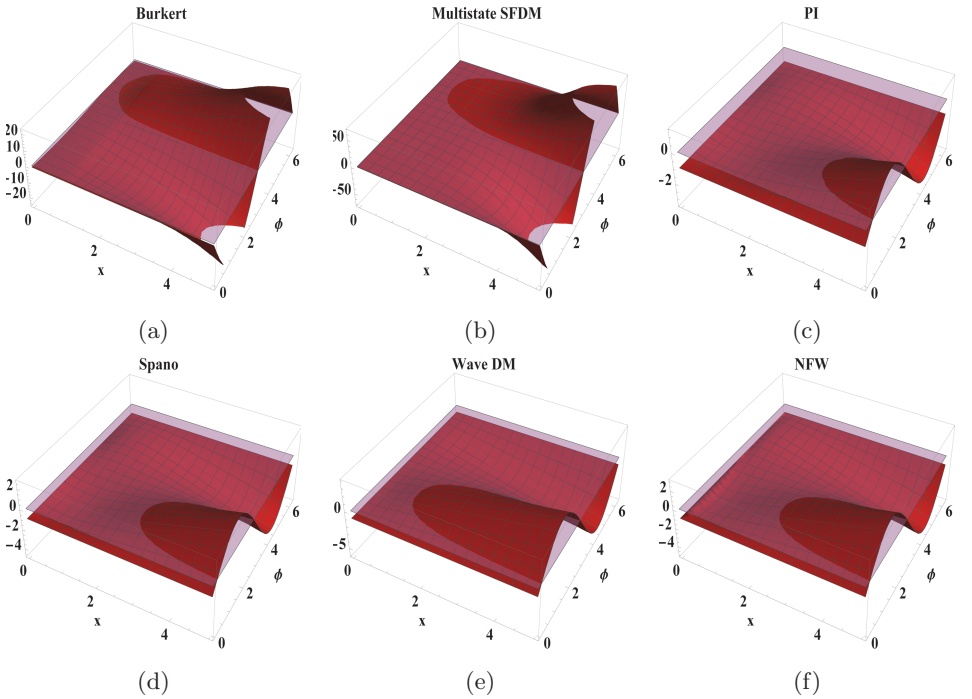

Fig. 2. Schematic of the surfaces representing the solutions of Eq. (13) for each profile on $z_0 = 1$ and $n = 1$. The pink plane intersecting each surface is the $P = 0$ plane. Observe that although the profiles present similar behaviour, the imaging formation process does not begin in the same values of x (neither the values of ϕ are the same).

observe that for the Burkert and Multistate profiles, this function have no roots, hence, they have no presence of Einstein rings for that positions of the source plane.

However, it is important to notice that these rings, are not the only images that could appear in this process. There is another branch of the caustic: a surface of revolution wrapped along the observation axis,[11] that also contributes to the images present on the lens plane, because a change to the source position does not lead to the change of the number of images unless a source moves along a caustic branch,[10] and this situation will appear, if the source and the lens plane are close enough, or in a position where this branch has contact with the source.

In this stage, we are only studying the simplest case, where we are not assuming that the source and the lens are close.

On the other hand, for $n \neq 0$, notice that in general, the deflection angle α is not an invertible function, therefore, it is necessary to find the solutions of Eq. (13) numerically. The above means to analyze Eq. (13) as a family of surfaces labeled by the n index, that are functions of x and ϕ (see Figs. 2).

By analyzing the intersections of these surfaces with the $P = 0$ plane, the image multiplicity according to the deflection angle α (see Fig. 2) can be found. The above

means to be able of identifying the differences on the values of x where the profile begins to generate images, or for the values of ϕ on each quadrant, where the images appear.

An important observation is that it has been shown that the DM central surface density μ_{DM} for all these profiles, is a constant (its values lie in the range $\mu_{DM} = (575 - 648) M_{\odot} \mathrm{pc}^{-2})$[2,7] and this fact will be very useful for eventual calculations on imaging formation, because this means that the r_s and ρ_s parameters are not independent from each other, and hence by fixing the conditions for one of them, we can establish the correct values for the β and σ parameters.

In fact, because the Navarro-Frenk-White (NFW) profile has been studied in several works,[8,9] it will be important to compare it with the other profiles, and these results must fit with the description of the physical behaviour in DM halos, for later comparing such information with that obtained in the NFW case based on experimental data, but only in the moment where all the profiles can be expressed in a comparable scale.

4. Conclusions

In this work, the analysis for the imaging formation process for dark matter halos has been performed. The goal is to understand if the optical information provided by the lens mapping, gives information about the physical processes that lies in the core of some types of galaxies.

The motivation behind this analysis, was to obtain the analytic equation for the optical mapping from the source plane to the lens plane, and translate directly such information into the images generated on the lens plane.

So far, we have find out that the formation of Einstein rings, depend on the solutions of Eq. (13), that is a projection of the $\mathbf{X}$ vector field (the equivalent of the usual lens mapping) on the lens plane. These calculations are helpful to differentiate the behavior of each profile, and this was carried out by obtaining the deflection angle, encoded in the $\mathbf{X}$ mapping, and later by analyzing the behavior of this function.

This was achieved by plotting the n surfaces that represent the solutions of Eq. (13) to identify the values that correspond to the zones where the imaging formation process begin.

An important observation is that, the ultimate goal for studying such process is to eventually address the problems of the ΛCDM on a small scale, because the NFW profile has problems in this region, and alternative models must be tested there. This means to have at hand an observational tool for testing the possible wave nature of the DM or the species diversity, basing the calculations in the soliton region, because it seems to be that this zone is established by means of an universal invariant μ_{DM} (with the correct values of r_s and ρ_s, that in turn determine our β and σ constants).

Finally, as a future goal based in this work, we consider that we will be able to "draw" the corresponding images mapped from sources (in this case lines) on the lens plane, that represent galaxies or other kind of cosmological objects, by making use of the **X** field. In fact, we already have used this process in the description of a Schwarzschild lens, and the plots allowed us to explicitly identify the positions of the images on the lens plane,[11] that is, by generating images to later compare them with visual data. We believe that the above, can be used as an efficient geometrical way to identify optical configurations, for later interpret the physical data encoded in such images in a nimbly way.

The self-gravitating Fermi gas in Newtonian gravity and general relativity

Pierre-Henri Chavanis

Laboratoire de Physique Théorique, Université de Toulouse, CNRS, UPS, France
E-mail: chavanis@irsamc.ups-tlse.fr

We review the history of the self-gravitating Fermi gas in Newtonian gravity and general relativity. We mention applications to white dwarfs, neutron stars and dark matter halos. We describe the nature of instabilities and phase transitions in the self-gravitating Fermi gas as energy (microcanonical ensemble) or temperature (canonical ensemble) is reduced. When $N < N_{\rm OV}$, where $N_{\rm OV}$ is the Oppenheimer-Volkoff critical particle number, the self-gravitating Fermi gas experiences a gravothermal catastrophe at E_c stopped by quantum mechanics (Pauli's exclusion principle). The equilibrium state has a core-halo structure made of a quantum core (degenerate fermion ball) surrounded by a classical isothermal halo. When $N > N_{\rm OV}$, a new turning point appears at an energy E_c'' below which the system experiences a gravitational collapse towards a black hole [P.H. Chavanis, G. Alberti, Phys. Lett. B **801**, 135155 (2020)]. When $N_{\rm OV} < N < N_*'$, the self-gravitating Fermi gas experiences a gravothermal catastrophe at E_c leading to a fermion ball, then a gravitational collapse at E_c'' leading to a black hole. When $N > N_*'$, the condensed branch disappears and the instability at E_c directly leads to a black hole. We discuss implications of these results for dark matter halos made of massive neutrinos.

Keywords: Fermi-Dirac statistics; White dwarfs; Neutron stars; Dark matter halos; Black holes

1. Introduction

The self-gravitating Fermi gas can have applications in different astrophysical systems ranging from white dwarfs and neutron stars to dark matter halos, where the fermions are electrons, neutrons and massive neutrinos respectively. The study of the self-gravitating Fermi gas is also of fundamental conceptual importance as it combines quantum mechanics and general relativity. Initially, fermionic models were developed at zero temperature ($T = 0$) but they have been later generalized at nonzero temperature, especially in the case of dark matter halos. In these Proceedings, we provide a brief history of the self-gravitating Fermi gas. A more detailed historical account of the statistical mechanics and thermodynamics of self-gravitating systems (classical and quantum) in Newtonian gravity and general relativity can be found in Refs.[1–4].

The statistical equilibrium state of a system of self-gravitating fermions can be determined from a maximum entropy principle. For systems with long-range interactions the mean field approximation becomes exact in an appropriate thermodynamic limit.[3,5] The most probable distribution of an isolated system of self-gravitating fermions at statistical equilibrium is obtained by maximizing the Fermi-Dirac

entropy S at fixed mass-energy $\mathcal{E} = Mc^2$ and particle number N:

$$\max \left\{ S \quad | \quad \mathcal{E} = Mc^2, \quad N \quad \text{fixed} \right\}. \tag{1}$$

The variational problem for the first variations reads

$$\delta S/k_B - \beta_\infty \delta \mathcal{E} + \alpha \delta N = 0, \tag{2}$$

where $\beta_\infty = 1/k_B T_\infty$ and $\alpha = \mu_\infty / k_B T_\infty$ are Lagrange multipliers associated with the conservation of mass-energy and particle number. Here, T_∞ and μ_∞ represent the temperature and the chemical potential measured by an observer at infinity. The maximization problem (1) is associated with the microcanonical ensemble. If the system is in contact with a thermal bath fixing the temperature T_∞ the statistical equilibrium state is obtained by minimizing the free energy $F = \mathcal{E} - T_\infty S$ at fixed particle number N:

$$\min \left\{ F = \mathcal{E} - T_\infty S \quad | \quad N \quad \text{fixed} \right\}. \tag{3}$$

This minimization problem is associated with the canonical ensemble. At $T = 0$ the equilibrium state is obtained by minimizing the mass-energy $\mathcal{E} = Mc^2$ at fixed particle number N. The equilibrium states in the microcanonical and canonical ensembles are the same. They are determined by the variational principle (2). However, their stability may differ in the two ensembles. This is the notion of ensemble inequivalence for systems with long-range interactions.[3,5] Microcanonical stability implies canonical stability but the converse is wrong.

The equilibrium state of a gas of self-gravitating fermions results from the balance between the repulsion due to the quantum pressure (Pauli's exclusion principle) and the gravitational attraction. The variational principle (2) yields all the equations that we need to determine the equilibrium state of the self-gravitating Fermi gas: (i) the Fermi-Dirac distribution function; (ii) the ideal equation of state of fermions; (iii) the Oppenheimer-Volkoff equations determining the condition of hydrostatic equilibrium in general relativity; (iv) the Tolman-Klein relations expressing how the local temperature $T(r)$ and the local chemical potential $\mu(r)$ are affected by the metric. We can solve these equations numerically and plot the caloric curve $T_\infty(\mathcal{E})$ relating the temperature to the energy. When $T > 0$ we need to enclose the system within a spherical box of radius R in order to prevent its evaporation and have equilibrium states with a finite mass. In the general case, the caloric curve depends on N and R. For convenience, instead of $T_\infty(\mathcal{E})$, we shall plot $\beta_\infty(-E)$ where $E = (M - Nm)c^2$ is the binding energy which reduces to the usual energy $E = K + W$ (kinetic + potential) in the nonrelativistic limit $c \to +\infty$. At $T = 0$, the system is self-confined (without the need of a box) and we shall plot the mass-radius relation $M(R)$ where R denotes here the radius where the density vanishes. The maximum entropy formalism for classical and quantum self-gravitating systems in Newtonian gravity and general relativity is reviewed in Refs.[3,4] where all the equations are derived and an exhaustive list of references is given.

2. Self-gravitating fermions at $T = 0$

The study of a self-gravitating gas of fermions started in the context of white dwarf stars when Fowler[6] first realized that these compact objects owe their stability to the quantum pressure of the degenerate electron gas. Indeed, the quantum pressure arising from the Pauli exclusion principle is able to counteract the gravitational attraction and explain the very high densities of white dwarf stars. Early studies were devoted to determining the ground state ($T = 0$) of the system. Nonrelativistic white dwarf stars are equivalent to a polytropic gas of index $n = 3/2$. Their density profile can be obtained by solving the Lane-Emden equation numerically. The density profile of white dwarf stars at $T = 0$ has a compact support, i.e., the density vanishes at a finite radius. The mass-radius relation of nonrelativistic white dwarf stars was first obtained by Stoner,[7] Milne[8] and Chandrasekhar.[9a] They showed that the radius of the star decreases as the mass increases according to the law $M = 91.9\,\hbar^6/(G^3m^8R^3)$ (see Fig. 1-a).[11] All the configurations of the series of equilibria are stable.

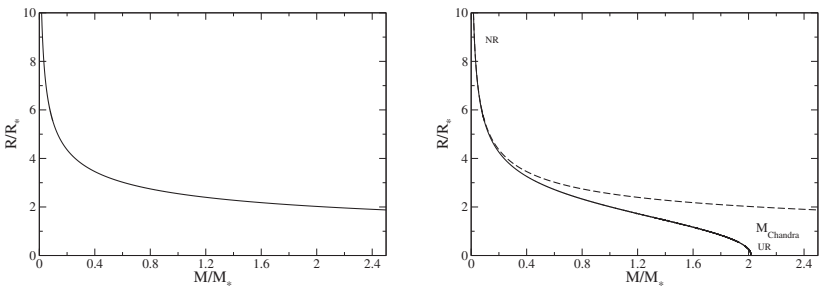

Fig. 1. Mass-radius relation of self-gravitating fermions at $T = 0$ in Newtonian gravity (the mass is normalized by $M_* = (3\pi/4)^{1/2}\hbar^{3/2}c^{3/2}/(G^{3/2}m^2)$ and the radius by $R_* = (3\pi/4)^{1/2}\hbar^{3/2}/(c^{1/2}G^{1/2}m^2)$). (a) Nonrelativistic white dwarf stars. (b) Special relativistic white dwarf stars.

The fact that relativistic effects become important in white dwarf stars whose mass is of the order of the solar mass was first reported by Frenkel[12] in a not well-known paper. However, he did not consider the implications of this result. Special relativistic effects in white dwarf stars were studied in detail by Anderson,[13] Stoner,[14] Chandrasekhar,[15] and Landau.[16] They found that no equilibrium state is possible above a maximum mass, now known as the Chandrasekhar limit.[b] These authors considered the equation of state of a relativistic Fermi gas at $T = 0$ and

[a]Stoner[7] developed an analytical approach based on a uniform density approximation for the star while Milne[8] and Chandrasekhar[9] developed a numerical approach based on the Lane-Emden theory of polytropes.[10]

[b]See the introduction of Ref.[17] for a short history of the discovery of the maximum mass of white dwarf stars.

used Newtonian gravity appropriate to white dwarf stars.[c] An ultrarelativistic Fermi gas at $T = 0$ is equivalent to a polytrope of index $n = 3$. Its density profile is obtained by solving the corresponding Lane-Emden equation and it has a compact support. For a polytrope $n = 3$, the mass-radius relation degenerates and indicates that different configurations with an arbitrary radius can exist at the same mass $M_{\rm Chandra} = 3.1\, M_P^3/m^2 = 1.5\, M_\odot$, where $M_P = (\hbar c/G)^{1/2}$ is the Planck mass and m is the proton mass. This argument immediately implies the existence of a critical mass.[15] In a more detailed study, Chandrasekhar[22] considered partially relativistic configurations and numerically obtained the complete mass-radius relation of white dwarf stars, valid for arbitrary densities, joining the nonrelativistic limit to the ultrarelativistic one (see Fig. 1-b).[d] As M approaches $M_{\rm Chandra}$ the radius of the star tends to zero while its density tends to infinity, leading to a Dirac peak. This study unambiguously shows the absence of equilibrium state above a maximum mass. Therefore, the quantum pressure arising from the Pauli exclusion principle cannot balance the gravitational attraction anymore when the star becomes sufficiently relativistic (or when its mass is too large). This is a striking effect of relativity combined with quantum mechanics and gravity. However, the result of Chandrasekhar[22] was severely criticized by Eddington[23] who argued that the absence of equilibrium states above a maximum mass leads to a *reductio ad absurdum* of the formula of relativistic degeneracy. Although the arguments of Eddington were entirely unfounded, his enormous prestige led to an early rejection of Chandrasekhar's work by many in the astronomical community. This pushed Chandrasekhar to abandon the subject, and delayed the discovery of the phenomenon of gravitational collapse and the concept of black hole.

In the following years, similar results were found by Oppenheimer and Volkoff[24] in connection to neutron stars. They solved the equations of general relativity with the relativistic equation of state for fermions at $T = 0$ and found that the mass-radius relation of neutron stars presents a turning point of mass (see Fig. 2).[e] As a result, no equilibrium state exists above a maximum mass $M_{\rm OV} = 0.384\, M_P^3/m^2 = 0.710\, M_\odot$, where m is the neutron mass, called the Oppenheimer-Volkoff limit (note that the density profile with the maximum mass $M_{\rm OV}$ is *not* singular contrary to the Newtonian density profile at the maximum mass $M_{\rm Chandra}$). They argued that, above that mass, the star undergoes gravitational collapse. This problem was specifically studied by Oppenheimer and Snyder[25] who obtained an analytical solution of the Einstein equations describing the collapse of a pressureless gas up to its

[c] In principle, general relativistic effects become important close to the Chandrasekhar maximum mass[18,19] but other phenomena like Coulomb corrections to the electron pressure and the formation of neutrons by inverse beta decay destabilize the star before general relativistic effects come into play.[20,21]

[d] A similar mass-radius relation was obtained earlier by Stoner[14] from an approximate analytical model based on uniform density stars.

[e] It was shown later that the mass-radius relation of neutron stars forms a spiral and that a mode of stability is lost at each turning point of mass.[21]

Schwarzschild radius. Strangely enough, these important results did not receive much attention until the 1960's. At that epoch, detailed models of compact objects with more realistic equations of state taking into account the repulsive effect of nuclear forces and connecting white dwarfs to neutron stars were constructed and the fundamental discoveries of Chandrasekhar, Landau and Oppenheimer and Volkoff were confirmed (unfortunately, the early contributions of Anderson and Stoner were forgotten).[21] Pulsars were discovered by Hewish *et al.*[26] in 1968. The same year, Gold[27,28] proposed that pulsars are rotating neutron stars, and this is generally accepted today. It is also at that moment that the name "black hole" was used by Wheeler[29] to designate the object resulting from gravitational collapse, and became popular.

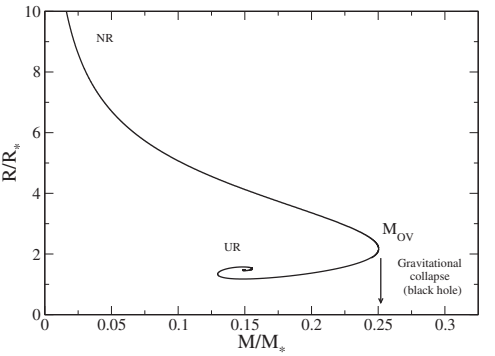

Fig. 2. Mass-radius relation of self-gravitating fermions at $T = 0$ in general relativity (neutron stars).

3. Nonrelativistic classical particles at $T > 0$ and self-gravitating radiation

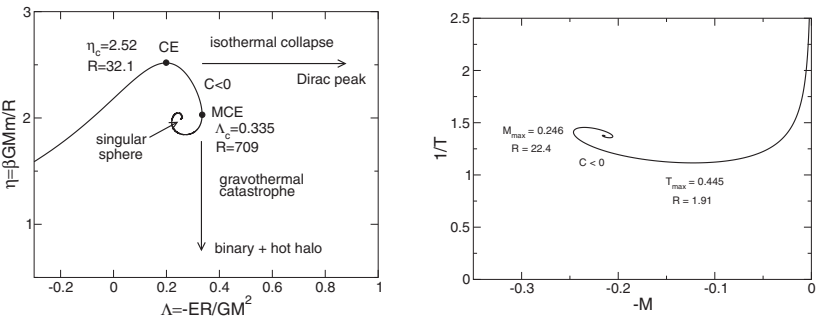
The thermodynamics of self-gravitating systems is a fascinating subject.[30–32] Its study started with the pioneering work of Antonov[33] who considered an isolated system of nonrelativistic classical particles in gravitational interaction. He used a microcanonical ensemble description in which the mass and the energy are conserved. This situation applies approximately to stellar systems like globular clusters. Their equilibrium state (most probable state) can be obtained by maximizing the Boltzmann entropy S at fixed mass M and energy E.[34] This leads to the mean field Boltzmann distribution which is self-consistently coupled to the Poisson equation. The Boltzmann-Poisson equation was previously introduced and studied in the context of isothermal stars.[10,11] It can be reduced to the Emden equation that has to be solved numerically. Antonov[33] observed that no maximum entropy state exists in an infinite domain (the solution of the Emden equation has an infinite mass), so he proposed to confine the particles within a spherical box of radius R.

This artifice prevents the evaporation of the system and leads to a well-defined mathematical problem. By computing the second variations of entropy, Antonov[33] showed that equilibrium states with a density contrast $\mathcal{R} = \rho_0/\rho(R) < 709$, where ρ_0 is the central density and $\rho(R)$ the density on the edge of the box, are thermodynamically stable (entropy maxima) while equilibrium states with a density contrast $\mathcal{R} > 709$ are thermodynamically unstable (saddle points of entropy). Lynden-Bell and Wood[35] rediscussed the results of Antonov[33] in more physical terms. They plotted the series of equilibria $E(\mathcal{R})$ and showed that it displays damped oscillations. As a result, there is no equilibrium state with an energy $E < E_c = -0.335\,GM^2/R$, where E_c corresponds to the first turning point of energy (with a density contrast $\mathcal{R}_c = 709$). Invoking the Poincaré turning point criterion,[36] they concluded that the series of equilibria becomes unstable at the minimum energy E_c. In this manner, they recovered the critical density contrast $\mathcal{R}_c = 709$ found by Antonov.[33] They also interpreted the Antonov instability in terms of a "gravothermal catastrophe" caused by the negative specific heat of the system in its densest parts. When this instability occurs, the system undergoes core collapse. This ultimately leads to a binary star surrounded by a hot halo. Lynden-Bell and Wood[35] considered other statistical ensembles, notably the canonical ensemble in which the temperature and the mass are fixed. In that case, the equilibrium state is obtained by minimizing the Boltzmann free energy $F = E - TS$ at fixed mass M. The series of equilibria $T(\mathcal{R})$ displays damped oscillations. No equilibrium state exists with a temperature $T < T_c = 0.397\,GMm/(k_B R)$, where T_c corresponds to the first turning point of temperature (with a density contrast $\mathcal{R}'_c = 32.1$).[f] Using the Poincaré turning point criterion,[36] they concluded that equilibrium states with a density contrast $\mathcal{R} < 32.1$ are thermodynamically stable (free energy minima) while equilibrium states with a density contrast $\mathcal{R} > 32.1$ are thermodynamically unstable (saddle points of free energy). Below T_c the system undergoes an "isothermal collapse" leading to a Dirac peak containing all the particles. Since the stability limits in the microcanonical and canonical ensembles differ, Lynden-Bell and Wood[35] encountered for the first time in statistical mechanics a situation of ensemble inequivalence. This is a peculiarity of systems with long-range interactions.[5] In the present context, it is related to the fact that negative specific heats are allowed in the microcanonical ensemble while they are forbidden in the canonical ensemble.[35] Similar results were obtained independently by Thirring.[37] Katz[38] plotted the caloric curve $\beta(E)$ of isothermal self-gravitating spheres and exhibited its spiral behavior (see Fig. 3-a).[g] He also extended the Poincaré theory on linear series of equilibria[36] to the case where there are several turning points and developed a general method to determine the thermodynamical stability of the equilibrium states from the topology of the caloric

[f] These results were first found by Emden.[10]

[g] This spiral behavior was previously observed for self-gravitating isothermal stars in other representations.[11,39–44] In the present case, it is associated with the damped oscillations of energy and temperature as a function of the density contrast.

curve $\beta(E)$. A change of stability can only occur at a turning point of energy in the microcanonical ensemble or at a turning point of temperature in the canonical ensemble. A mode of stability is lost if the curve $\beta(-E)$ turns clockwise and gained if it turns anticlockwise. In this manner, one can determine the thermodynamical stability of the system by simply plotting the caloric curve (series of equilibria). The seminal works of Antonov,[33] Lynden-Bell and Wood,[35] and Katz[38] were followed by many other studies (see, e.g., Refs.[45–52]).



(a) (b)

Fig. 3. (a) Caloric curve of nonrelativistic classical self-gravitating particles (cold spiral).[32] We have plotted the normalized inverse temperature $\eta = \beta GMm/R$ as a function of minus the normalized binding energy $\Lambda = -ER/GM^2$. (b) Caloric curve of the self-gravitating radiation in general relativity (hot spiral).[54] We have plotted the normalized inverse temperature $\hbar^{3/4}c^{7/4}/(k_B T_\infty G^{1/4}R^{1/2})$ as a function of minus the normalized energy $-GM/Rc^2$.

The statistical mechanics of the self-gravitating black-body radiation (photon star) confined within a cavity in general relativity was investigated by Sorkin *et al.*[53] and, more recently, by Chavanis.[54] They showed that the caloric curve $\beta_\infty(\mathcal{E})$ forms a spiral (see Fig. 3-b). There is no equilibrium state above a maximum mass-energy $M_{\max}c^2 = 0.246\, Rc^4/G$ (corresponding to a density contrast 22.4) or above a maximum temperature $(T_\infty)_{\max} = 0.445\, \hbar^{3/4}c^{7/4}/(k_B G^{1/4}R^{1/2})$ (corresponding to a density contrast 1.91). In that case, the system is expected to collapse towards a black hole. We note that the "hot spiral" (see Fig. 3-b) of the self-gravitating radiation in general relativity (ultrarelativistic limit) is inverted with respect to the "cold spiral" of the nonrelativistic classical self-gravitating gas (see Fig. 3-a).

4. Classical particles at $T > 0$ in general relativity

The statistical mechanis of classical particles in general relativity has been considered by Roupas[55] and, independently, by Alberti and Chavanis.[1] The caloric curve depends on one parameter, the particle number N (more precisely N/R). Generically, the caloric curve $\beta_\infty(E)$ has the form of a double spiral (see Fig. 4) which combines the aspects of the "cold spiral" corresponding to a nonrelativistic gas and the aspects of the "hot spiral" corresponding to an ultrarelativistic gas discussed

in Sec. 3.[h] There is no equilibrium state below a minimum energy (resp. minimum temperature) and above a maximum energy (resp. maximum temperature) in the microcanonical (resp. canonical) ensemble. When the number of particles N increases, the two spirals approach each other, merge, form a loop, and finally disappear (by reducing to a point) at $N_{\max} = 0.1764\, Rc^2/Gm$. For $N > N_{\max}$, there is no equilibrium state whatever the value of mass-energy and temperature.

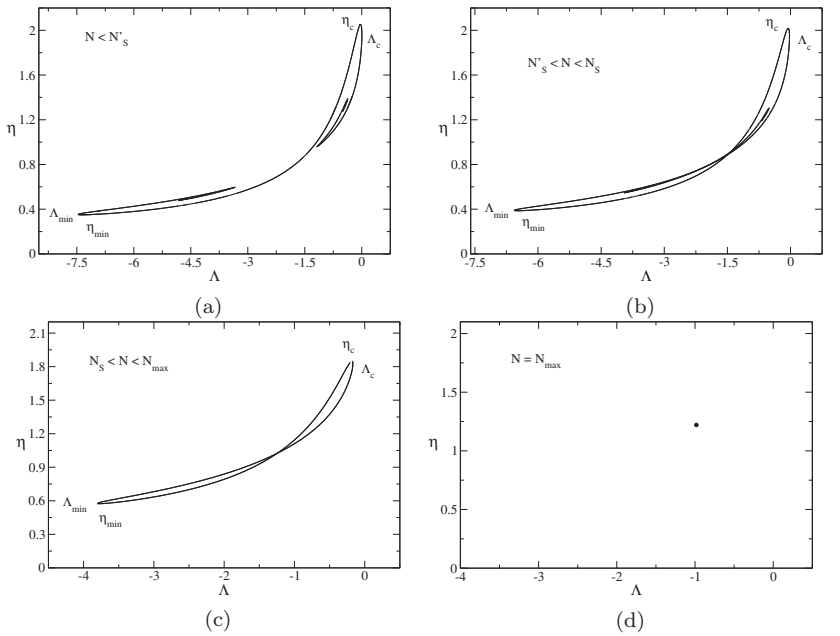


Fig. 4. Caloric curve of classical particles in general relativity. We have plotted the normalized inverse temperature $\eta = \beta_\infty GNm^2/R$ as a function of minus the normalized binding energy $\Lambda = -ER/GN^2m^2$ for different values of the normalized particle number $\nu = GNm/Rc^2$. (a) Double spiral (b) Merging (c) Loop (d) Point.[1]

5. Nonrelativistic fermions at $T > 0$

The statistical mechanics of self-gravitating fermions at nonzero temperature was first studied by Hertel and Thirring[56,57] as a simple (nonrelativistic) model of neutron stars. In that case, the density profile decreases with the distance as r^{-2} and we need to confine the system within a box in order to have an equilibrium state with a finite mass. Hertel and Thirring[56] rigorously proved that the mean field approximation (which amounts to neglecting correlations among the particles) and the Thomas-Fermi approximation (which amounts to neglecting the quantum potential)

[h]The hot spiral of ultrarelativistic classical particles in general relativity is similar, but not identical, to the hot spiral of the self-gravitating radiation.[1,3,54]

become exact in a proper thermodynamic limit where $N \to +\infty$. This leads to the Fermi-Dirac-Poisson equations, also known as the temperature-dependent Thomas-Fermi equations. Hertel and Thirring[57] solved these equations numerically and plotted the caloric curve. The caloric curve depends on one parameter, the box radius R (more precisely NR^3). They found that, for sufficiently large systems ($R > R_{\rm CCP} = 12.8\,\hbar^2/(N^{1/3}Gm^3)$), a negative specific heat region occurs in the microcanonical ensemble (see Fig. 5). Since negative specific heats are forbidden in the canonical ensemble, this implies that the statistical ensembles are inequivalent. The region of negative specific heats which is allowed in the microcanonical ensemble is replaced by a first order phase transition in the canonical ensemble. This phase transition is expected to take place at a transition temperature T_t connecting the gaseous phase to the condensed phase through a horizontal Maxwell plateau in the caloric curve $T(E)$. This is accompanied by a discontinuity of energy. There is also a lower critical temperature T_c (spinodal point) at which the metastable gaseous phase disappears and the system collapses (zeroth order phase transition). This collapse is associated with the isothermal collapse of classical self-gravitating systems.[10,49] However, for self-gravitating fermions, the collapse stops when quantum degeneracy comes into play. In that case, the system achieves a "core-halo" configuration made of a quantum core (fermion ball) containing almost all the mass surrounded by a tenuous isothermal atmosphere. There is also a higher critical temperature T_* (spinodal point) at which the metastable condensed phase disappears and the system explodes. These results were exported by Bilic and Viollier[58] to the context of dark matter.

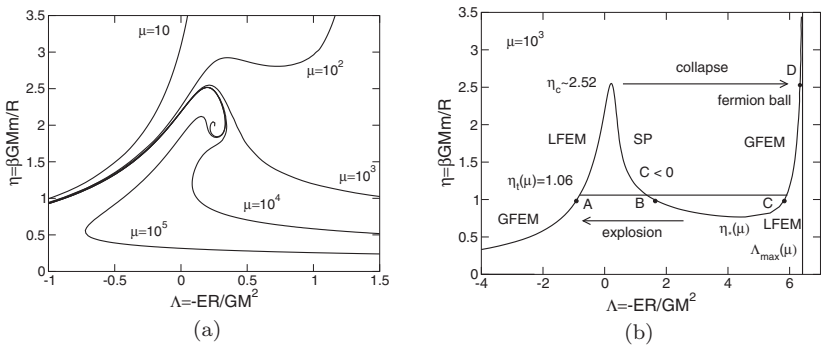

Fig. 5. Caloric curve of nonrelativistic self-gravitating fermions.[32] We have plotted the normalized inverse temperature $\eta = \beta GMm/R$ as a function of minus the normalized energy $\Lambda = -ER/GM^2$ for different values of the normalized radius, or degeneracy parameter $\mu = \eta_0\sqrt{512\pi^4 G^3 MR^3}$, where $\eta_0 = 2m^4/h^3$ is the maximum possible value of the distribution function fixed by the Pauli exclusion principle. (a) Dependence of the series of equilibria on the size of the system. (b) For small systems, the caloric curve has an N-shape structure.

An exhaustive study of phase transitions in the self-gravitating Fermi gas was made by Chavanis[32,59] in both canonical and microcanonical ensembles.

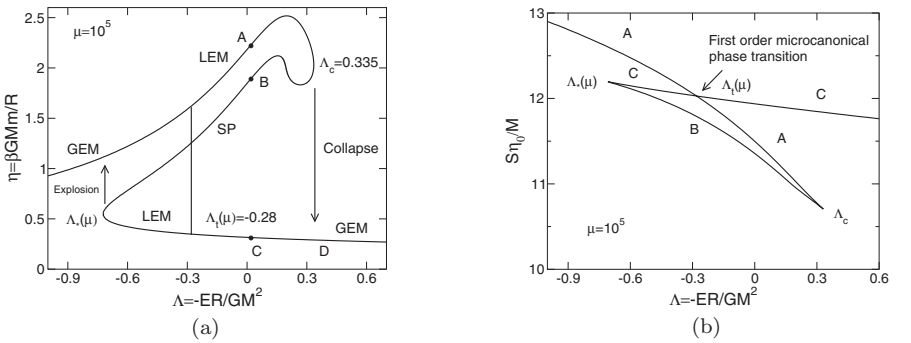

Fig. 6. Caloric curve of nonrelativistic self-gravitating fermions.[32] (a) For large systems, the caloric curve has a Z-shape structure resembling a dinosaur's neck. (b) Illustration of the microcanonical first order phase transition on the $S(E)$ curve.

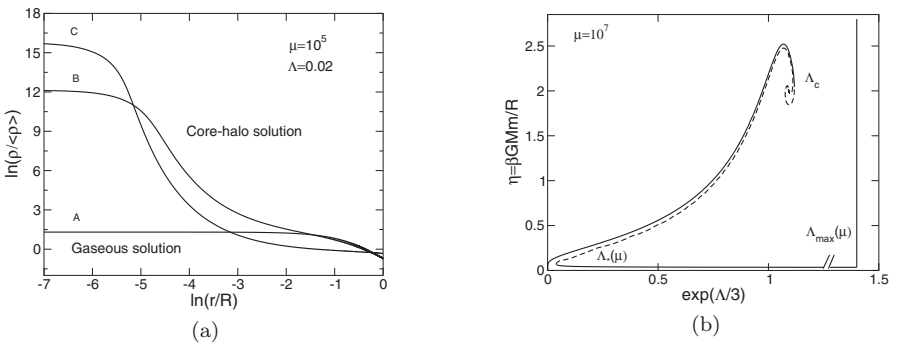

Fig. 7. (a) Density profiles corresponding to the gaseous and core-halo solutions.[32] (b) The classical limit $\mu \to +\infty$ (very large systems).[32] According to the Poincaré-Katz criterion,[36,38] the equilibrium states are unstable in the microcanonical (resp. canonical) ensemble between the first and the last turning points of energy (resp. temperature).

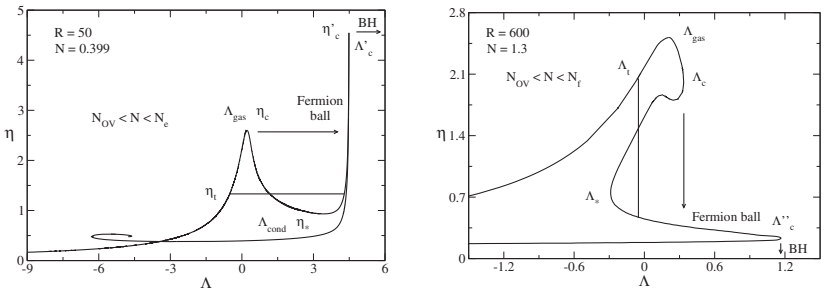
He confirmed the phase transition in the canonical ensemble previously found by Hertel and Thirring[57] and evidenced, for sufficiently large systems ($R > R_{\rm MCP} = 130\,\hbar^2/(N^{1/3}Gm^3)$), a first order phase transition in the microcanonical ensemble (see Fig. 6). This phase transition is expected to take place at a transition energy E_t connecting the gaseous phase to the condensed phase through a vertical Maxwell plateau in the caloric curve $T(E)$. This is accompanied by a discontinuity of temperature. There is also a lower critical energy E_c (spinodal point) at which the metastable gaseous phase disappears and the system collapses (zeroth order phase transition). This collapse is associated with the gravothermal catastrophe of classical self-gravitating systems.[33,35] However, for self-gravitating fermions, the collapse stops when quantum degeneracy comes into play. In that case, the system achieves a core-halo configuration[60] made of a quantum core (fermion ball) containing a moderate fraction of the total mass surrounded by a massive isothermal atmosphere

(see Fig. 7-a). There is also a higher critical energy E_* (spinodal point) at which the metastable condensed phase disappears and the system explodes. As a result, there exist two distinct critical points in the self-gravitating Fermi gas, one in each ensemble, above which phase transitions occur. For small systems ($R < R_{\rm CCP}$), there is no phase transition, for intermediate size systems ($R_{\rm CCP} < R < R_{\rm MCP}$) a phase transition takes place in the canonical ensemble but not in the microcanoncal ensemble, and for large systems ($R > R_{\rm MCP}$) a phase transition takes place in both ensembles. When $R \to +\infty$, the series of equilibria rotates several times before unwinding (see Fig. 7-b) and we recover the classical spiral from Fig. 3-a. Chavanis[32] determined the phase diagram of the nonrelativistic self-gravitating Fermi gas. He also argued that the lifetime of metastable states is extremely long, scaling as e^N where N is the number of particles, so that the first order phase transitions do not take place in practice.[61] Only zeroth order phase transitions associated with the spinodal points are physically meaningful.

6. General relativistic fermions at $T > 0$

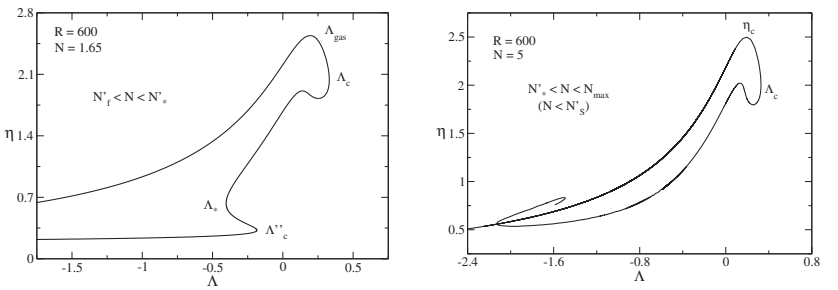
The statistical mechanics of self-gravitating fermions at nonzero temperature in general relativity was first considered by Bilic and Viollier.[62] As before, the system has to be confined within a spherical box of radius R in order to prevent its evaporation. The caloric curve depends on two parameters, the box radius R and the particle number N. Bilic and Viollier[62] studied the case where R is relatively small and $N < N_{\rm OV}$. In that case, the results are qualitatively similar to those obtained for nonrelativistic fermions (see Sec. 5). There is a first order phase transition in the canonical ensemble which replaces the region of negative specific heat present in the microcanonical ensemble. An equilibrium state, which is either "gaseous" (corresponding to the classical isothermal sphere) or "condensed" (made of a fermion ball surrounded by a classical isothermal envelope), exists for any value of temperature T_∞ and binding energy E. General relativistic effects only introduce a small correction to the Newtonian results.

A more general study was performed by Alberti, Chavanis and Roupas[2,63,64] who considered arbitrary values of R and N. When $N > N_{\rm OV}$, they identified the existence of a new turning point of temperature in the canonical ensemble and a new turning point of binding energy in the microcanonical ensemble below which the system collapses and forms a black hole of mass $M_{\rm OV}$ (see Fig. 8). This is the finite temperature generalization of the result originally found by Oppenheimer and Volkoff[24] at $T = 0$. These results lead to the following scenario (we restrict ourselves to the microcanonical ensemble which is the most relevant). At high energies, the system is in the gaseous phase. Below a critical energy E_c it becomes thermodynamically unstable and experiences a gravothermal catastrophe. However, core collapse stops when quantum mechanics (Pauli's exclusion principle) comes into play. This leads to the formation of a fermion ball surrounded by a hot halo. Below E_c'', the condensed phase becomes thermodynamically and dynamically unstable



(a) (b)

Fig. 8. Caloric curve of self-gravitating fermions in general relativity when $N > N_{\rm OV}$.[2] We have plotted the normalized inverse temperature $\eta = \beta_\infty GNm^2/R$ as a function of minus the normalized binding energy $\Lambda = -ER/GN^2m^2$ for different values of the normalized radius $R/R_{\rm OV}$ and normalized particle number $N/N_{\rm OV}$. (a) Small systems: As T decreases the system experiences an isothermal collapse at T_c leading to a fermion ball, then a gravitational collapse at T_c' leading to a black hole. (b) Large systems: As E decreases the system experiences a gravothermal catastrophe at E_c leading to a fermion ball surrounded by a hot halo, then a gravitational collapse at E_c'' leading to a black hole.



(a) (b)

Fig. 9. Caloric curve of self-gravitating fermions in general relativity.[2] When $N > N_*'$ the condensed branch disappears completely so that only the collapse at E_c towards a black hole is possible.

(in a general relativistic sense) and collapses towards a black hole. Alberti and Chavanis[2] also evidenced a critical particle number N_*' above which the condensed phase completely disappears (see Fig. 9). In that case, there is no possibility to form a fermion ball. The gravothermal catastrophe at E_c directly leads to a black hole. In conclusion, for $N < N_{\rm OV}$ the system forms a fermion ball; for $N_{\rm OV} < N < N_*'$ the system generically forms a fermion ball, then (possibly) a black hole; for $N > N_*'$ the system directly forms a black hole. Alberti and Chavanis[2] emphasized the core-halo structure of the equilibrium states in the microcanonical ensemble and mentioned the relation to red-giants (leading to white dwarfs) and supernovae (leading to neutron stars and black holes) suggested in Refs.[64–67]. They also provided the complete phase diagram of the general relativistic Fermi gas.

7. Truncated models

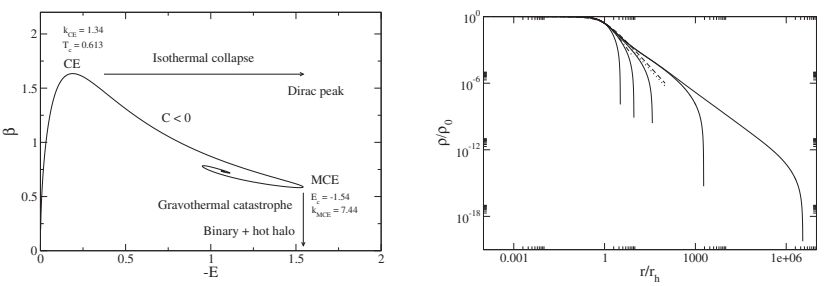
The study of phase transitions in the self-gravitating Fermi gas can be extended to the fermionic King model described by the distribution function

$$f = A\frac{e^{-\beta(\epsilon-\epsilon_m)}-1}{1+\frac{A}{\eta_0}e^{-\beta(\epsilon-\epsilon_m)}} \qquad (\epsilon \leq \epsilon_m). \tag{4}$$

The fermionic King model was introduced heuristically by Ruffini and Stella[68] as a generalization of the classical King model[69]

$$f = A\left[e^{-\beta(\epsilon-\epsilon_m)}-1\right] \qquad (\epsilon \leq \epsilon_m). \tag{5}$$

The fermionic King model was also introduced independently by Chavanis[70] who derived it from a kinetic theory based on the fermionic Landau equation. The fermionic King model is more realistic than the usual fermionic model because it avoids the need of an artificial box to confine the system. The nonrelativistic fermionic King model was studied by Chavanis *et al.*[71,72] who showed that the density profiles generically have a core-halo structure with a quantum core (fermion ball) and a tidally truncated isothermal halo leading to flat rotation curves.[i] They also studied the caloric curves, the thermodynamical stability of the equilibrium states, and the phase transitions between gaseous and condensed states (see Figs. 10 and 11). They showed that the phenomenology of phase transitions in the fermionic King model is the same as in the case of box-confined systems obtained in Refs.[32,59]. The results of Chavanis *et al.*[72] have been generalized by Argüelles *et al.*[73] to the fermionic King model in general relativity. They also found that the phenomenology of phase transitions in the general relativistic fermionic King model is the same as in the case of box-confined systems obtained in Refs.[2,63,64].



(a) (b)

Fig. 10. (a) Caloric curve of the nonrelativistic classical King model.[71] (b) Density profiles along the series of equilibria.[71] The marginal (critical) King profile at the point of gravothermal instability is relatively close to the Burkert[74] profile (dashed line) which provides a good fit of the density profile of dark matter halos.

[i]The name "fermionic King model" was introduced in Ref.[72].

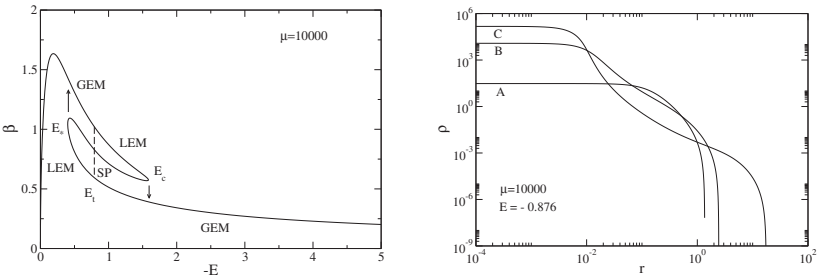


Fig. 11. (a) Caloric curve of the nonrelativistic fermionic King model for large systems.[72] (b) Density profiles corresponding to the stable gaseous phase (A), the stable condensed phase (C), and the unstable intermediate solution (B).[72]

8. Application to dark matter halos

In addition to white dwarfs and neutron stars,[75] the self-gravitating Fermi gas model has been applied in the context of dark matter halos made of massive neutrinos. The suggestion that dark matter is made of massive neutrinos was originally proposed by Markov[76] and Cowsik and McClelland.[77,78] This suggestion has been developed by numerous authors (see the introduction of Ref.[3] for an exhaustive list of references). The first models decribed dark matter halos at $T = 0$ using the equation of state of a completely degenerate fermion gas either in the nonrelativistic limit or in general relativity. Subsequent models considered dark matter halos at nonzero temperature showing that they have a core-halo structure consisting of a dense core (fermion ball) solving the core-cusp problem of classical cold dark matter surrounded by a dilute isothermal atmosphere leading to flat rotation curves. Most models were based on the ordinary Fermi-Dirac distribution in Newtonian gravity or general relativity. Some models were based on the more realistic fermionic King model (describing tidally truncated fermionic dark matter halos). The self-gravitating Fermi gas was also studied in relation to the violent relaxation of collisionless self-gravitating systems described by the Lynden-Bell[79] distribution which is formally similar to the Fermi-Dirac distribution. As argued in Refs.[71,72], the theory of violent relaxation may justify how a collisionless gas of self-gravitating fermions, such as a dark matter halo, can reach a statistical equilibrium state described by the Fermi-Dirac distribution on a timescale smaller than the age of the universe.[j]

The detailed study of the motion of S-stars near the Galactic center has revealed the presence of a very massive central object, Sagittarius A* (Sgr A*). This central object is usually associated with a supermassive black hole (SMBH) of mass

[j]The relaxation time due to close gravitational encounters exceeds the age of the universe by many orders of magnitude. The collisional relaxation time may be shorter if the fermions are self-interacting.[80]

$M = 4.2 \times 10^6\, M_\odot$ and Schwarzschild radius $R_S = 4.02 \times 10^{-7}\,\mathrm{pc}$. Whatever the object may be, its radius must be smaller than $R_\mathrm{P} = 6 \times 10^{-4}\,\mathrm{pc}$ ($R_\mathrm{P} = 1492\, R_S$), the S2 star pericenter. Similar objects are expected to reside at the center of most spiral and elliptical galaxies, in active galactic nuclei (AGN). Although it is commonly believed that these objects are SMBHs, this is not yet established on a firm observational basis in all cases. Some authors have proposed that such objects could be fermion balls or boson stars that could mimic a SMBH. Let us consider this possibility in the framework of the fermionic dark matter model. More precisely, let us investigate if a fermion ball can mimic a SMBH at the center of the Galaxy.

Bilic *et al.*[81] developed a general relativistic model of fermionic dark matter halos at nonzero temperature with a fermion mass $m = 15\,\mathrm{keV/c^2}$ that describes both the center and the halo of the Milky Way in a unified manner. The density profile has a core-halo structure made of a quantum core (fermion ball) surrounded by a classical isothermal atmosphere. The core and the halo are separated by an extended plateau. By using the usual Fermi-Dirac distribution and choosing parameters so as to fit observational data at large distances, they found a fermion ball of mass $M_c = 2.27 \times 10^6\, M_\odot$ and radius $R_c = 18\,\mathrm{mpc}$ and argued that this fermion ball can mimic a SMBH like Sgr A*. Unfortunately, its radius is larger by a factor 100 than the bound $R_P = 6 \times 10^{-4}\,\mathrm{pc}$ set by later observations. This is why Bilic and coworkers abandoned this fermion ball scenario (R. Viollier, private communication). The same problem was encountered later by Ruffini *et al.*[82] who developed a similar model with a fermion mass $m \sim 10\,\mathrm{keV/c^2}$.

More recently, Argüelles *et al.*[83] considered the general relativistic fermionic King model accounting for a tidal confinement. They applied this model to the Milky Way and determined the parameters by fitting the core-halo profile to the observations. For a fermion mass $m = 48\,\mathrm{keV/c^2}$ they obtained a fermion ball of mass $M_c = 4.2 \times 10^6\, M_\odot$ and radius $R_c = R_P = 6 \times 10^{-4}\,\mathrm{pc}$ which, this time, is consistent with the observational constraints of Sgr A*. Therefore, in order to obtain accurate results, it is important to use the fermionic King model[72,83] instead of the usual fermionic model.[32,81,82] Argüelles *et al.*[83] managed to fit the entire density profile and the entire rotation curve of the Milky Way with the fermionic King distribution and argued that a fermion ball can mimic the effect of a SMBH like Sgr A*. This scenario is very attractive because it can explain the whole structure of the galaxy, the supermassive central object and the isothermal halo, by a single distribution (the fermionic King model[68,70]).

Developing the theory of phase transitions in the self-gravitating Fermi gas, Chavanis *et al.*[72] argued that the core-halo solution considered by Bilic *et al.*,[81] Ruffini *et al.*,[82] and Argüelles *et al.*[83] with a small fermion ball mimicking a SMBH surrounded by a classical isothermal atmosphere, which was claimed to reproduce the structure of the Milky Way, is thermodynamically unstable because it lies in the intermediate branch of the caloric curve between the first and the last turning points of energy (see Fig. 7-b). As a result, it is a saddle point of entropy, not an entropy maximum. Therefore, Chavanis *et al.*[72] concluded that this type of solution

is not likely to result from a natural evolution and, consequently, they questioned the possibility that a fermion ball could mimic a central SMBH.

Following this study,[72] Argüelles *et al.*[73] computed the caloric curve of the fermionic King model in general relativity (see Fig. 12). They showed that the core-halo solution of Ref.[83] which provides a good agreement with the structure of the Milky Way lies just *after* the turning point (b) of energy (see the inset of Fig. 12), so that it is thermodynamically stable in the microcanonical ensemble which is the correct ensemble to consider.[k] This is a very interesting result because it shows that this core-halo structure *may* arise from a natural evolution in the sense of Lynden-Bell. This gives further support to the scenario according to which a fermion ball could mimic a SMBH at the center of the galaxies.

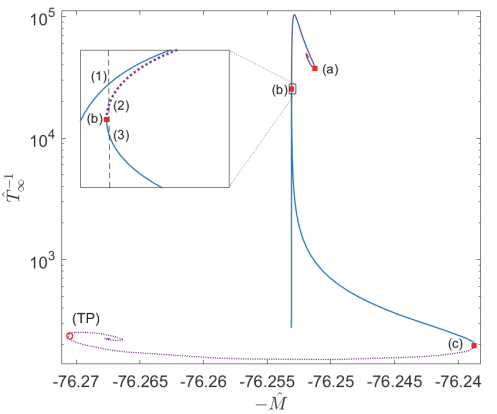

Fig. 12. Caloric curve of the general relativistic fermionic King model (from Ref.[73]).

However, it does not prove that this core-halo structure with a very high central density will necessarily arise from a natural evolution. The reason is that violent relaxation is in general incomplete.[79] The fluctuations of the gravitational potential that are the engine of the collisionless relaxation can die out before the system has reached statistical equilibrium. Therefore, it is not clear if violent relaxation can produce this type of structures.[l] In order to vindicate this scenario, the next step would be to perform direct numerical simulations of collisionless fermionic matter to

[k]Chavanis *et al.*[72] did not focus on the stable branch of condensed states located after point (b) because they argued that these solutions are not astrophysically relevant. Indeed, by considering particular solutions of the condensed branch, they observed that these solutions have a too extended envelope that is not consistent with the structure of dark matter halos (see solution C in Fig. 11-b and Figs. 38-45 of Ref.[72]). Although this claim is correct for most of the solutions on the condensed branch, it turns out that the solutions located just after point (b) *are* astrophysically relevant and correspond to the core-halo solutions studied by Argüelles *et al.*[83]

[l]It may be easier to form core-halo configurations with a very high central density if the fermions are self-interacting and if the Fermi-Dirac equilibrium state results from a collisional relaxation of nongravitational origin instead of a collisionless relaxation as suggested in Ref.[80].

see if they spontaneously generate fermion balls with the characteristics of SMBHs. A purely gaseous solution without quantum core, which is also a maximum entropy state, may be easier to reach through a violent relaxation process and is consistent with the observations. However, it does not account for a massive central object at the center of the galaxies. In that case, we either have to introduce a primordial SMBH "by hand" or advocate a scenario of gravitational collapse such as the one described below.[80]

For a fermion mass $m = 48\,\mathrm{keV/c^2}$, the mass $M_h = 10^{11}\,M_\odot$ of the Milky Way is larger than the OV mass $M_{\rm OV} = 2.71 \times 10^8\,M_\odot$, so we have to take into account general relativity in the caloric curve. As first shown by Alberti and Chavanis[2,64] for box-confined fermionic systems, and recovered by Argüelles *et al.*[73] for tidally truncated models, relativistic effects create a new turning point of energy in the caloric curve at which the condensed branch terminates (see Figs. 8, 9 and point (c) in Fig. 12). Below E_c'' the system collapses towards a black hole.

Suppose that violent relaxation selects the gaseous solution. On a secular timescale, because of collisions, the system follows the upper branch of the series of equilibria (gaseous states) up to the point of minimum energy E_c. At that point, it becomes thermodynamically unstable and undergoes a gravothermal catastrophe. However, core collapse is stopped by quantum mechanics, leading to the formation of a fermion ball. Then, if the energy keeps decreasing, the system follows the lower branch of the series of equilibria up to the point of minimum energy E_c'' where it becomes thermodynamically and dynamically unstable (in a general relativistic sense) and collapses towards a SMBH of mass $M_{\rm OV}$. A similar outcome arises if violent relaxation selects the core-halo solution where the fermion ball mimics a SMBH. On a secular timescale, the system follows the lower branch of the series of equilibria up to the point of minimum energy E_c'' at which it collapses towards a SMBH. In the two cases, the ultimate fate of the system is to form a SMBH of mass $M_{\rm OV}$ surrounded by an envelope. However, the formation of a SMBH may take time (more than the age of the universe) so that the two objects (fermion ball or SMBH) are possible in practice.

For a fermion mass $m = 48\,\mathrm{keV/c^2}$, the OV mass $M_{\rm OV} = 2.71 \times 10^8\,M_\odot$ is too large to account for the mass of a SMBH like Sgr A* at the center of the Milky Way. This suggests that the object at the center of the Galaxy (Sgr A*) is a fermion ball instead of a SMBH as argued by Argüelles *et al.*[73] However, for very large halos ($N > N_*'$), it is shown by Alberti and Chavanis[2] that the condensed branch disappears (see panel (b) of Fig. 9). In that case, there is no stable solution with a fermion ball and the system necessarily collapses towards a SMBH. Therefore, medium size galaxies like the Milky Way should harbor a fermion ball of mass $M_c = 4.2 \times 10^6\,M_\odot$ while very large galaxies like ellipticals should harbor a SMBH of mass $M_{\rm OV} = 2.71 \times 10^8\,M_\odot$ that could even grow by accretion. This scenario[80] could account for the mass of SMBHs in AGNs like the one recently photographed in M87 ($M_h \sim 10^{13}\,M_\odot$ and $M_{\rm BH} \sim 10^{10}\,M_\odot$).

On the other hand, for a much larger fermion mass $m = 386\,\mathrm{keV/c^2}$, the OV mass $M_{\rm OV} = 4.2\times10^6\,M_\odot$ is comparable to the mass of Sgr A*. Furthermore, when applied to the Milky Way, the caloric curve corresponding to $m = 386\,\mathrm{keV/c^2}$ is similar to the one reported in panel (b) of Fig. 9 so there is no possibility to form a fermion ball. In that case, the Milky Way could have undergone a gravitational collapse at E_c leading to a SMBH of mass $M_{\rm OV} = 4.2\times10^6\,M_\odot$.[80] In this process, the halo surrounding the SMBH is left undisturbed and could correspond to a marginal classical King profile, which is known[71,72] to give a good agreement with the empirical Burkert[74] profile of observed dark matter halos (see Fig. 10-b).

Different scenarios are possible depending on the value of the fermion mass m. Argüelles *et al.*[73,83] determined the mass of the fermionic dark matter particle in such a way that the fermion ball that would be at the center of a large fermionic dark matter halo, like the one that surrounds the Milky Way, mimics the effect of a SMBH of mass $M_c = 4.2\times10^6\,M_\odot$ and radius $R_c = 6\times10^{-4}\,\mathrm{pc}$ like Sgr A*. This leads to a fermion mass $m = 48\,\mathrm{keV/c^2}$.[m] Alternatively, Chavanis[80,86] determined the mass of the fermionic dark matter particle by arguing that the smallest halos observed in the universe (dSphs like Fornax) with a typical mass $M\sim10^8\,M_\odot$ and a typical radius $R\sim1\,\mathrm{kpc}$ represent the ground state of the self-gravitating Fermi gas at $T = 0$. This yields a much smaller fermion mass $m = 165\,\mathrm{eV/c^2}$. When this model is applied to the Milky Way,[80] it leads to a large fermion ball of mass $M_c = 9.45\times10^9\,M_\odot$ and radius $R_c = 240\,\mathrm{pc}$. Therefore, it predicts the existence of a large dark matter bulge at the center of the Galaxy instead of a compact fermion ball mimicking a SMBH.[n] A large dark matter bulge is not inconsistent with the observations and may even solve some issues. For example, De Martino *et al.*[87] have argued that the presence of a bosonic dark matter bulge (soliton) of mass $M_c\simeq10^9\,M_\odot$ and radius $R_c\simeq100\,\mathrm{pc}$ at the center of the Galaxy may account for the dispersion velocity peak observed in the Milky Way. A large dark matter bulge made of fermions should have the same effect.[80]

Finally, we mention potential difficulties or, alternatively, potentially important predictions associated with the model of Argüelles *et al.*[73,83] If the fermion mass is $m = 48\,\mathrm{keV/c^2}$, dark matter halos of mass $M_h = 10^8\,M_\odot$ such as dSphs like Fornax should have a very pronounced core-halo structure since they do not correspond to the ground state of the self-gravitating Fermi gas (unlike the model of Ref.[80] with $m = 165\,\mathrm{eV/c^2}$). More precisely, the fermionic dark matter model with a fermion mass $m = 48\,\mathrm{keV/c^2}$ predicts that dSphs of mass $M_h = 10^8\,M_\odot$ should contain a fermion ball of mass $M_c = 1.57\times10^4\,M_\odot$ and radius $R_c = 5.42\,\mathrm{mpc}$ possibly

[m] In very recent works, Becerra-Vergara *et al.*[84,85] showed that the gravitational potential of a fermion ball (with a particle mass $m = 56\,\mathrm{keV/c^2}$) leads to a better fit of the orbits of all the 17 best resolved S-stars orbiting Sgr A* (including the S2 and G3 objects) with respect to the one obtained by the central SMBH model.

[n] In that case, a primordial SMBH has to be introduced "by hand" at the center of the Galaxy in order to account for the presence of Sgr A*.

mimicking an intermediate mass black hole.[80] This result is consistent with the detailed work of Argüelles *et al.*[88] who obtained dense cores of mass between $M_c = 10^3\,M_\odot$ and $M_c = 10^6\,M_\odot$ depending on the central effective temperature of the fermions. This is either a very important prediction (if confirmed by observations) or the evidence that this model is incorrect (if invalidated by observations). It would be extremely important to clarify this issue by confronting the model of Argüelles *et al.*[73,83] to ultracompact halos in order to determine which of the two models (the model of Argüelles *et al.*[73,83] with $m = 48\,\mathrm{keV/c^2}$ or the one developed by Chavanis[80] with $m = 165\,\mathrm{eV/c^2}$ or $m \sim 1\,\mathrm{keV}/c^2$) is the most relevant for dark matter halos.

9. Conclusion

In these Proceedings, we have provided a brief history of the self-gravitating Fermi gas in Newtonian gravity and general relativity. We have focused exclusively on papers that discuss the caloric curves and the mass-radius relations of the self-gravitating Fermi gas. We have shown how these curves become more and more complex, displaying various types of phase transitions and instabilities, when gravity effects, thermal effects, quantum effects, relativity effects and tidal effects are progressively taken into account. Of course, there are many more interesting papers on self-gravitating fermions that are not reviewed here. A detailed bibliography on the subject can be found in Refs.[3,80] and in standard textbooks of astrophysics.

We have applied the self-gravitating Fermi gas model to dark matter halos. The Fermi-Dirac distribution may be justified either from the theory of collisionless violent relaxation[72,79] or from a collisional relaxation of nongravitational origin if the fermions are self-interacting.[80] If the fermions have a small mass ($m \lesssim 1\,\mathrm{keV}/c^2$), the caloric curve applied to the Milky Way has an N-shape structure (see Fig. 5-b) and the equilibrium states display a large quantum bulge of mass $M_c \sim 10^{10}\,M_\odot$ and radius $R_c \sim 100\,\mathrm{pc}$ surrounded by an isothermal atmosphere similar to the Burkert profile.[80] If the fermions have a large mass ($m \sim 50\,\mathrm{keV}/c^2$), the caloric curve has a Z-shape structure (see Fig. 6-a). It displays a nonrelativistic turning point of energy at E_c triggering the gravothermal catastrophe. For nonrelativistic fermions, the gravothermal catastrophe is stopped by quantum degeneracy (Pauli's exclusion principle).[60] This may lead to a compact fermion ball of mass $M_c \sim 4.2\times 10^6\,M_\odot$ and radius $R_c \sim 6\times 10^{-4}\,\mathrm{pc}$ mimicking a SMBH surrounded by an isothermal atmosphere.[73] When $N > N_{\rm OV}$, which is the case for the Milky Way, a new turning point of energy appears at E_c'' due to general relativity (see Figs. 8-b and 12). It triggers a gravitational collapse towards a SMBH. This new turning point of energy was first evidenced in Refs.[2,63,64] for box-confined fermions and confirmed in Ref.[73] for the fermionic King model. The possibility to form either a fermion ball or a SMBH at the center of the galaxies depends on the size of the galaxy. In medium size galaxies like the Milky Way (when $N < N_*'$) we expect to form a fermion ball of mass $M_c \sim 4.2\times 10^6\,M_\odot$ but in large galaxies (when $N > N_*'$) the condensed branch

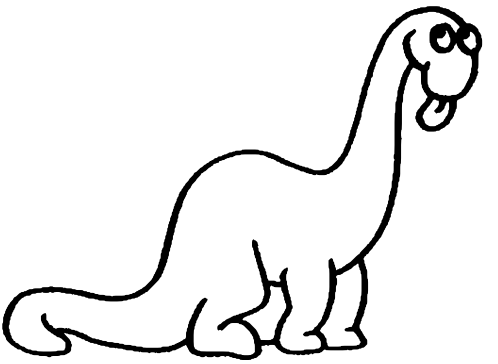

Fig. 13. Dinosaur (artistic view) similar to Fig. 6-a.

disappears (see Fig. 9-b) and the gravothermal catastrophe necessarily results in the formation of a SMBH of mass $M_{\rm OV} \sim 10^8\, M_\odot$.

It is interesting to study the effect of the dimension of space d on phase transitions in the self-gravitating Fermi gas. This is done in Refs.[17, 89–91]. In particular, it is shown that fermion stars are unstable in a universe with $d \geq 4$ dimensions. In that case, quantum mechanics cannot stabilize matter against gravitational collapse even in the nonrelativistic regime.[17, 89, 90] This is similar to a result found by Ehrenfest[92] who considered the effect of the dimension of space on the laws of physics and showed that planetary motion and the Bohr atom would not be stable in a space of dimension $d \geq 4$. Therefore, the dimension $d = 3$ of our Universe is very particular with possible implications regarding the Anthropic Principle.

Finally, it is interesting to compare the results obtained for fermion stars with those obtained for boson stars and self-gravitating Bose-Einstein condensates (BECs) (see our contribution[93] in these Proceedings). Similarly to fermionic dark matter halos, BEC dark matter halos also have a core-halo structure in which the "fermion ball" is replaced by a "soliton". The analogy between fermionic and bosonic dark matter halos is discussed in Refs.[80, 86, 94].

Experimental observations and theoretical arguments point out that Dark Matter (DM) particles are one of the most prominent component of the Universe. This motivated the pioneer DAMA experiment to investigate the presence of these particles in the galactic halo, by exploiting the model independent signature of the DM annual modulation of the rate and very highly radio-pure apparatus in underground site. In this paper the results obtained by other two annual cycles of DAMA/LIBRA–phase2 are presented and the long-standing model-independent annual modulation effect measured by DAMA deep underground at the Gran Sasso National Laboratory (LNGS) of the I.N.F.N. with different experimental configurations is summarized. In particular, the DAMA/LIBRA–phase2 apparatus, $\simeq$ 250 kg highly radio-pure NaI(Tl), profits from a second generation high quantum efficiency photomultipliers and of new electronics with respect to DAMA/LIBRA–phase1. The improved experimental configuration has also allowed to lower the software energy threshold. Including the results of these other two annual cycles presented here, the total exposure of DAMA/LIBRA–phase2 over 8 annual cycles is 1.53 ton $\times$ yr. DAMA/LIBRA–phase2 confirms the evidence of a signal that meets all the requirements of the model independent Dark Matter annual modulation signature, at 11.8 σ C.L. in the energy region (1–6) keV. In the energy region between 2 and 6 keV, where data are also available from DAMA/NaI and DAMA/LIBRA–phase1 (14 additional annual cycles), the achieved C.L. for the full exposure (2.86 ton $\times$ yr) is 13.7 σ; the modulation amplitude of the *single-hit* scintillation events is: (0.01014 $\pm$ 0.00074) cpd/kg/keV,

the measured phase is (142.4 ± 4.2) days and the measured period is (0.99834 ± 0.00067) yr, all these values are well in agreement with those expected for DM particles. No systematics or side reaction able to mimic the exploited DM signature (i.e. to account for the whole measured modulation amplitude and to simultaneously satisfy all the requirements of the signature), has been found or suggested by anyone throughout some decades thus far.

Keywords: Scintillation detectors; elementary particle processes; Dark Matter; annual modulation.

1. Introduction

The DAMA/LIBRA[1–23] experiment, as the pioneer DAMA/NaI,[24–51] has the main aim to investigate the presence of DM particles in the galactic halo by exploiting the DM annual modulation signature (originally suggested in Ref.[52,53]). In addition, the developed highly radio-pure NaI(Tl) target-detectors[1,6,9,54] ensure sensitivity to a wide range of DM candidates, interaction types and astrophysical scenarios (see e.g. Refs.[2,14,16–18,25–32,35–42], and in literature).

The origin of the DM annual modulation signature and of its peculiar features is due to the Earth motion with respect to the DM particles constituting the Galactic Dark Halo. In fact, as a consequence of the Earth's revolution around the Sun, which is moving in the Galaxy with respect to the Local Standard of Rest towards the star Vega near the constellation of Hercules, the Earth should be crossed by a larger flux of DM particles around $\simeq$ 2 June and by a smaller one around $\simeq$ 2 December. In the former case the Earth orbital velocity is summed to that of the solar system with respect to the Galaxy, while in the latter the two velocities are subtracted. The DM annual modulation signature is very distinctive since the effect induced by DM particles must simultaneously satisfy all the following requirements: the rate must contain a component modulated according to a cosine function (1) with one year period (2) and a phase that peaks roughly $\simeq$ 2 June (3); this modulation must only be found in a well-defined low energy range, where DM particle induced events can be present (4); it must apply only to those events in which just one detector of many actually "fires" (*single-hit* events), since the DM particle multi-interaction probability is negligible (5); the modulation amplitude in the region of maximal sensitivity must be $\lesssim 7\%$ of the constant part of the signal for usually adopted halo distributions (6), but it can be larger in case of some proposed scenarios such as e.g. those in Ref.[55–59] (even up to $\simeq 30\%$). Thus this signature has many peculiarities and, in addition, it allows to test a wide range of parameters in many possible astrophysical, nuclear and particle physics scenarios.

This DM signature might be mimicked only by systematic effects or side reactions able to account for the whole observed modulation amplitude and to simultaneously satisfy all the requirements given above.

The full description of the DAMA/LIBRA set-up and the adopted procedures during the phase1 and phase2 and other related arguments have been discussed in details e.g. in Refs.[1–6,19–21,23].

At the end of 2010 all the photomultipliers (PMTs) were replaced by a second generation PMTs Hamamatsu R6233MOD, with higher quantum efficiency (Q.E.) and with lower background with respect to those used in phase1; they were produced after a dedicated R&D in the company, and tests and selections.[6,54] The new PMTs have Q.E. in the range 33-39% at 420 nm, wavelength of NaI(Tl) emission, and in the range 36-44% at peak. The commissioning of the DAMA/LIBRA–phase2 experiment was successfully performed in 2011, allowing the achievement of the software energy threshold at 1 keV, and the improvement of some detector's features such as energy resolution and acceptance efficiency near software energy threshold.[6]

The adopted procedure for noise rejection near software energy threshold and the acceptance windows are the same unchanged along all the DAMA/LIBRA–phase2 data taking, throughout the months and the annual cycles. The typical behaviour of the overall efficiency for *single-hit* events as a function of the energy is also shown in Ref.[6]; the percentage variations of the efficiency follow a gaussian distribution with $\sigma = 0.3\%$ and do not show any modulation with period and phase as expected for the DM signal (for a partial data release see Ref.[21]).

At the end of 2012 new preamplifiers and special developed trigger modules were installed and the apparatus was equipped with more compact electronic modules.[60] Here we just remind that the sensitive part of DAMA/LIBRA–phase2 set-up is made of 25 highly radio-pure NaI(Tl) crystal scintillators (5-rows by 5-columns matrix) having 9.70 kg mass each one; quantitative analyses of residual contaminants are given in Ref.[1]. In each detector two 10 cm long UV light guides (made of Suprasil B quartz) act also as optical windows on the two end faces of the crystal, and are coupled to two low background PMTs working in coincidence at single photoelectron level. The detectors are housed in a sealed low-radioactive copper box installed in the center of a low-radioactive Cu/Pb/Cd-foils/polyethylene/paraffin shield; moreover, about 1 m concrete (made from the Gran Sasso rock material) almost fully surrounds (mostly outside the barrack) this passive shield, acting as a further neutron moderator. The shield is decoupled from the ground by a metallic structure mounted above a concrete basement; a neoprene layer separates the concrete basement and the floor of the laboratory. The space between this basement and the metallic structure is filled by paraffin for several tens cm in height.

A threefold-level sealing system prevents the detectors from contact with the environmental air of the underground laboratory and continuously maintains them in HP (high-purity) Nitrogen atmosphere. The whole installation is under air conditioning to ensure a suitable and stable working temperature. The huge heat capacity of the multi-tons passive shield ($\approx 10^6$ cal/^{o}C) guarantees further relevant stability of the detectors' operating temperature. In particular, two independent systems of air conditioning are available for redundancy: one cooled by water refrigerated by a dedicated chiller and the other operating with cooling gas. A hardware/software monitoring system provides data on the operating conditions. In particular, several probes are read out and the results are stored with the production data.

Moreover, self-controlled computer based processes automatically monitor several parameters, including those from DAQ, and manage the alarms system. All these procedures, already experienced during DAMA/LIBRA–phase1,[1–5] allow us to control and to maintain the running conditions stable at a level better than 1% also in DAMA/LIBRA–phase2 (see e.g. Ref.[21,23]).

The light response of the detectors during phase2 typically ranges from 6 to 10 photoelectrons/keV, depending on the detector. Energy calibration with X-rays/γ sources are regularly carried out in the same running condition down to few keV (for details see e.g. Ref.[1]; in particular, double coincidences due to internal X-rays from ^{40}K (which is at ppt levels in the crystals) provide (when summing the data over long periods) a calibration point at 3.2 keV close to the software energy threshold. The DAQ system records both *single-hit* events (where just one of the detectors fires) and *multiple-hit* events (where more than one detector fires) up to the MeV region despite the optimization is performed for the lowest energy.

The radio-purity and details are discussed e.g. in Refs.[1–5,54] and references therein. The adopted procedures provide sensitivity to large and low mass DM candidates inducing nuclear recoils and/or electromagnetic signals.

The data of the former DAMA/NaI setup and, later, those of the DAMA/LIBRA-phase1 have already given (with high confidence level) positive evidence for the presence of a signal that satisfies all the requirements of the exploited DM annual modulation signature.[2–5,35,36]

In this paper the model independent result of eight annual cycles of DAMA/LIBRA–phase2 is presented. The total exposure of DAMA/LIBRA–phase2 is: 1.53 ton $\times$ yr with an energy threshold at 1 keV; when including also that of the first generation DAMA/NaI experiment and DAMA/LIBRA–phase1 the cumulative exposure is 2.86 ton $\times$ yr, corresponding to twenty-two independent annual cycles.

2. The DAMA/LIBRA–phase2 annual cycles

The details of the annual cycles of DAMA/LIBRA–phase2 are reported in Table 1. The first annual cycle was dedicated to the commissioning and to the optimizations towards the achievement of the 1 keV software energy threshold.[6] This period has: i) no data before/near Dec. 2, 2010 (the expected minimum of the DM signal); ii) data sets with some set-up modifications; iii) $(\alpha - \beta^2) = 0.355$ well different from 0.5 (i.e. the detectors were not being operational evenly throughout the year). Thus, this period cannot be used for the annual modulation studies; however, it has been used for other purposes.[6,13] Therefore, as shown in Table 1 the considered annual cycles of DAMA/LIBRA–phase2 are eight (exposure of 1.53 ton$\times$yr). The cumulative exposure, also considering the former DAMA/NaI and DAMA/LIBRA–phase1, is 2.86 ton$\times$yr.

The total number of events collected for the energy calibrations during the eight annual cycles of DAMA/LIBRA–phase2 is about 1.6×10^8, while about

Table 1. Details about the annual cycles of DAMA/LIBRA–phase2. The mean value of the squared cosine is $\alpha = \langle cos^2\omega(t-t_0)\rangle$ and the mean value of the cosine is $\beta = \langle cos\omega(t-t_0)\rangle$ (the averages are taken over the live time of the data taking and $t_0 = 152.5$ day, i.e. June 2^{nd}); thus, the variance of the cosine, $(\alpha - \beta^2)$, is $\simeq 0.5$ for a detector being operational evenly throughout the year.

DAMA/LIBRA–phase2 annual cycle	Period	Mass (kg)	Exposure (kg×day)	$(\alpha - \beta^2)$
1	Dec. 23, 2010 – Sept. 9, 2011	commissioning of phase2		
2	Nov. 2, 2011 – Sept. 11, 2012	242.5	62917	0.519
3	Oct. 8, 2012 – Sept. 2, 2013	242.5	60586	0.534
4	Sept. 8, 2013 – Sept. 1, 2014	242.5	73792	0.479
5	Sept. 1, 2014 – Sept. 9, 2015	242.5	71180	0.486
6	Sept. 10, 2015 – Aug. 24, 2016	242.5	67527	0.522
7	Sept. 7, 2016 – Sept. 25, 2017	242.5	75135	0.480
8	Sept. 25, 2017 – Aug. 20, 2018	242.5	68759	0.557
9	Aug. 24, 2018 – Oct. 3, 2019	242.5	77213	0.446
DAMA/LIBRA–phase2	Nov. 2, 2011 – Oct. 3, 2019	557109 kg×day $\simeq$ 1.53 ton×yr		0.501
DAMA/NaI + DAMA/LIBRA–phase1 + DAMA/LIBRA–phase2:			2.86 ton×yr	

1.7×10^5 events/keV have been collected for the evaluation of the acceptance window efficiency for noise rejection near the software energy threshold.[1,6]

As it can be inferred from Table 1, the duty cycle of the experiment is high, ranging between 76% and 86%. The routine calibrations and, in particular, the data collection for the acceptance windows efficiency mainly affect it.

3. The annual modulation of the residual rate

Fig. 1 shows the time behaviour of the experimental residual rates of the *single-hit* scintillation events in the (1–3), and (1–6) keV energy intervals for DAMA/LIBRA–phase2. The residual rates are calculated from the measured rate of the *single-hit* events after subtracting the constant part, as described in Refs.[2–5,35,36]. The null modulation hypothesis is rejected at very high C.L. by χ^2 test: $\chi^2 = 176$ and 202, respectively, over 69 d.o.f.. The P-values are P = 2.6×10^{-11}, and P = 5.6×10^{-15}, respectively. The residuals of the DAMA/NaI data (0.29 ton × yr) are given in Ref.[2,5,35,36], while those of DAMA/LIBRA–phase1 (1.04 ton × yr) in Ref.[2–5].

The former DAMA/LIBRA–phase1 and the new DAMA/LIBRA–phase2 residual rates of the *single-hit* scintillation events are reported in Fig. 2. The energy interval is from 2 keV, the software energy threshold of DAMA/LIBRA–phase1, up to 6 keV. The null modulation hypothesis is rejected at very high C.L. by χ^2 test: $\chi^2/d.o.f. = 240/119$, corresponding to P-value = 3.5×10^{-10}.

The *single-hit* residual rates of the DAMA/LIBRA–phase2 (Fig. 1) have been fitted with the function: $A\cos\omega(t-t_0)$, considering a period $T = \frac{2\pi}{\omega} = 1$ yr and a phase $t_0 = 152.5$ day (June 2^{nd}) as expected by the DM annual modulation signature; this can be repeated for the only case of (2-6) keV energy interval also including the former DAMA/NaI and DAMA/LIBRA–phase1 data. The goodness of the fits

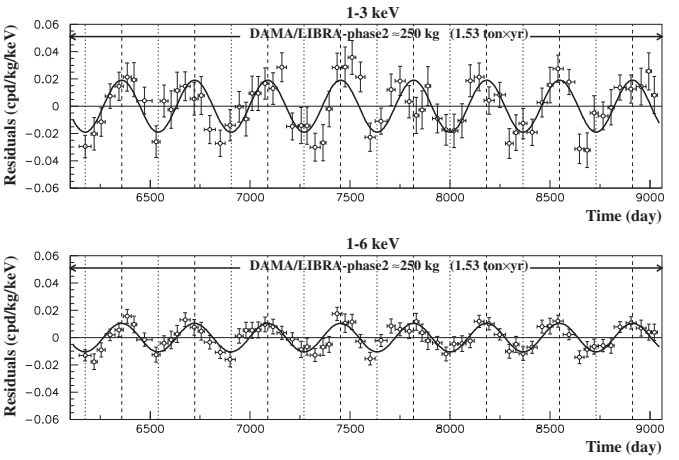

Fig. 1. Experimental residual rate of the *single-hit* scintillation events measured by DAMA/LIBRA–phase2 over eight annual cycles in the (1–3), and (1–6) keV energy intervals as a function of the time. The time scale is maintained the same of the previous DAMA papers for consistency. The data points present the experimental errors as vertical bars and the associated time bin width as horizontal bars. The superimposed curves are the cosinusoidal functional forms $A\cos\omega(t-t_0)$ with a period $T=\frac{2\pi}{\omega}=1$ yr, a phase $t_0=152.5$ day (June 2^{nd}) and modulation amplitudes, A, equal to the central values obtained by best fit on the data points of the entire DAMA/LIBRA–phase2. The dashed vertical lines correspond to the maximum expected for the DM signal (June 2^{nd}), while the dotted vertical lines correspond to the minimum.

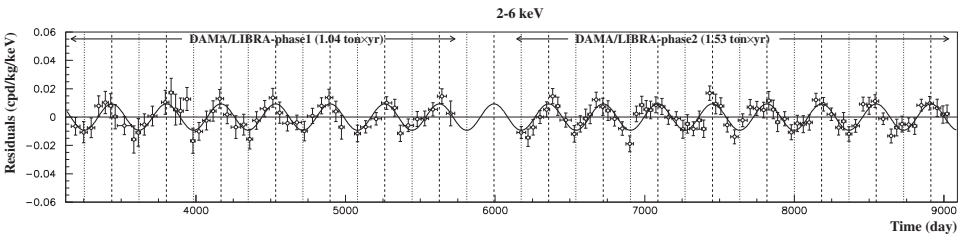

Fig. 2. Experimental residual rate of the *single-hit* scintillation events measured by DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 in the (2–6) keV energy intervals as a function of the time. The superimposed curve is the cosinusoidal functional forms $A\cos\omega(t-t_0)$ with a period $T=\frac{2\pi}{\omega}=1$ yr, a phase $t_0=152.5$ day (June 2^{nd}) and modulation amplitude, A, equal to the central value obtained by best fit on the data points of DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2. For details see Fig. 1.

is well supported by the χ^2 test; for example, $\chi^2/d.o.f. = 81.6/68, 66.2/68, 130/155$ are obtained for the (1–3) keV and (1–6) keV cases of DAMA/LIBRA–phase2, and for the (2–6) keV case of DAMA/NaI, DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2, respectively. The results of the best fits in the different cases are summarized in Table 2. Table 2 also reports the cases when the period and the phase are kept free in the fitting procedure. The period and the phase are well compatible with expectations for a DM annual modulation signal. In particular, the phase is consistent with

Table 2. Modulation amplitude, A, obtained by fitting the *single-hit* residual rate of DAMA/LIBRA–phase2, as reported in Fig. 1, and also including the residual rates of the former DAMA/NaI and DAMA/LIBRA–phase1. It was obtained by fitting the data with the formula: $A\cos\omega(t-t_0)$. The period $T=\frac{2\pi}{\omega}$ and the phase t_0 are kept fixed at 1 yr and at 152.5 day (June 2^{nd}), respectively, as expected by the DM annual modulation signature, and alternatively kept free. The results are well compatible with expectations for a signal in the DM annual modulation signature.

	A (cpd/kg/keV)	$T=\frac{2\pi}{\omega}$ (yr)	t_0 (days)	C.L.
DAMA/LIBRA–phase2:

1-6 keV	(0.01048±0.00090)	1.0	152.5	11.6 σ
2-6 keV	(0.00933±0.00094)	1.0	152.5	9.9 σ
1-3 keV	(0.0191±0.0020)	(0.99952±0.00080)	149.6±5.9	9.6 σ
1-6 keV	(0.01058±0.00090)	(0.99882±0.00065)	144.5±5.1	11.8 σ
2-6 keV	(0.00954±0.00076)	(0.99836±0.00075)	141.1±5.9	12.6 σ
DAMA/LIBRA–phase1 + phase2:				
2-6 keV	(0.00941±0.00076)	1.0	152.5	12.4 σ
2-6 keV	(0.00959±0.00076)	(0.99835±0.00069)	142.0±4.5	12.6 σ
DAMA/NaI + DAMA/LIBRA–phase1 + phase2:				
2-6 keV	(0.00996±0.00074)	1.0	152.5	13.4 σ
2-6 keV	(0.01014±0.00074)	(0.99834±0.00067)	142.4±4.2	13.7 σ

about June 2^{nd} and is fully consistent with the value independently determined by Maximum Likelihood analysis (see later). For completeness, we recall that a slight energy dependence of the phase could be expected (see e.g. Refs.[38, 58, 59, 61–63]), providing intriguing information on the nature of Dark Matter candidate and related aspects.

4. Absence of modulation of the background

As done in previous data releases, absence of any significant background modulation in the energy spectrum has also been verified in the present data taking for energy regions not of interest for DM. In fact, the background in the lowest energy region is essentially due to "Compton" electrons, X-rays and/or Auger electrons, muon induced events, etc., which are strictly correlated with the events in the higher energy region of the spectrum. Thus, if a modulation detected in the lowest energy region were due to a modulation of the background (rather than to a signal), an equal or larger modulation in the higher energy regions should be present.

For example, the measured rate integrated above 90 keV, R_{90}, as a function of the time has been analysed. Fig. 3 shows the distribution of the percentage variations of R_{90} with respect to the mean values for all the detectors in DAMA/LIBRA–phase2. It shows a cumulative gaussian behaviour with $\sigma \simeq 1\%$, well accounted for by the statistical spread expected from the used sampling time.

Moreover, fitting the time behaviour of R_{90} including a term with phase and period as for DM particles, a modulation amplitude $A_{R_{90}}$ compatible with zero has

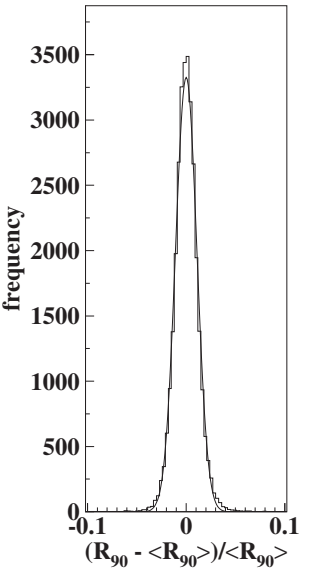

Fig. 3. Distribution of the percentage variations of R_{90} with respect to the mean values for all the detectors in the DAMA/LIBRA–phase2 (histogram); the superimposed curve is a gaussian fit.

been found for all the annual cycles (see Table 3). This also excludes the presence of any background modulation in the whole energy spectrum at a level much lower than the effect found in the lowest energy region for the *single-hit* scintillation events. In fact, otherwise – considering the R_{90} mean values – a modulation amplitude of order of tens cpd/kg would be present for each annual cycle, that is $\simeq 100\ \sigma$ far away from the measured values.

Table 3. Modulation amplitudes, $A_{R_{90}}$, obtained by fitting the time behaviour of R_{90} in DAMA/LIBRA–phase2, including a term with a cosine function having phase and period as expected for a DM signal. The obtained amplitudes are compatible with zero, and incompatible ($\simeq 100\ \sigma$) with modulation amplitudes of tens cpd/kg. Modulation amplitudes, $A_{(6-14)}$, obtained by fitting the time behaviour of the residual rates of the *single-hit* scintillation events in the (6–14) keV energy interval. In the fit the phase and the period are at the values expected for a DM signal. The obtained amplitudes are compatible with zero.

DAMA/LIBRA–phase2 annual cycle	$A_{R_{90}}$ (cpd/kg)	$A_{(6-14)}$ (cpd/kg/keV)
2	(0.12±0.14)	(0.0032±0.0017)
3	-(0.08±0.14)	(0.0016±0.0017)

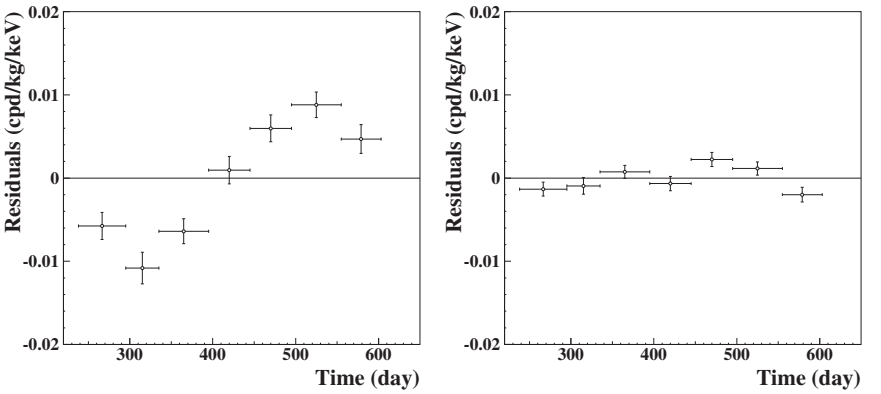

Fig. 4. Experimental *single-hit* residuals in the (1–6) keV and in the (10–20) keV energy regions for DAMA/LIBRA–phase2 as if they were collected in a single annual cycle (i.e. binning in the variable time from the January 1st of each annual cycle). The data points present the experimental errors as vertical bars and the associated time bin width as horizontal bars. The initial time of the figures is taken at August 7^{th}. A clear modulation satisfying all the peculiarities of the DM annual modulation signature is present in the lowest energy interval with A=(0.00956 ± 0.00090) cpd/kg/keV, while it is absent just above: A=(0.0007 ± 0.0005) cpd/kg/keV.

Similar results are obtained when comparing the *single-hit* residuals in the (1–6) keV with those in other energy intervals; for example Fig. 4 shows the *single-hit* residuals in the (1–6) keV and in the (10–20) keV energy regions for DAMA/LIBRA–phase2 as if they were collected in a single annual cycle (i.e. binning in the variable time from the January 1st of each annual cycle).

Moreover, Table 3 shows the modulation amplitudes obtained by fitting the time behaviour of the residual rates of the *single-hit* scintillation events in the (6–14) keV energy interval for the DAMA/LIBRA–phase2 annual cycles. In the fit the phase and the period are at the values expected for a DM signal. The obtained amplitudes are compatible with zero.

A further relevant investigation on DAMA/LIBRA–phase2 data has been performed by applying the same hardware and software procedures, used to acquire and to analyse the *single-hit* residual rate, to the *multiple-hit* one. Since the probability that a DM particle interacts in more than one detector is negligible, a DM signal can be present just in the *single-hit* residual rate. Thus, the comparison of the results of the *single-hit* events with those of the *multiple-hit* ones corresponds to compare the cases of DM particles beam-on and beam-off. This procedure also allows an additional test of the background behaviour in the same energy interval where the positive effect is observed.

In particular, in Fig. 5 the residual rates of the *single-hit* scintillation events collected during DAMA/LIBRA–phase2 are reported, as collected in a single cycle, together with the residual rates of the *multiple-hit* events, in the considered energy intervals. While, as already observed, a clear modulation, satisfying all the

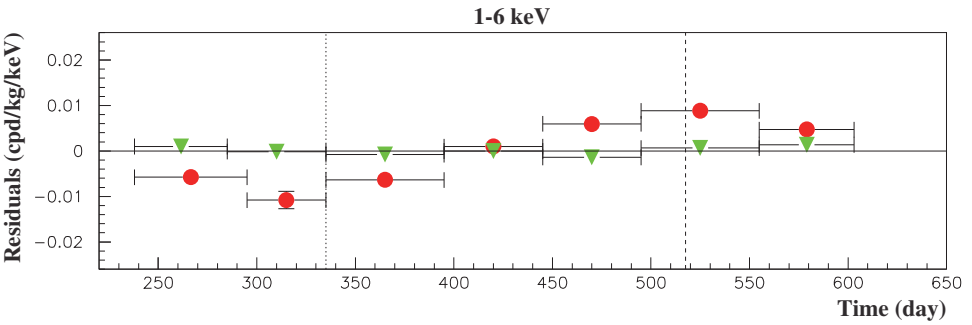

Fig. 5. Experimental residual rates of DAMA/LIBRA–phase2 *single-hit* events (filled red on-line circles), class of events to which DM events belong, and for *multiple-hit* events (filled green on-line triangles), class of events to which DM events do not belong. They have been obtained by considering for each class of events the data as collected in a single annual cycle and by using in both cases the same identical hardware and the same identical software procedures. The initial time of the figure is taken on August 7^{th}. The experimental points present the errors as vertical bars and the associated time bin width as horizontal bars. Analogous results were obtained for DAMA/NaI (two last annual cycles) and DAMA/LIBRA–phase1.[2–5, 36]

peculiarities of the DM annual modulation signature, is present in the *single-hit* events, the fitted modulation amplitude for the *multiple-hit* residual rate is well compatible with zero: (0.00030 ± 0.00032) cpd/kg/keV in the (1–6) keV energy region. Thus, again evidence of annual modulation with proper features as required by the DM annual modulation signature is present in the *single-hit* residuals (events class to which the DM particle induced events belong), while it is absent in the *multiple-hit* residual rate (event class to which only background events belong). Similar results were also obtained for the two last annual cycles of DAMA/NaI[36] and for DAMA/LIBRA–phase1.[2–5] Since the same identical hardware and the same identical software procedures have been used to analyse the two classes of events, the obtained result offers an additional strong support for the presence of a DM particle component in the galactic halo.

In conclusion, no background process able to mimic the DM annual modulation signature (that is, able to simultaneously satisfy all the peculiarities of the signature and to account for the measured modulation amplitude) has been found or suggested by anyone throughout some decades thus far (see also discussions e.g. in Ref.[1–5, 7, 8, 19–21, 23, 34–36]).

5. The analysis in frequency

To perform the Fourier analysis of the DAMA/LIBRA–phase1 and phase2 data in a wider region of considered frequency, the *single-hit* events have been grouped in 1 day bins. Due to the low statistics in each time bin, a procedure detailed in Ref.[64] has been followed. The whole power spectra up to the Nyquist frequency and the zoomed ones are reported in Fig. 6. A clear peak corresponding to a period of

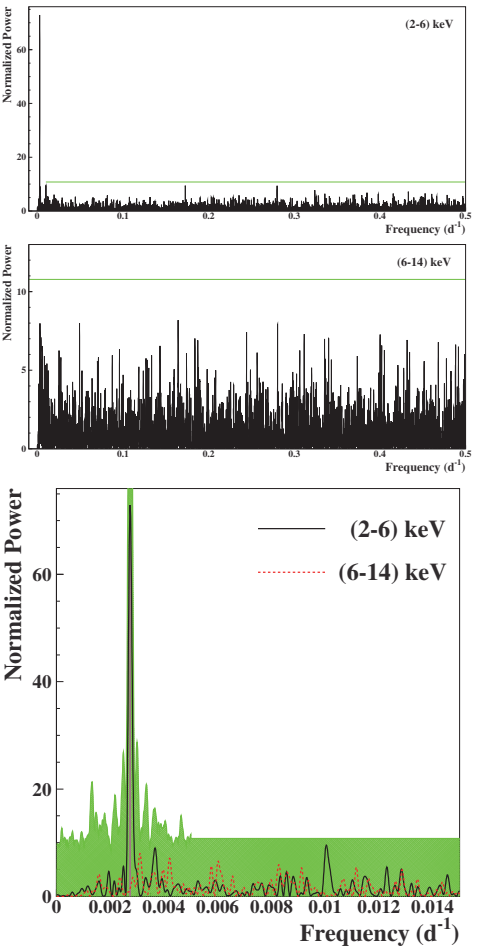

Fig. 6. Power spectra of the time sequence of the measured *single-hit* events for DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 grouped in 1 day bins. From top to bottom: spectra up to the Nyquist frequency for (2–6) keV and (6–14) keV energy intervals and their zoom around the 1 y^{-1} peak, for (2–6) keV (solid line) and (6–14) keV (dotted line) energy intervals. The main mode present at the lowest energy interval corresponds to a frequency of 2.74×10^{-3} d^{-1} (vertical line, purple on-line). It corresponds to a period of $\simeq 1$ year. A similar peak is not present in the (6–14) keV energy interval. The shaded (green on-line) area in the bottom figure – calculated by Monte Carlo procedure – represents the 90% C.L. region where all the peaks are expected to fall for the (2–6) keV energy interval. In the frequency range far from the signal for the (2–6) keV energy region and for the whole (6–14) keV spectrum, the upper limit of the shaded region (90% C.L.) can be calculated to be 10.8 (continuous lines, green on-line).

1 year is evident for the lowest energy interval; the same analysis in the (6–14) keV energy region shows only aliasing peaks instead. Neither other structure at different frequencies has been observed.

As to the significance of the peaks present in the periodogram, we remind that the periodogram ordinate, z, at each frequency follows a simple exponential

distribution e^{-z} in the case of the null hypothesis or white noise.[65] Therefore, if M independent frequencies are scanned, the probability to obtain values larger than z is: $P(>z) = 1 - (1 - e^{-z})^M$.

In general M depends on the number of sampled frequencies, the number of data points N, and their detailed spacing. It turns out that M is very nearly equal to N when the data points are approximately equally spaced, and when the sampled frequencies cover the frequency range from 0 to the Nyquist frequency.[66,67]

The number of data points used to obtain the spectra in Fig. 6 is $N = 5047$ (days measured over the 5479 days of the 15 DAMA/LIBRA–phase1 and phase2 annual cycles) and the full frequencies region up to Nyquist frequency has been scanned. Therefore, assuming $M = N$, the significance levels $P = 0.10$, 0.05 and 0.01, correspond to peaks with heights larger than $z = 10.8$, 11.5 and 13.1, respectively, in the spectra of Fig 6.

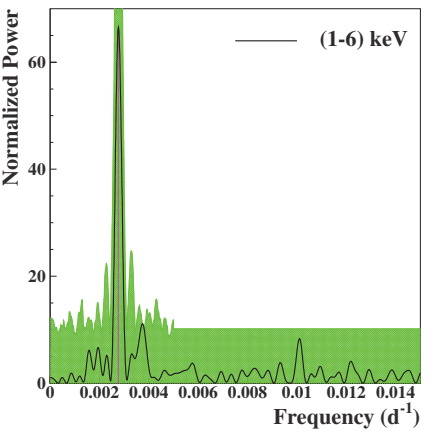

Fig. 7. Power spectrum of the time sequence of the measured *single-hit* events in the (1–6) keV energy interval for DAMA/LIBRA–phase2 grouped in 1 day bin. The main mode present at the lowest energy interval corresponds to a frequency of 2.77×10^{-3} d^{-1} (vertical line, purple on-line). It corresponds to a period of $\simeq$ 1 year. The shaded (green on-line) area – calculated by Monte Carlo procedure – represents the 90% C.L. region where all the peaks are expected to fall for the (1–6) keV energy interval.

In the case below 6 keV, a signal is present; thus, to properly evaluate the C.L. the signal must be included. This has been done by a dedicated Monte Carlo procedure where a large number of similar experiments has been simulated. The 90% C.L. region (shaded, green on-line) where all the peaks are expected to fall for the (2–6) keV energy interval is reported in Fig 6. Several peaks, satellite of the one year period frequency, are present.

In conclusion, apart from the peak corresponding to a 1 year period, no other peak is statistically significant either in the low and high energy regions.

Moreover, for each annual cycle of DAMA/LIBRA–phase1 and phase2, the annual baseline counting rates have been calculated for the (2–6) keV energy interval. Their power spectrum in the frequency range $0.00013 - 0.0019$ d^{-1} (corresponding to a period range 1.4–21.1 year) has been calculated according to Ref.[5]. No statistically-significant peak is present at frequencies lower than 1 y^{-1}. This implies that no evidence for a long term modulation in the counting rate is present.

Finally, the case of the (1–6) keV energy interval of the DAMA/LIBRA–phase2 data is reported in Fig. 7. As previously the only significant peak is the one corresponding to one year period. No other peak is statistically significant being below the shaded (green on-line) area obtained by Monte Carlo procedure.

6. The modulation amplitudes by the maximum likelihood approach

The annual modulation present at low energy can also be pointed out by depicting the energy dependence of the modulation amplitude, $S_m(E)$, obtained by maximum likelihood method considering fixed period and phase: T =1 yr and $t_0 = 152.5$ day. For such purpose the likelihood function of the *single-hit* experimental data in the $k-$th energy bin is defined as: $\mathbf{L_k} = \mathbf{\Pi}_{ij} e^{-\mu_{ijk}} \frac{\mu_{ijk}^{N_{ijk}}}{N_{ijk}!}$, where N_{ijk} is the number of events collected in the i-th time interval (hereafter 1 day), by the j-th detector and in the k-th energy bin. N_{ijk} follows a Poisson's distribution with expectation value $\mu_{ijk} = [b_{jk} + S_i(E_k)]\, M_j \Delta t_i \Delta E \epsilon_{jk}$. The b_{jk} are the background contributions, M_j is the mass of the $j-$th detector, Δt_i is the detector running time during the i-th time interval, ΔE is the chosen energy bin, ϵ_{jk} is the overall efficiency. The signal can be written as:

$$S_i(E) = S_0(E) + S_m(E) \cdot \cos \omega (t_i - t_0),$$

where $S_0(E)$ is the constant part of the signal and $S_m(E)$ is the modulation amplitude. The usual procedure is to minimize the function $y_k = -2ln(\mathbf{L_k}) - const$ for each energy bin; the free parameters of the fit are the $(b_{jk} + S_0)$ contributions and the S_m parameter.

The modulation amplitudes for the whole data sets: DAMA/NaI, DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 (total exposure 2.86 ton×yr) are plotted in Fig. 8; the data below 2 keV refer only to the DAMA/LIBRA-phase2 exposure (1.53 ton×yr). It can be inferred that positive signal is present in the (1–6) keV energy interval, while S_m values compatible with zero are present just above. All this confirms the previous analyses. The test of the hypothesis that the S_m values in the (6–14) keV energy interval have random fluctuations around zero yields $\chi^2/d.o.f.$ equal to 20.3/16 (P-value = 21%).

For the case of (6–20) keV energy interval $\chi^2/d.o.f. = 42.2/28$ (P-value = 4%). The obtained χ^2 value is rather large due mainly to two data points, whose centroids are at 16.75 and 18.25 keV, far away from the (1–6) keV energy interval. The P-values obtained by excluding only the first and either the points are 14% and 23%.

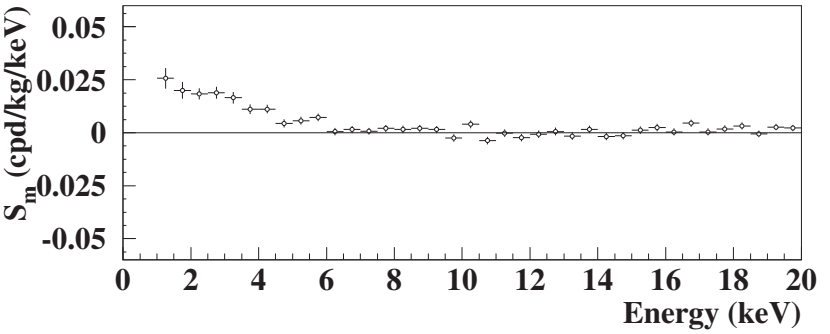

Fig. 8. Modulation amplitudes, S_m, for the whole data sets: DAMA/NaI, DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 (total exposure 2.86 ton×yr) above 2 keV; below 2 keV only the DAMA/LIBRA-phase2 exposure (1.53 ton × yr) is available and used. The energy bin ΔE is 0.5 keV. A clear modulation is present in the lowest energy region, while S_m values compatible with zero are present just above. In fact, the S_m values in the (6–20) keV energy interval have random fluctuations around zero with $\chi^2/d.o.f.$ equal to 42.2/28 (P-value is 4%).

6.1. *The S_m distributions*

The method also allows the extraction of the S_m values for each detector. In particular, the modulation amplitudes S_m integrated in the range (2–6) keV for each of the 25 detectors for the DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 periods can be produced. They have random fluctuations around the weighted averaged value confirmed by the χ^2 analysis. Thus, the hypothesis that the signal is well distributed over all the 25 detectors is accepted.

As previously done for the other data releases,[2–5,19–21,23] the S_m values for each detector for each annual cycle and for each energy bin have been obtained. The S_m are expected to follow a normal distribution in absence of any systematic effects. Therefore, the variable $x = \frac{S_m - \langle S_m \rangle}{\sigma}$ has been considered to verify that the S_m are statistically well distributed in the 16 energy bins ($\Delta E = 0.25$ keV) in the (2–6) keV energy interval of the seven DAMA/LIBRA–phase1 annual cycles and in the 20 energy bins in the (1–6) keV energy interval of the eight DAMA/LIBRA–phase2 annual cycles and in each detector. Here, σ are the errors associated to S_m and $\langle S_m \rangle$ are the mean values of the S_m averaged over the detectors and the annual cycles for each considered energy bin.

Defining $\chi^2 = \Sigma x^2$, where the sum is extended over all the 272 (192 for the 16^{th} detector[4]) x values, $\chi^2/d.o.f.$ values ranging from 0.8 to 2.0 are obtained, depending on the detector.

The mean value of the 25 $\chi^2/d.o.f.$ is 1.092, slightly larger than 1. Although this can be still ascribed to statistical fluctuations, let us ascribe it to a possible systematics. In this case, one would derive an additional error to the modulation amplitude measured below 6 keV: $\leq 2.4 \times 10^{-4}$ cpd/kg/keV, if combining quadratically the errors, or $\leq 3.6 \times 10^{-5}$ cpd/kg/keV, if linearly combining them. This possible

additional error: $\leq 2.4\%$ or $\leq 0.4\%$, respectively, on the DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 modulation amplitudes is an upper limit of possible systematic effects coming from the detector to detector differences.

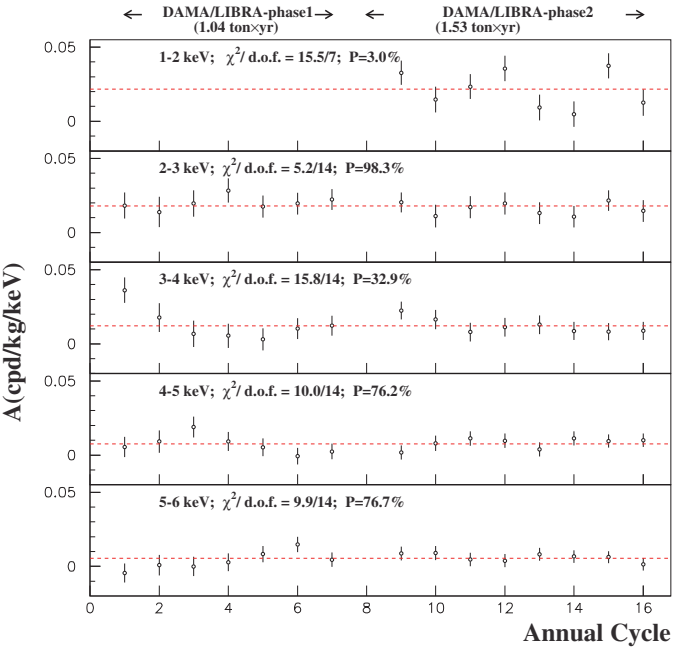

Fig. 9. Modulation amplitudes of each single annual cycle of DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2. The error bars are the 1σ errors. The dashed horizontal lines show the central values obtained by best fit over the whole data set. The χ^2 test and the *run test* accept the hypothesis at 95% C.L. that the modulation amplitudes are normally fluctuating around the best fit values.

Among further additional tests, the analysis of the modulation amplitudes as a function of the energy separately for the nine inner detectors and the remaining external ones has been carried out for DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2, as already done for the other data sets.[2–5, 19–21, 23] The obtained values are fully in agreement; in fact, the hypothesis that the two sets of modulation amplitudes belong to same distribution has been verified by χ^2 test, obtaining e.g.: $\chi^2/d.o.f. = 1.9/6$ and $36.1/38$ for the energy intervals (1–4) and (1–20) keV, respectively ($\Delta E = 0.5$ keV). This shows that the effect is also well shared between inner and outer detectors.

Fig. 9 shows the modulation amplitudes singularly calculated for each annual cycle of DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2. To test the hypothesis that the amplitudes are compatible and normally fluctuating around their mean values, the χ^2 test has been performed. The $\chi^2/d.o.f.$ values and the P-values are also shown in Fig. 9. In addition to the χ^2 test, another independent statistical test has been applied: the *run test* (see e.g. Ref.[69]); it verifies the hypothesis that the

positive (above the mean value) and negative (under the mean value) data points are randomly distributed. The lower (upper) tail probabilities obtained by the *run test* are: 89(37)%, 87(30)%, 17(94)%, 17(94)% and 30(85)%, respectively. This analysis confirms that the data collected in all the annual cycles with DAMA/LIBRA–phase1 and phase2 are statistically compatible and can be considered together.

7. Investigation of the annual modulation phase

Let us, finally, release the assumption of the phase $t_0 = 152.5$ day in the procedure to evaluate the modulation amplitudes. In this case the signal can be alternatively written as:

$$\begin{aligned} S_i(E) &= S_0(E) + S_m(E)\cos\omega(t_i - t_0) + Z_m(E)\sin\omega(t_i - t_0) \\ &= S_0(E) + Y_m(E)\cos\omega(t_i - t^*). \end{aligned} \tag{1}$$

For signals induced by DM particles one should expect: i) $Z_m \sim 0$ (because of the orthogonality between the cosine and the sine functions); ii) $S_m \simeq Y_m$; iii) $t^* \simeq t_0 = 152.5$ day. In fact, these conditions hold for most of the dark halo models; however, as mentioned above, slight differences can be expected in case of possible contributions from non-thermalized DM components (see e.g. Refs.[38, 58, 59, 61–63]).

Considering cumulatively the data of DAMA/NaI, DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 the obtained 2σ contours in the plane (S_m, Z_m) for the (2–6) keV and (6–14) keV energy intervals are shown in Fig. 10–*left* while in Fig. 10–*right* the obtained 2σ contours in the plane (Y_m, t^*) are depicted. Moreover, Fig. 10 also shows only for DAMA/LIBRA–phase2 the 2σ contours in the (1–6) keV energy interval.

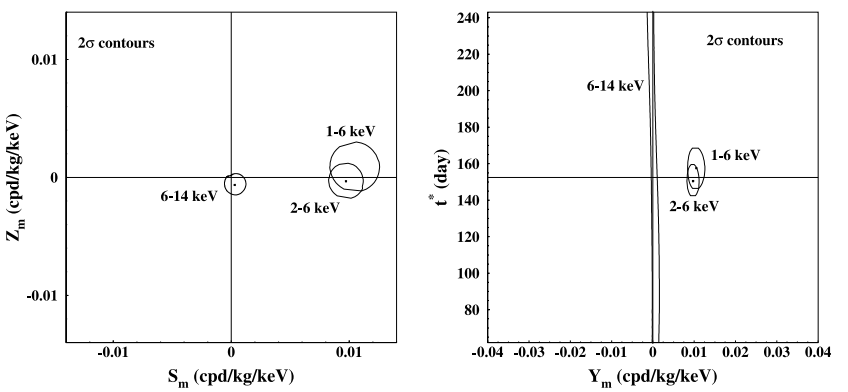

Fig. 10. 2σ contours in the plane (S_m, Z_m) (*left*) and in the plane (Y_m, t^*) (*right*) for: i) DAMA/NaI, DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 in the (2–6) keV and (6–14) keV energy intervals (light areas, green on-line); ii) only DAMA/LIBRA–phase2 in the (1–6) keV energy interval (dark areas, blue on-line). The contours have been obtained by the maximum likelihood method. A modulation amplitude is present in the lower energy intervals and the phase agrees with that expected for DM induced signals.

The best fit values in the considered cases (1σ errors) for S_m versus Z_m and Y_m versus t^* are reported in Table 4.

Table 4. Best fit values (1σ errors) for S_m versus Z_m and Y_m versus t^*, considering: i) DAMA/NaI, DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 in the (2–6) keV and (6–14) keV energy intervals; ii) only DAMA/LIBRA–phase2 in the (1–6) keV energy interval. See also Fig. 10.

E (keV)	S_m (cpd/kg/keV)	Z_m (cpd/kg/keV)	Y_m (cpd/kg/keV)	t^* (day)
DAMA/NaI+DAMA/LIBRA–phase1+DAMA/LIBRA–phase2:				
2–6	(0.0097 ± 0.0007)	-(0.0003 ± 0.0007)	(0.0097 ± 0.0007)	(150.5 ± 4.0)
6–14	(0.0003 ± 0.0005)	-(0.0006 ± 0.0005)	(0.0007 ± 0.0010)	undefined
DAMA/LIBRA–phase2:				
1–6	(0.0104 ± 0.0007)	(0.0002 ± 0.0007)	(0.0104 ± 0.0007)	(153.5 ± 4.0)

Finally, setting S_m in eq. (1) to zero, the Z_m values as function of the energy have also been determined by using the same procedure. The Z_m values as a function of the energy for DAMA/NaI, DAMA/LIBRA–phase1, and DAMA/LIBRA–phase2 data sets are expected to be zero. The χ^2 test applied to the data supports the hypothesis that the Z_m values are simply fluctuating around zero; in fact, in the (1–20) keV energy region the $\chi^2/d.o.f.$ is equal to 40.6/38 corresponding to a P-value = 36%.

The energy behaviors of the Y_m and of the phase t^* are produced for the cumulative exposure of DAMA/NaI, DAMA/LIBRA–phase1, and DAMA/LIBRA–phase2. As in the previous analyses, an annual modulation effect is present in the lower energy intervals and the phase agrees with that expected for DM induced signals. No modulation is present above 6 keV and the phase is undetermined.

8. Perspectives

To further increase the experimental sensitivity of DAMA/LIBRA and to disentangle some of the many possible astrophysical, nuclear and particle physics scenarios in the investigation on the DM candidate particle(s), an increase of the exposure in the lowest energy bin and a further decreasing of the software energy threshold are needed. This is pursued by running DAMA/LIBRA–phase2 and upgrading the experimental set-up to lower the software energy threshold below 1 keV with high acceptance efficiency.

Firstly, particular efforts for lowering the software energy threshold have been done in the already-acquired data of DAMA/LIBRA–phase2 by using the same technique as before with dedicated studies on the efficiency. As consequence, a new data point has been added in the modulation amplitude as function of energy down to 0.75 keV, see Fig. 11. A modulation is also present below 1 keV, from 0.75 keV.

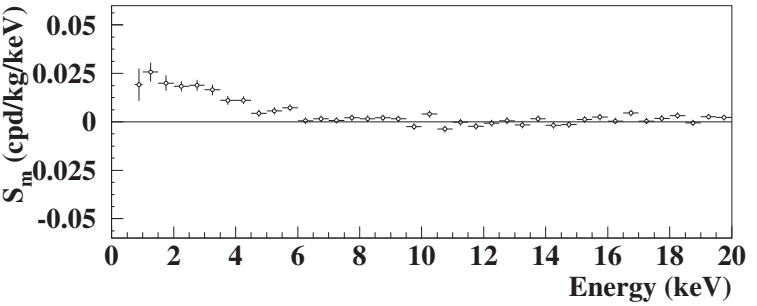

Fig. 11. As Fig. 8; the new data point below 1 keV, with software energy threshold at 0.75 keV, shows that an annual modulation is also present below 1 keV. This preliminary result confirms the necessity to lower the software energy threshold by a hardware upgrade and to improve the experimental error on the first energy bin.

This preliminary result confirms the necessity to lower the software energy threshold by a hardware upgrade and an improved statistics in the first energy bin.

This dedicated hardware upgrade of DAMA/LIBRA–phase2 is underway. It consists in equipping all the PMTs with miniaturized low background new concept preamplifier and HV divider mounted on the same socket, and related improvements of the electronic chain, mainly the use of higher vertical resolution 14-bit digitizers.

9. Conclusions

DAMA/LIBRA–phase2 confirms a peculiar annual modulation of the *single-hit* scintillation events in the (1–6) keV energy region satisfying all the many requirements of the DM annual modulation signature; the cumulative exposure by the former DAMA/NaI, DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 is 2.86 ton $\times$ yr.

As required by the exploited DM annual modulation signature: 1) the *single-hit* events show a clear cosine-like modulation as expected for the DM signal; 2) the measured period is well compatible with the 1 yr period as expected for the DM signal; 3) the measured phase is compatible with the roughly $\simeq 152.5$ days expected for the DM signal; 4) the modulation is present only in the low energy (1–6) keV interval and not in other higher energy regions, consistently with expectation for the DM signal; 5) the modulation is present only in the *single-hit* events, while it is absent in the *multiple-hit* ones as expected for the DM signal; 6) the measured modulation amplitude in NaI(Tl) target of the *single-hit* scintillation events in the (2–6) keV energy interval, for which data are also available by DAMA/NaI and DAMA/LIBRA–phase1, is: (0.01014 ± 0.00074) cpd/kg/keV (13.7 σ C.L.). No systematic or side processes able to mimic the signature, i.e. able to simultaneously satisfy all the many peculiarities of the signature and to account for the whole measured modulation amplitude, has been found or suggested by anyone throughout some decades thus far. In particular, arguments related to any possible role of

some natural periodical phenomena have been discussed and quantitatively demonstrated to be unable to mimic the signature (see references; e.g. Refs.[7,8]). Thus, on the basis of the exploited signature, the model independent DAMA results give evidence at 13.7σ C.L. (over 22 independent annual cycles and in various experimental configurations) for the presence of DM particles in the galactic halo.

The new data, released in this Conference, determine the modulation parameters with increasing precision and allow us to disentangle with larger C.L. among different DM candidates, DM models and astrophysical, nuclear and particle physics scenarios.

The DAMA model independent evidence is compatible with a wide set of astrophysical, nuclear and particle physics scenarios for high and low mass candidates inducing nuclear recoil and/or electromagnetic radiation, as also shown in various literature. Moreover, both the negative results and all the possible positive hints, achieved so-far in the field, can be compatible with the DAMA model independent DM annual modulation results in many scenarios considering also the existing experimental and theoretical uncertainties; the same holds for indirect approaches. For a discussion see e.g. Ref.[5] and references therein.

Finally, we stress that to efficiently disentangle among at least some of the many possible candidates and scenarios an increase of exposure in the new lowest energy bin and the decrease of the software energy threshold below the present 1 keV is important. The experiment is collecting data and the hardware efforts towards the lowering of the software energy threshold is in progress.

Dark Matter candidate particles able to induce nuclear recoils can also be studied using the so-called directionality approach. In this case the correlation between the nuclear recoils direction and the Earth motion in the galactic frame is studied. Several experimental techniques to explore the directionality approach have been proposed. In this talk, a review of such experimental techniques will be addressed.

Keywords: Dark Matter; Directionality; Nuclear Recoil.

1. Introduction

Astrophysical observations have pointed out the presence of Dark Matter (DM) on all astrophysical scales and many arguments have been suggested that a large fraction of it should be in form of relic DM particles.

Currently, several approaches are exploited to investigate DM particles in the galactic halo; here, we will focus our attention on a particular direct strategy: the directionality approach.

In direct detection experiments, a model-independent signature is a powerful tool to provide a DM signal identification with respect to the background. In fact, as originally pointed out in Refs. 1, 2 and discussed in Refs. 3, 4, independently of the considered DM scenario, the events induced by a physical reaction in a target detector depend on the product between the cross-section of the process and the relative velocity between the incident DM particle (DMp) and the target. Such a product is expected to have a characteristic time behaviour in case of DM annual modulation: annual variation of the interaction rate due to Earth motion around the Sun which is moving in the Galaxy, successfully exploited by DAMA collaboration.[5–9]

Besides this main one, other possible signatures are expected: a diurnal modulation, due to the Earth revolution around its axis;[10] a daily variation of the interaction rate due to the different Earth depth crossed by the DMp[11] and the directionality signature, due to the correlation of DM impinging direction with Earth's galactic motion, in case of DMp able to induce nuclear recoils.[12] In fact, the dynamics of the rotation of the Milky Way galactic disc through the halo of DM causes the Earth to experience a wind of DM particles seemingly flowing along a direction opposite to that of the solar motion relative to the DM halo.

Therefore, the observation of an anisotropy in the distribution of nuclear recoil directions could give further evidence and information for such DM candidate particles and the related astrophysics scenario. Thus, a direction-sensitive detector is needed.

2. Dark matter signal in case of elastic DMp–nucleus scattering

Direct detection experiments, using the directionality approach, look for the signal of DMp via their elastic scattering interactions with detector nuclei. Therefore, due to kinematic consideration, the recoil nucleus direction is correlated with the direction of the impinging DMp (see Fig. 1). Assuming an elastic DMp–nucleus scattering (see Fig. 1), the nucleus kinetic energy after the interaction with the impinging DM particle is:

$$E_R = \frac{4M_A M_{DM}}{(M_{DM} + M_A)^2} \cos^2(\theta)\, E_{DM} \tag{1}$$

where, M_A is the mass of target nucleus, M_{DM} and E_{DM} are the incoming DMp mass and kinetic energy (laboratory system), respectively, E_R is the recoil nucleus kinetic energy (laboratory frame) and θ is the scattering angle of the recoil nucleus in the lab frame. According to the equation (1), depending on the value of $M_A \sim 1{-}200$ GeV, considering a very simple isothermal halo model with $v \sim 300$ km/s $\cong 10^{-3}c$, thus with $E_{DM} \sim 0.5 \times 10^{-6}\, M_{DM}$, the maximum E_R can be $\ll 200$ keV up to $\sim$ 200 keV (without considering the quenching effect in the direct detection of

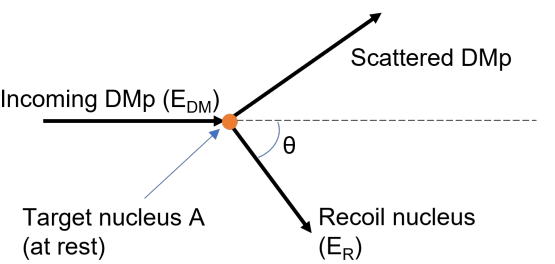

Fig. 1. DMp–nucleus elastic scattering diagrams for the laboratory coordinate systems.

the nuclear recoiling energy). Considering this information, the maximum range of nuclear recoiling is of the order of mm in low pressure gas medium, μm in liquid and less in solid medium.[13–15]

Thus, Low-Pressure Time Projection Chamber looks advantaged, but some drawbacks are present and will be discussed later.

To evaluate the direction of DMp in the laboratory frame, we can determine the detector velocity in the galactic rest frame, $\overrightarrow{v_d}(t)$, which varies with time. To study $\overrightarrow{v_d}(t)$ it is possible to consider various coordinate frames; in particular, following the formalism in,[12] we consider the horizontal coordinate frame located at the North pole, described by the "polar–zenith", $\Theta_z(t)$, and by the "polar–azimuth", $\phi_a(t)$. In this frame the area described in the sky by the direction of $\overrightarrow{v_d}(t)$ is shown in Fig. 2 (green band). Considering an experiment performed at a latitude similar to, e.g., the latitude of the Gran Sasso National Laboratory (LNGS) of I.N.F.N. ($42°27'12''$ N latitude and $13°34'26''$ E longitude), we can assume that Θ_z is always near 40°. In fact, at a certain time of the day ($\approx$ 21:00 h LST) the DMp come mainly from the top, while 12 h later they come near the horizon and from North (see Fig. 2). Thus, assuming $\overrightarrow{v}$ to be the velocity of the DMp in the laboratory frame, the DMp velocity in the galactic rest frame is $\overrightarrow{v} + \overrightarrow{v_d}(t)$; finally we can indicate with $f(\overrightarrow{v} + \overrightarrow{v_d}(t))$ the DM velocity distribution in the galactic rest frame (having assumed a specific DM halo model) and $\frac{\xi\rho_0}{M_{DM}} v f(\overrightarrow{v} + \overrightarrow{v_d}(t))$ is the flux of the considered DMp candidate, where ξ is the fraction of the local DM halo density (ρ_0) of the considered candidate; M_{DM} is the mass of the DM candidate particle.

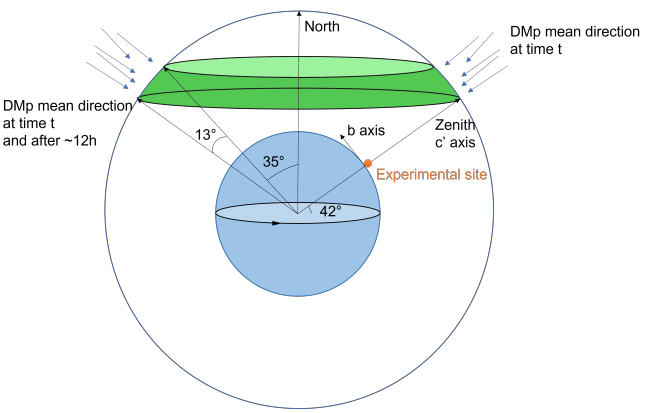

Fig. 2. Schematic representation of the experimental approach mentioned in the text. The detector is considered as placed at the Gran Sasso National Laboratory (LNGS) with the axis in the vertical direction and another axis is pointing to the North. The area in the sky from which the DM particles are preferentially expected is highlighted.

The expected counting rate of the signal, in the window (E_1,E_2) of the detected energy spectrum, as a function of the time t is:

$$R(E_1, E_2, t) = \int d^3\overrightarrow{v} \int d\Omega_{cm} \frac{\xi \rho_0 N_A}{M_{DM}} v f(\overrightarrow{v} + \overrightarrow{v_d}(t)) \frac{d\sigma_A}{d\Omega_{cm}} + \frac{1}{2} erf\left(\frac{q_A(\Omega_{out})E_R - E_1}{\sqrt{2}\Delta}\right) - \frac{1}{2} erf\left(\frac{q_A(\Omega_{out})E_R - E_2}{\sqrt{2}\Delta}\right)$$

where N_A is the number of target–nuclei of the A–th species per mass unit; Ω_{cm} is the nuclear recoil direction in the center of mass (c.m.) frame; $\frac{d\sigma_A}{d\Omega_{cm}}$ is the differential cross section in the c.m. frame, which is assumed to be isotropic; $q_A(\Omega_{out})$ is the quenching factor (Q.F.) which can depend on the direction of the nuclear recoil in the laboratory frame; and Δ is the detector energy resolution.

3. Detectors attempts

Current directional detectors are at the research and development stage. The experimental strategies are classifiable in two main groups: tracking detectors and detectors using anisotropic features. The first one bases the detection principle on the possibility of evaluating the direction of the nuclear recoils; the second one, instead, uses an anisotropic response of the detector with respect to the direction of the nuclear recoil strongly correlated with the impinging direction of the DMp.

Experiments based on Low-Pressure TPC aims to develop a TPC for directional DM searches and solar neutrino spectroscopy. Some of big drawbacks are the energy threshold, angular and spatial resolutions. Moreover, the total mass is often modest (in the literature are present liquid TPCs very big as ICARUS, DUNE, etc., but they are not applicable to DM sector). Another of the most critical issues is the low angular resolution at very low energy. Other important drawbacks are: low background techniques are not mature; some systematic effects with respect to the direction of the electric field are present in case of high charge gain; the data analysis is based on a strong software gamma rejection, introducing systematics.

The NEWSdm collaboration uses a nuclear emulsion-based detector acting both as a target and as a solid tracking device,[16] declaring a spatial threshold of (120 ± 5) nm. The radioactive contaminants of nuclear emulsion are mainly dominated by contamination of ^{14}C and U/Th chains. The main drawback is to reach enough spatial and angle resolution to be sensible to a range of nuclear recoiling, that at maximum is a few 100 nm, without compromising the emulsion path and minimizing the systematics during the data analysis and with a reasonable duty cycle.

We also mention two other ideas. A proposed method consists in identifying the direction of an incident DMp using the spectroscopy of quantum defects in macroscopic solid-state crystals as diamonds.[17] Instead, in Ref. 18 an odd type of DM detector made of DNA (or RNA) is proposed.

The second main group of detectors is based on the anisotropic response, showing a signal that varies with the direction of impinging particles. In particular, in literature, there are attempts to use (i) carbon nanotubes, (ii) columnar recombination in a TPC dual-phase, (iii) a realistic and very promising technique using anisotropic crystal scintillators.

The first one is an idea based on the use of a large number of carbon nanotubes vertically aligned (VA-CNT). There are weak indications that an electron is extracted from this VA-CNT forrest with a higher probability if the impinging direction of a particle is parallel to the VA-CNT, as compared to the impinging direction perpendicular to the VA-CNT. This possible effect could be implemented to develop an anisotropic sensor.[19]

The second case exploits a dual-phase time projection chamber (TPC) is filled with a liquid noble gas. In those devices, the scintillation light (S1) in the liquid phase and the ionization charge signals (generated in the liquid phase), which is drifted to the gas phase and there converted into a proportional scintillation signal (S2), are measured. Along the drift path, the electrons, due to several reasons, are partially recombined with the medium. It is expected that in case the initial electrons are generated along a direction perpendicular to the electric field (due to the direction of the nuclear recoil scattered from the impinging DMp), the columnar recombination could be less than in case the electrons are generated along the direction of the electron field. If detectable, the S2 signal, in the first case, is expected higher than in the second case as supposed in Ref. 20. The only study, using a very small LAr-TPC (SCENE detector), is published in Ref. 21, with a very poor indication of this phenomenon (see Fig. 21 of Ref. 21). For more information, a synoptic survey on liquid noble gases for DM searches is reported in Ref. 22, where the very low energy application of double phase noble gas detectors is analysed and compared; the main technical aspects of the existing experimental applications have been discussed and some implications have been outlined.

All these practical limitations and problems about these ideas can be overcome using the third approach, i.e. anisotropic scintillation detectors in a suitable low background experimental set-up located deep underground.

4. Anisotropic crystal scintillator

In anisotropic scintillators, the detector response to heavy particles depends on their impinging direction with respect to crystal axes. Therefore, in the case of nuclear recoils induced by DMp, the measured energy spectrum at low energy is expected to change its shape during the sidereal day as a consequence of the changing orientation of the crystal axes with respect to the DM wind. This effect can be pointed out as a peculiar variation of the counting rate measured in a given low energy window and offers the possibility to highlight the DM signal with respect to the electromagnetic background (for details, see, e.g., in Refs. 3, 4, 12).

The use of anisotropic scintillators to study the directionality signature was proposed for the first time in Ref. 3 and revisited in Ref. 4, where the case of anthracene detector was preliminarily analysed and several practical difficulties in the feasibility of such an experiment were underlined. Nevertheless, the authors suggested that competitive sensitivities could be reached with new devoted R&D's of anisotropic scintillators having significantly larger size, higher light response, better stiffness, higher atomic weights and anisotropic features similar as – or even better than – those of the anthracene scintillator.

4.1. *$ZnWO_4$ anisotropic scintillator*

The potential offered by the anisotropic properties of $ZnWO_4$ crystal scintillator in the search for DM with the directionality approach was indicated for the first time in Ref. 23. Recent measurements and R&D show that the $ZnWO_4$ detector can offer suitable features for the purpose.[12,24–27] In the light of this, the Anisotropic detectors for DArk Matter Observation (ADAMO) project[12,28] was considered and R&Ds have been progressed.

In particular, in the last years various $ZnWO_4$ detectors have been developed in the framework of the collaboration between the DAMA group of INFN (Istituto Nazionale di Fisica Nucleare) and the INR-Kyiv group.[26–36] Formerly, some crystals were produced by the Institute for Scintillation Materials (ISMA, Kharkiv, Ukraine) and, later on, a collaboration with the Nikolaev Institute of Inorganic Chemistry (Novosibirsk, Russia) has started and an R&D to produce ultra-radiopure $ZnWO_4$ by using the low-thermal gradient Czochralski technique in a platinum crucible is ongoing.[37] The produced crystals have been put in measurement in the DAMA/R&D underground facility at the Gran Sasso laboratory (LNGS) of INFN.[26,27,35,36] Measurements and R&D works have shown the competitiveness of $ZnWO_4$ scintillators for a DM experiment based on the directionality. In fact, the light output and the time profile of the scintillation pulse for heavy particles (p, α, nuclear recoils) depends on the direction of such particles with respect to the crystal axes while no difference is observed for γ/β radiation.[23] The shape of the scintillation pulse is also different for $\gamma(\beta)$ radiation and heavy particles (α). This pulse shape discrimination capability can potentially be of interest not only for a DM experiment but also for double beta decay searches. The $ZnWO_4$ also offers a high atomic weight and the possibility to realize single crystals with masses of a few kg.[37] Moreover, the presence of three target nuclei with very different masses (Zn, W and O) makes these scintillators sensitive to both small and large mass DM candidates, as also the NaI(Tl) is. The recently developed $ZnWO_4$ scintillators have a very high level of radiopurity. The upper limits for ^{228}Th are < 0.17 μBq/kg – < 1.3 μBq/kg, for ^{40}K are < 20 μBq/kg and for ^{226}Ra are < 2 μBq/kg.[24,26] A further radio-purification of $ZnWO_4$ crystal scintillators is feasible. The R&D is still ongoing[25,38,39] and very good results have also been obtained in improving the light transmission. The next step will be to suitably increase the size of crystals.

As confirmed by the measurements performed at LNGS, the crystals have relatively high light output at room temperature, being about 20% of the NaI(Tl) scintillator. It appears feasible to further improve the light output of the crystal considering that it can increase when working at low temperature.[40] To study this feature a small cryostat is currently under test at LNGS to realize and optimize the cooling system; this system will allow to reach a stable working temperature around -50°C.

In order to employ the $ZnWO_4$ for DM investigation with the directionality approach it is crucial to measure and quantify the anisotropy of the scintillator for nuclear recoils. For this purpose a campaign of measurements was performed by using a 7.99 g mass $ZnWO_4$ crystal scintillator of $(10 \times 10 \times 10.4)$ mm^3, in the framework of the ADAMO project. The crystal has been obtained by a second crystallization procedure using the low-thermal gradient Czochralski technique from zinc tungstate crystals made from tungsten oxide additionally purified by double sublimation of tungsten chlorides.[41] The crystallographic axes were identified by the producer and experimentally verified.

Before measuring the response of the $ZnWO_4$ crystal with a monochromatic neutron source at ENEA-CASACCIA, the crystal was irradiated with α particles at LNGS. In the following the obtained results are briefly reported.

4.2. *Measurements with α particles*

The small $ZnWO_4$ crystal was coupled to a HAMAMATSU H11934-200 PMT (Ultra Bialkali photocathode with an effective area of (23×23) mm^2 and quantum efficiency $\simeq 43\%$ at 400 nm and $\simeq 25\%$ at 500 nm). The scintillation pulses coming from the detector were recorded by a LeCroy WaveSurf24X-sA oscilloscope (4 chn, 2.5 GSamples/s, 200 MHz) in a time window of 100 μs. The measurements were performed by using an ^{241}Am source and various sets of thin mylar films as absorbers to decrease the α energy. The beam of α particles was collimated before reaching the crystal face. The energies of α particles were measured with a CANBERRA Alpha Spectrometer (model 7401VR). The energy scale of the crystal for each measurement was calibrated by using ^{137}Cs and ^{22}Na γ sources.

The typical energy distributions of the α particles impinging along the three axes of the crystal are shown in Fig. 3-left. The $ZnWO_4$ crystal was irradiated in the directions perpendicular to the (100), (001) and (010) crystal planes: hereafter crystal axes I (blue on-line), II (green on-line) and III (red on-line), respectively in Fig. 3.

In the Fig. 3-right the dependence of the α/β ratio as a function of the energy for the three different directions of the α beam relatively to the crystal axes is shown. In particular, the quenching factor for α particles measured along the crystal axis III is about 1.2 times larger than that measured along the crystal axes I and II. Instead, the quenching factors measured along the crystal axes I and II are quite similar. The error bars are mainly due to the uncertainty of the alpha energy which is slightly degraded in air.

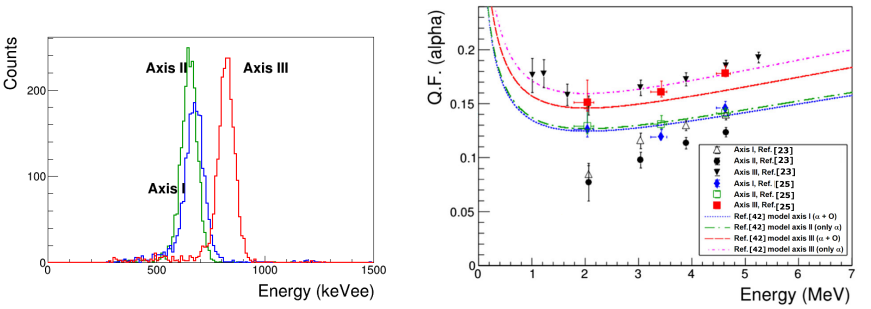

Fig. 3. Left: energy spectra of 4.63 MeV α particles impinging along the three axes of the crystal. Right: dependence of the α/β ratio on the energy of the α particles measured with a $ZnWO_4$ scintillator in Ref. 23 (black points) compared with those reported in Ref. 25 (colored points). The anisotropic behavior of the crystal is evident. The models for each crystal axis, obtained as global fits on all the data (from α's and from recoils; see also later) of Ref. 25 following the prescription of Ref. 42, is also reported.

The quenching factors and the anisotropic effect reported in Ref. 25 are in reasonable agreement with those of Ref. 23, as shown in Fig. 3-right; in the figure the behavior of the α/β ratio as expected for each crystal axis in the model of Ref. 42 are also reported.

Therefore, the data confirm the anisotropic features of $ZnWO_4$ crystal scintillator in case of α particles.

4.3. *Measurements with neutrons*

Monochromatic neutrons were generated by the Thermo Scientific portable generator MP 320. Neutrons are produced in the $d(t,\alpha)n$ reaction with energy around 14.7 MeV by accelerating deuterons toward a tritium target in electric potential. For the requirements of the experiment a configuration with beam acceleration voltage of 60 kV and a beam current of 40 μA was adopted in order to optimize the neutron yield and the stability of the beam operation; the production rate was around 10^7 n/s. In the experimental setup, neutrons leaving the target at 90 degrees to the forward direction were used; at this angle, simple kinematics predicts a value $E_n = 14.05$ MeV for a beam acceleration voltage of 60 kV.

The scattered neutron in the crystal is detected by two neutron detectors placed at a given scattering angle. In such a configuration the energy and the direction of the recoiling nucleus are fixed and, by measuring the energy released in the $ZnWO_4$ detector – in keV electron equivalent (keVee) – it is possible to determine the quenching factor. By changing the crystal axes orientation the quenching factor for the different axes can be measured.

A scheme of the set-up is shown in Fig. 4. The $ZnWO_4$ detector is placed in front of the neutron channel on a revolving platform around a vertical axis (O axis), which allows us to fix the direction of the crystal axis with respect to the impinging neutrons: the α angle as depicted in Fig. 4. The $ZnWO_4$ crystal is centered on

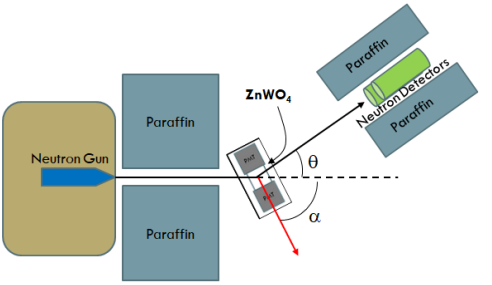

Fig. 4. Schematic view from the top of the experimental set-up. The two neutron detectors are one above the other.

the O axis and is optically coupled to two HAMAMATSU H11934-200 PMTs on opposite faces. In the set-up, the PMTs are on the faces perpendicular to the crystal axis III; thus, α identifies the angle between the crystal axis III and the impinging neutrons direction. The crystal axis I is also on the horizontal plane, while the axis II is vertical. The neutrons scattered off the $ZnWO_4$ crystal are tagged by two neutron detectors by Scionix employing EJ-309 liquid scintillator. The EJ-309 scintillator has a very high capability to discriminate neutrons interactions from the gamma background by Pulse Shape Discrimination (PSD). The neutron detectors are placed 82 cm far from O axis, one above the other to maintain the same neutron scattering angle θ (see Fig. 4) and to improve the solid angle acceptance. They are held by an arm and free to rotate around the O axis.

The signals from the two PMTs coupled to the $ZnWO_4$ detector are summed and recorded by a CAEN DT5720 transient digitizer with 250 MSamples/s. The trigger is obtained by the coincidence between a signal in the $ZnWO_4$ detector and in the EJ-309 detectors within ± 500 ns.

The energy detected in the $ZnWO_4$ detector is evaluated from the digitized pulse area. ^{133}Ba and ^{137}Cs sources were used to calibrate the detector energy scale. The typical energy resolution was $\sigma/E = 4.4\%$ at the 662 keV γ peak of ^{137}Cs. The energy calibration was performed before and after the neutrons irradiation.

Neutron events in the EJ-309 detectors were selected by a PSD data analysis based on: i) head/tail analysis; ii) analysis of the mean time, τ, of the time profile of the pulse. A typical example of the separation between gamma and neutrons exploiting the two techniques is reported in Fig. 5-left and in Fig. 5-right, respectively.

To select the nuclear recoils induced by the elastic scattering of neutrons over the background an important quantity is the TOF between the $ZnWO_4$ detector and the neutron detectors EJ-309. The expectation value of TOF due to the typical velocity of the scattered neutrons is around 15 ns. It can be defined the variable $\Delta t = t_0^{EJ} - t_0^{ZWO}$, where t_0^{EJ} (t_0^{ZWO}) is the starting time of the EJ-309 ($ZnWO_4$) pulse. The transit time of the neutron detectors PMT is ≈ 40 ns while it is ≈ 6 ns for the HAMAMATSU H11934-200. The Δt variable is shifted with respect to TOF

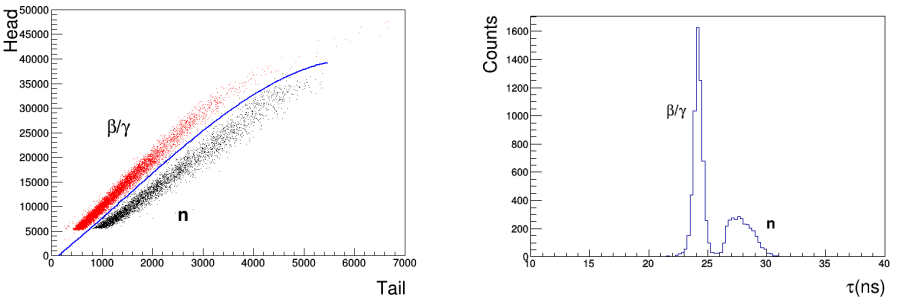

Fig. 5. Example of gamma/neutron separation by PSD in EJ-309 liquid scintillator. Left: head/tail analysis. Right: distribution of the mean time, τ, variable.

and it has been calibrated considering the coincidences between high energy events in the $ZnWO_4$ detector and gamma events in the neutron detectors. A $\Delta t \approx 34$ ns has been obtained from the data in agreement with the expectation. This TOF calibration has been taken into account in the analysis.

For a fixed scattering angle θ and crystal axis, the event pattern searched for was represented by a scintillation pulse in the $ZnWO_4$ detector in coincidence with a neutron in the EJ-309 detectors.

In Fig. 6-left the TOF distribution is depicted for the case of $\theta = 70°$ and crystal axis I, while in Fig. 6-right the bi-dimensional plot TOF vs $ZnWO_4$ energy is presented (E_{ZWO} is in keVee). These plots show a continuum due to random coincidences, a clear excess of events with energy around 80 keVee and TOF in agreement with the expectation for scattered neutrons on target nuclei. The peak in the TOF variable shows a tail on the left due to the first photoelectron delay in $ZnWO_4$ (effective average scintillation decay time ≈ 24 μs[23]). The observed excess can be ascribed to the O recoils in the $ZnWO_4$ detector and its position provides the quenching factor of this nucleus for the used scattering angle and crystal axis. The Zn and W recoils are expected to be well below the energy threshold that has been used in the present experimental conditions.

The behavior of the TOF distribution can be explained by considering that events belong to the sum of two main contributions: 1) a peak due to the coincidences caused by the elastic scatterings of neutrons off the $ZnWO_4$ nuclei, and 2) the random flat coincidences (f_{rnd}). To build a model for the TOF behavior some assumptions can be considered: i) the signal of the neutron detectors is "prompt" (that is the time delay between the neutron interaction and the starting time of the EJ-309 pulse is mostly equal to the PMT transit time); ii) the $ZnWO_4$ time delay between the neutron interaction and the starting time of the pulse is given by the PMT transit time plus the delay of the first photoelectron in $ZnWO_4$ detector; iii) the probability to have the first photoelectron in $ZnWO_4$ at the time t is $\frac{1}{\tau}e^{-t/\tau}$, where τ is the characteristic time decay of the process; iv) the fluctuations of the

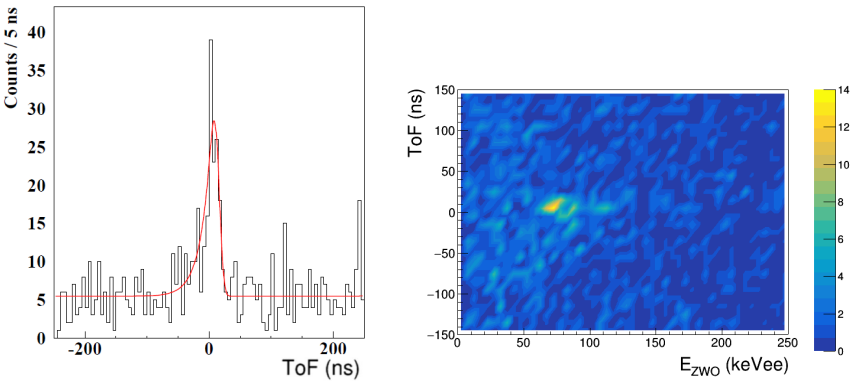

Fig. 6. TOF distribution and bi-dimensional plot TOF vs $ZnWO_4$ energy for coincidences obtained after selecting neutrons in the neutron detectors, for the case of scattering angle $\theta = 70°$ and axis I. Left: The TOF distribution shows a continuum due to random coincidences and a clear peak, that is in agreement with the expected TOF for neutrons after elastic scattering off the nuclei of $ZnWO_4$ detector. The peak shows a tail on the left part due to the first photoelectron delay in $ZnWO_4$. The fit with the function of eq. 3 is superimposed (See text). Right: A clear peak is present at the proper value of TOF and at the given energy. The peak position in the E_{ZWO} distribution provides the quenching factor of the O nucleus for the used scattering angle and crystal axis.

transit times of the PMTs of the $ZnWO_4$ and of the EJ-309 detectors, and the time resolution of the used digitizer (2 ns bin size for the neutron detectors and 4 ns for the $ZnWO_4$ detector) are taken into account by making a convolution of the time distribution with a Gaussian function having a characteristic spread σ. Thus, the model function of TOF can be written as:

$$f(TOF|f_{rnd}, A, \tau, \sigma, TOF_0) = f_{rnd} + A \int_0^\infty e^{-x/\tau} e^{-\frac{(x+TOF-TOF_0)^2}{2\sigma^2}} dx \qquad (2)$$

where TOF_0 represents the expectation value of the neutrons time of flight and A is a normalization factor. By solving the integral one gets:

$$f(TOF) = f_{rnd} + Be^{-\frac{TOF_0-TOF}{\tau}} \left[1 - erf\left(-\frac{TOF_0 - TOF}{\sqrt{2}\sigma} + \frac{\sigma}{\sqrt{2}\tau}\right)\right] \qquad (3)$$

where B includes only constant factors: $B = A\sqrt{\frac{\pi}{2}}\sigma e^{\frac{\sigma^2}{2\tau^2}}$. The result of the fit of the TOF distribution with the function given in eq. 3 is plotted in Fig. 6-left; it gives: $f_{rnd} \approx 5.5$ counts/ 5 ns, $B \approx 21.6$ counts/ 5 ns, $\tau \approx 16.9$ ns, $\sigma \approx 5.8$ ns and $TOF_0 \approx 15.4$ ns. The model reproduce well the experimental data and is in a good agreement with the expectations. A Monte Carlo simulation gives similar results.

For the estimation of the quenching factors three scattering angles were considered. Since the responses of the crystal axes I and II are rather similar, only the

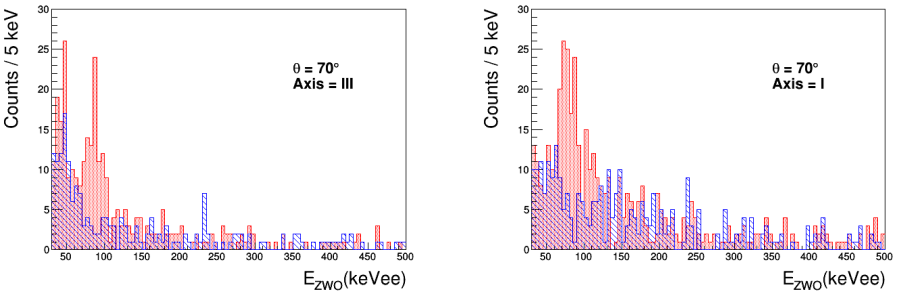

Fig. 7. Energy distributions of the detected energy, E_{ZWO}, in the $ZnWO_4$ detector, measured in keV electron equivalent (keVee) for the case of $\theta = 70°$ and axes III and I. Only events identified as recoils due to neutrons scattering, with subsequent registration of the scattered neutron in the neutrons detectors, are selected. Light (red on-line) histogram: events selected in the proper window of the TOF variable (-20 ns $< TOF <$ 30 ns). Dashed (blue on-line) histogram: events selected in the off-window (60 ns $< TOF <$ 110 ns).

case of axis I was considered. Figure 7 shows an example of the energy distributions of the detected energy, E_{ZWO}, in the $ZnWO_4$ detector, measured in keV electron equivalent ($\theta = 70°$ and axes III and I). Two distributions are reported for each plot: one is obtained by selecting events in the time window expected for the TOF of neutrons elastically scattered off the nuclei of $ZnWO_4$ detector, -20 ns $< TOF <$ 30 ns (light red histogram); the other is presented by selecting off-window events (random coincidences), 60 ns $< TOF <$ 110 ns (blue histogram). The off-window events are related to random coincidences and, therefore, their distribution is the background distribution in the histogram of the in-window events. The peaks are evident and can be ascribed to the oxygen nuclear recoils. The positions of the peaks are obtained by fitting them with a Gaussian curve plus an exponential function that simulates the background of the random coincidences. The energy resolutions, σ, of the peaks are between 8 and 12 keVee; the values are well in agreement with the energy dependence: $\sigma \propto \sqrt{E}$.

In Table 1 the summary of the peak positions measured for the three considered angles is reported. The expected recoil energies for the oxygen nucleus, $E_{R,O}$, are also given. The obtained quenching factors are calculated as the ratio $E_{ZWO}/E_{R,O}$ and the last column reports the degree of anisotropy for each scattering-angle/recoil energy.

In Fig. 8 the obtained values for the quenching factors are plotted together with the models for the considered crystal axes derived from Ref. 42 for a single kB parameter. This parameter has been estimated, for each axis, taking into account both the response of $ZnWO_4$ to α particles and to oxygen recoils ($kB = 12.06$ mg MeV^{-1} cm^{-2} for axis I, $kB = 11.80$ mg MeV^{-1} cm^{-2} for axis II – only α data are considered – and $kB = 9.98$ mg MeV^{-1} cm^{-2} for axis III, respectively).

Table 1. Summary table of the peak position due to oxygen nuclear recoils. For each scattering angle, θ, and for the different axes of the $ZnWO_4$ crystal, the peak position, E_{ZWO}, the energy resolution, σ, the expected recoil energies for the oxygen nucleus, $E_{R,O}$, the quenching factors, Q, and the anisotropy, Q_{III}/Q_I ratio, are reported.

Scattering angle, θ	Crystal axis	E_{ZWO} (keVee)	σ (keVee)	$E_{R,O}$ (keV)	Quenching factor, Q	Q_{III}/Q_I
80°	III	99.3 ± 2.5	9	1402	0.0708 ± 0.0018	1.174 ± 0.051
	I	84.5 ± 2.9	12		0.0603 ± 0.0021	
70°	III	86.5 ± 2.0	7	1128	0.0767 ± 0.0018	1.121 ± 0.038
	I	77.2 ± 1.9	10		0.0684 ± 0.0017	
60°	III	75.4 ± 1.8	9	866	0.0871 ± 0.0021	1.166 ± 0.059
	I	64.7 ± 2.9	10		0.0747 ± 0.0033	

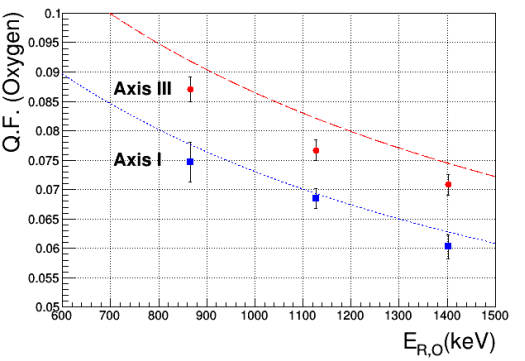

Fig. 8. Quenching factors for oxygen nuclear recoils in $ZnWO_4$ for the crystal axes I and III as function of the expected recoil energies $E_{R,O}$. In the plot the expected behavior of quenching factor for the considered crystal axes is also shown; it has been obtained by the global fits on the α and oxygen recoil data, following the prescription of Ref. 42 (for more details see Ref. 25).

5. Conclusion

The directionality investigates the correlation between the direction of the nuclear recoils induced by DMp and the motion of the Earth in the galactic rest frame. In fact, due to the solar motion in the DM halo, a wind of DMp is expected on the Earth with an seemingly opposite direction with respect to the Earth velocity in the galactic rest frame. As a consequence of the Earth's rotation, an observer on the Earth's surface experiences a change in the DM average arrival direction during a sidereal day. The induced nuclear recoils' directions are expected to be strongly correlated with that of the DM particles. Thus, the study of the nuclear recoils directions can also be pursued to investigate the class of DM candidate particles interacting via elastic-scattering on target nuclei.

A brief review of the R&Ds present in the literature has been addressed. In particular, we have briefly discussed the case of Low-Pressure TPC, the emulsion-based detector, columnar recombination, and some other ideas like the use of DNA based detector, diamonds or VA-CNT. However, such techniques suffer of several big problems, such as the short range of nuclear recoil, high radioactivity level, stability during the running condition, mass limitation etc., making this measurement really difficult. On the other hand, the anisotropic crystal scintillators offer a unique possibility of overcoming all these problems and giving a realistic technique to exploit the directionality approach (see Refs. 12, 25 for details). In fact, the results confirm the anisotropic response of the $ZnWO_4$ crystal scintillator to α particles and to oxygen nuclear recoils. The presence of a good anisotropic response also in the lower energy region is supported by the trend of the measured quenching factors at lower energy. In particular, for nuclear recoils induced by neutrons, the anisotropic response of the $ZnWO_4$ crystal scintillator has been determined at 5.4 standard deviations. This opens a possibility to realize a pioneer experiment to investigate the mentioned DM candidates by means of the directionality with the help of $ZnWO_4$ anisotropic scintillators. The features and the potentiality of these detectors can achieve – in some of the many possible scenarios and for some DM candidates able to induce a nuclear recoil – sensitivities not far from that of the DAMA/LIBRA positive result:[5–7,43] a low background pioneer experiment named ADAMO (Anisotropic detectors for DArk Matter Observation) located deep underground.[12,28]

For the near future, the DAMA, INR–Kyiv and ENEA/Casaccia collaboration plans to further investigate the light response of $ZnWO_4$ concerning the operation temperature (to increase the light-yield eventually), the light response at very low energy in case of the electromagnetic excitation and the Q.F. for nuclear recoils of W and Zn and other scattered angles of oxygen nucleus.

The article reviews our recent experimental results on the Continuous Spontaneous Localization (CSL) model and on the gravity related collapse model developed by Diósi and Penrose (DP). These models of dynamical reduction of the wave function consist in non-linear and stochastic modifications of the Schröedinger equation, which lead to a progressive breakdown of the superposition principle, as the size of the system increases. We performed a high sensitivity survey of the spontaneous radiation phenomenon, predicted by the collapse models, in a dedicated experiment operated in the extremely low background of the Gran Sasso underground National Laboratory of INFN in Italy. Our studies set the strongest bounds on the CSL parameters, in a broad region of the parameters space, and rule out the DP in its present formulation.

Keywords: Collapse Models; Spontaneous Radiation; Germanium Detectors.

1. Dynamical collapse models and spontaneous radiation

Quantum Theory (QT) is the basis of our understanding of the physical world. Since its inception QT successfully described plenty of puzzling experimental phenomena, it explained the spectrum of the black body radiation and the atomic structure, it was the cornerstone of the development of modern chemistry, of nuclear physics and of quantum field theory, just to give some examples, and presently fuels the growth of vanguard technologies. Despite its success and the outstanding precision of the experimental validations, QT still contains a conundrum in its grounding pillars. Why the superposition principle, characterizing the evolution of microscopic systems, does not carry over to macroscopic objects? Why in the act of measuring the deterministic dynamics is replaced by a probabilistic behaviour governed by the Born rule?

Models of dynamical reduction of the wave function represent phenomenological, and testable, concrete solutions to the problem (see e.g.,[1–8] for a review and references see also[9]). They consist in non-linear and stochastic modifications of the

Schröedinger equation, which preserve the QT predictions in the microscopic regime, and go over to classical mechanics in the macroscopic limit, by breaking down the quantum linear evolution proportionally to the growing size of the system.

Besides interferometric experiments (see e.g.[10–14]), which aim to measure the interference pattern of the spatial superposition which is created in an interferometer, collapse models can be also probed with indirect tests (see e.g.[15–27]). Common denominator of this second class of experiments is to exploit the random motion associated to the collapse mechanism, which allows to test the effect of the models predictions on macroscopic objects. Clear advantage is the magnification effect, which leads to the stronger constraints on the collapse models, this is the case of micrometer cantilever,[16] gravitational wave detectors[28,29] and X/γ-ray measurements,[25–27] the latter being the subject of this paper.

We will review in this paper our latest experimental results on the Continuous Spontaneous Localization (CSL) and on the Diósi-Penrose (DP) models. In the CSL model[4–6] the non-linear and stochastic terms are characterized by the interaction with a continuous set of independent noises, with zero average, Gaussian correlation in space and, in the simplest version, white correlation in time. The model is defined in terms of two phenomenological parameters, denoted by λ and r_C. λ has the dimensions of a rate and sets the strength of the collapse. r_C is a correlation length which determines the spatial resolution of the collapse, the collapse is weak if the superposition size is much smaller than r_C, while becomes effective for delocalizations which are much larger than r_C. Different theoretical considerations lead to alternative choices for the parameters: Ghirardi, Rimini and Weber[3] proposed $\lambda = 10^{-17}\mathrm{s}^{-1}$ and $r_C = 10^{-7}\mathrm{m}$, Adler[30] proposed $\lambda = 10^{-8\pm2}\mathrm{s}^{-1}$ for $r_C = 10^{-7}\mathrm{m}$, and $\lambda = 10^{-6\pm2}\mathrm{s}^{-1}$ for $r_C = 10^{-6}\mathrm{m}$.

Roger Penrose argued[7,8] that when a system is found in a spatial quantum superposition, a corresponding superposition of two different space-times is generated. The superposition is unstable and decays in time. The more massive the system in the superposition, the larger the difference in the two space-times and the faster the wave-function collapse. The average collapse time τ would then be given by the expression $\tau \approx \hbar/E_g$, where $\hbar$ is the reduced Planck's constant and E_g is the gravitational self-energy of the difference between two (stationary) mass distributions of the superposition. Lajos Diósi developed a dynamical theory of gravity-related wave function collapse[1,2] which predicts the same form for the collapse time. Considered that the gravitational self-interaction energy diverges for point-like constituents, Diósi introduced[31] a minimum length R_0, which limits the spatial resolution of the mass density. E_g is then a function of R_0, the smaller R_0 the faster the collapse.

An unavoidable consequence of the dynamics of both the CSL and the gravity related collapse developed by Diósi, is that the non-linear interaction with the noise-filed induces a Brownian-like diffusion motion for the particles which, if charged, emits radiation. This phenomenon, which is not predicted in the context of QT, is usually called *spontaneous radiation*, and represents the observable which was investigated in our experimental surveys. The spontaneous radiation rate, due to

the emission of protons in the atomic nuclei, was calculated in Refs.[26,27] and is given by:

$$\left.\frac{d\Gamma}{dE}\right|_t = N_{atoms} \cdot N_A^2 \cdot \frac{\hbar\, e^2}{4\,\pi^2\,\epsilon_0\,c^3\,m_0^2} \cdot \frac{\lambda}{r_C^2}\frac{1}{E}\,, \tag{1}$$

for the CSL model, and by:

$$\left.\frac{d\Gamma}{dE}\right|_t = N_{atoms} \cdot N_A^2 \cdot \frac{2}{3}\frac{G\,e^2}{\pi^{3/2}\,\epsilon_0\,c^3} \cdot \frac{1}{R_0^3 E}\,, \tag{2}$$

for the DP model. N_{atoms} is the number of atoms in the system with atomic number N_A, c is the speed of light, ϵ_0 is the vacuum permittivity, m_0 is the nucleon mass, G is the universal gravitational constant, E and t are the energy and the time. Electrons are relativistic in the energy range which was considered in our analyses, hence their contribution to the spontaneous radiation emission can not be considered.

The paper is organized as follows: in Section 2 the experimental apparatus is described, in Section 3 is given a brief description of the statistical analysis and the constraints on the characteristic parameters of the CSL and DP models are summarized, while concluding remarks and the future developments of our studies are outlined in Section 4.

2. The experimental setup

The experimental apparatus was based on a coaxial p-type High Purity Germanium detector (HPEGe) surrounded by multiple shielding layers: the inner shielding consisting of 5cm thick electrolytic copper, the external part of lead (30 cm from the bottom and 25 cm from the sides). Both the shielding and the cryogenic system were enclosed in an air tight steel housing, flushed with boil-off nitrogen, in order to suppress radon contamination (see Fig. 2 in Ref.[26] for a schematic representation of the setup, further details on the setup structure can be found in Ref.[26] and therein references). The experiment was operated in the extremely low background environment of the Gran Sasso underground National Laboratory of INFN in Italy.

The goal of the measurement was to disentangle a faint contribution of the spontaneous radiation emission process, to the measured spectrum, from environmental background. To this aim an accurate characterization of the whole apparatus was performed with a validated Monte Carlo (MC) code[32] based on the GEANT4 software library.[33]

The measured spectrum (corresponding to an exposure of 124 kg $\cdot$ day) is shown in black in Fig. 1, in the range $\Delta E = (1000 \div 3800)$keV (this is a reproduction of the original Fig. 1 in Ref.[27]). The energy range fulfills the theoretical requirements for the validity of the calculated rates (Eqs. (1) and (2)). In ΔE the main contribution to the background was found to be originated by residual radionuclides, present

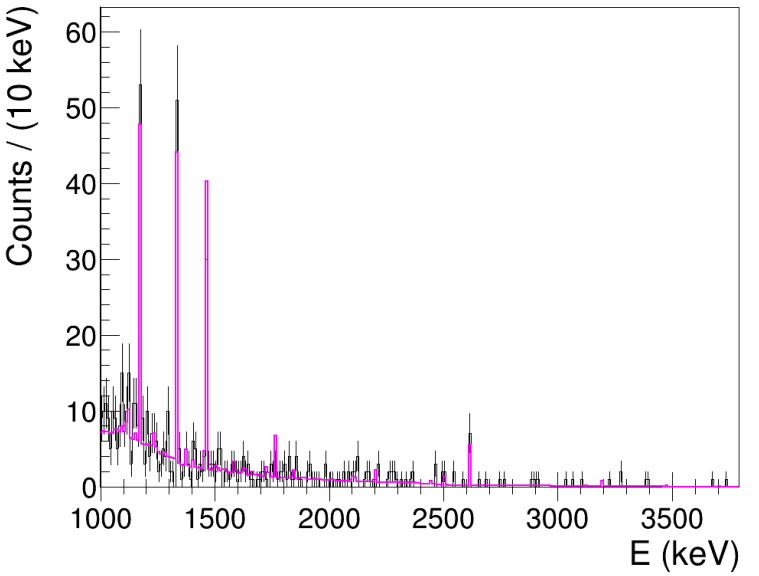

Fig. 1. The measured X-ray spectrum is shown in black in the selected energy range $\Delta E = (1000 - 3800)$ keV. The simulated background distribution is also shown in magenta.

in the materials of the setup, whose measured activities represented the inputs of the MC simulations. The magenta distribution in Fig. 1 represents the simulated background, 88% of the measured spectrum can be described in terms of known emission processes.

The simulation also allowed to compute the efficiencies, as a function of the energy, for the detection of spontaneously emitted photons in each component of the setup. To this end 10^8 photons, with uniform spatial distribution, were generated in each material in steps of 200 keV (i.e. 15 points in the ΔE). The efficiency functions $\epsilon_i(E)$ (i labelling the material of the detector) were then estimated by means of polynomial fits of the corresponding distributions, for each component of the detector which gives an appreciable contribution. The results of this analysis are summarized in Fig. 2 and Table 1 of Ref.[27].

3. Summary of the data analyses and results

The strategy of the Bayesian statistical analysis was to perform a comparison of the theoretically predicted spontaneous emission rate, generated by each component of the apparatus and weighted by the experimental efficiency and acceptance, with the measured distribution, accounting for the estimated background.

Given the calculated efficiency functions, and the theoretical rate (Eqs. (1) and (2)), the expected number of measured events, due to the spontaneous emission by

protons belonging to the i-th material, during the acquisition time T is:

$$\int_{\Delta E} \left.\frac{d\Gamma}{dE}\right|_t T\,\epsilon_i(E)\,dE. \tag{3}$$

Summation over i yields the total expected signal contribution, which is a function of the phenomenological parameters (λ, r_C) or R_0, depending on the selected collapse model. The measured counts were assumed to fluctuate according to a Poissonian distribution and the probability density functions for the expected number of counts were derived, from which the following constraints on the models parameters were calculated, corresponding to a probability of 0.95:

$$\frac{\lambda}{r_C^2} < 52\,\mathrm{s}^{-1}\mathrm{m}^{-2}\,; \qquad R_0 > 0.54\cdot 10^{-10}\mathrm{m}\,, \tag{4}$$

see Refs.[26,27] for more details concerning the data analysis.

The first limit in Eq. (4) represents the stronger existing bound on the CSL model for values of the correlation length $r_C \leq 10^{-6}$m. The limit on R_0 (right side in Eq. (4)) is about three orders of magnitude stronger than previous bounds in the literature.[29] If R_0 is chosen as the size of the nucleus's wave function (as suggested by Penrose), our result is to be compared with the square-root of the mean square displacement of a nucleus in the lattice. For the Germanium crystal, cooled down at the liquid Nitrogen temperature, this would amount to an R_0 value of about $0.05\cdot 10^{-10}$m, which is more than one order of magnitude less than the lower limit set by our experiment.

4. Conclusions and perspectives

We summarized the results of a dedicated measurement, performed at the Gran Sasso underground National Laboratory of INFN. The study was devoted to the search of spontaneous radiation emission, predicted by the CSL and the DP models of wave function collapse. We set the strongest bounds on the CSL phenomenological parameters in the region $r_C \leq 10^{-6}$m. Penrose's proposal for a gravity-related collapse of the wave function, in the present formulation, is ruled out. Our result indicates that the idea of gravity-related wave function collapse, which remains very appealing, will probably require a new approach. Indeed new theoretical developments are seeking for non-Markovian and/or dissipative versions of the collapse models, predicting a lower rate of spontanoeus radiation depending on the photon frequency. Both Penrose and Diósi are also pursuing the idea of a radiation free gravity-related collapse.

This pushes our efforts through further refinements our experimental techniques and data analyses methods. We are presently expanding our sensitive energy region from the MeV to few keV, with experimental setups based on Broad Energy Germanium detectors and ultra-radio pure targets. We are investigating the application of Machine Learning algorithms to identify the faint signal of the dynamical collapse, towards a deeper understanding of the foundations of Quantum Mechanics.

Leptophilic dark matter at linear colliders

P. S. Bhupal Dev

Department of Physics and McDonnell Center for the Space Sciences, Washington University, St. Louis, MO 63130, USA
E-mail: bdev@wustl.edu

Leptophilic dark matter (LDM) could naturally arise in many beyond the Standard Model scenarios and could address certain experimental anomalies. We discuss some model-independent collider constraints on the LDM effective couplings with the Standard Model sector, considering its production at a future electron-positron linear collider (with polarized and unpolarized beam options) in both mono-photon and mono-Z channels.[1]

Keywords: Dark Matter, Effective Field Theory, Lepton Collider

1. Introduction

Many of the existing experimental constraints on dark matter (DM) crucially rely on the DM interactions with nucleons, and therefore, can be largely weakened if the DM predominantly interacts with the Standard Model (SM) leptons, but not quarks at tree-level. Such *leptophilic* DM (LDM) could arise naturally in many beyond the Standard Model (BSM) scenarios,[2–23] some of which could even explain various experimental anomalies, such as the muon anomalous magnetic moment,[24] DAMA/LIBRA annual modulation,[25] anomalous cosmic ray positron excess,[26–29] the galactic center gamma-ray excess,[30] and XENON1T electron excess.[31] Dedicated searches for LDM in direct detection[32–34] and beam dump[35,36] experiments have also been discussed.

In this proceedings based on Ref.[1], we focus on the LDM searches at lepton colliders, which are complementary to the direct and indirect detection searches. We adopt an effective field theory (EFT) approach, which has been widely used in the context of collider searches for DM following the early works of Refs.[37–45] The same interactions responsible for DM pair-annihilation in the early universe leading to their thermal freeze-out guarantee their direct production at colliders, as long as kinematically allowed. This will give a characteristic mono-X signature, where the large missing transverse momentum carried away by the DM pair is balanced by a visible sector particle X (which can be either a photon, jet, W, Z, or Higgs, depending on the model) emitted from an initial, intermediate or final state (see Refs.[46,47] for reviews). Specifically, the mono-jet signature has become emblematic for LHC DM searches.[48–51] However, for an LDM with loop-suppressed interactions to the SM quarks, the hadron colliders like the LHC are not expected to provide a better limit than the existing constraints from indirect searches, such as from AMS-02,[52,53] at least within the EFT framework with contact interactions.

On the other hand, lepton colliders provide an ideal testing ground for the direct production of LDM and its subsequent detection via either mono-photon[42,45,54–63] or mono-Z[64–67] signatures. We go beyond the existing literature and perform a comprehensive and comparative study of both mono-photon and mono-Z signatures of LDM at future e^+e^- colliders in a model-independent, EFT approach.[1] Our analysis is generically applicable to all future e^+e^- colliders, such as the ILC,[68] CLIC,[69] CEPC[70] and FCC-ee,[71] but for concreteness, we have taken the $\sqrt{s} = 1$ TeV ILC as our case study for numerical simulations. We also assume the DM to be fermionic and limit ourselves to the dimension-6 operators, but taking into consideration all possible dimension-6 operators of scalar-pseudoscalar (S-P), vector-axialvector (V-A) and tensor-axialtensor (T-AT) type as applicable for the most general DM-electron coupling. Within the minimal EFT approach, the only relevant degrees of freedom in our analysis are the DM mass and an effective cut-off scale Λ which determines the strength of the four-Fermi operators. This enables us to derive model-independent ILC sensitivities on LDM in the (m_χ, Λ) plane in both mono-photon and mono-Z (leptonic and hadronic) channels, after taking into account all relevant backgrounds and systematic uncertainties. We consider both unpolarized and polarized beam options,[68,72] and find that with the proper choice of polarizations for the e^- and e^+ beams (which depends on the operator type), the DM sensitivities could be significantly enhanced.

2. Effective operators

Our primary assumptions are (i) the DM particle χ couples directly only to the SM leptons but not to the quarks (hence leptophilic), and (ii) the energy scale of the associated new physics is large compared to the collider energies under consideration, thus allowing us to integrate out the heavy mediators and parametrize the DM-SM interactions using effective higher-dimensional operators. For concreteness, we assume that the DM particles are Dirac fermions, and therefore, the leading order DM-SM interactions are the dimension-six four-Fermi interactions, with the most-general effective Lagrangian given by[37]

$$\mathcal{L}_{\text{eff}} = \frac{1}{\Lambda^2} \sum_j \left(\overline{\chi}\Gamma^j_\chi \chi\right) \left(\overline{\ell}\Gamma^j_\ell \ell\right) , \tag{1}$$

where Λ is the cut-off scale for the EFT description and the index j corresponds to different Lorentz structures, as shown below. Since our main focus is on e^+e^- colliders, we will just set $\ell = e$ in Eq. (1) and assume this to be the only leading-order coupling, but our discussion below could be easily extended to other cases, e.g. future muon colliders[73] by setting $\ell = \mu$.

A complete set of Lorentz-invariant operators consists of scalar (S), pseudoscalar (P), vector (V), axial-vector (A), tensor (T) and axial-tensor (AT) currents.

We classify them as follows:

$$\begin{aligned}
&\text{S-P type}: && \Gamma_\chi = c_S^\chi + ic_P^\chi\gamma_5\,, && \Gamma_e = c_S^e + ic_P^e\gamma_5\,,\\
&\text{V-A type}: && \Gamma_\chi^\mu = (c_V^\chi + c_A^\chi\gamma_5)\,\gamma^\mu\,, && \Gamma_{e\mu} = (c_V^e + c_A^e\gamma_5)\,\gamma_\mu\,,\\
&\text{T-AT type}: && \Gamma_\chi^{\mu\nu} = (c_T^\chi + ic_{AT}^\chi\gamma_5)\,\sigma^{\mu\nu}\,, && \Gamma_{e\mu\nu} = \sigma_{\mu\nu}\,,
\end{aligned} \tag{2}$$

where $\sigma^{\mu\nu} = \frac{i}{2}[\gamma^\mu, \gamma^\nu]$ is the spin tensor and $c_j^{\chi,e}$ are dimensionless, real couplings. For simplicity, in Eq. (1) we have used a common cut-off scale Λ for all Lorentz structures. Furthermore, in our subsequent numerical analysis, we will consider one type of operator at a time, by setting the corresponding couplings $c_j^{\chi,e} = 1$ without loss of generality and all other couplings equal to zero, unless otherwise specified. For instance, setting $c_S^\chi = c_P^\chi = c_S^e = c_P^e = 1$ and all other couplings equal to zero gives us the (S+P)-type operator, which we will simply refer to as the **SP**-type in the following discussion. Similarly, we will denote the $c_V^\chi = c_A^\chi = c_V^e = c_A^e = 1$ case simply as the **VA**-type, and $c_T^\chi = c_{AT}^\chi = 1$ as the **TAT**-type for presenting our numerical results in the (m_χ, Λ) plane. For other choices of the couplings, our results for the sensitivity on Λ can be easily scaled accordingly.

We will impose a theoretical limit of $\Lambda > \sqrt{s}$ for the EFT validity. For relatively larger DM mass, we must also have $\Lambda > 2m_\chi$ in order to describe DM pair annihilation by the EFT. In fact, using $\Lambda = 2m_\chi$ induces 100% error in the EFT prediction for s-channel UV completions. Therefore, we will use $\Lambda > \max\{\sqrt{s}, 3m_\chi\}$ as a conservative lower bound[74] to ensure the validity of our EFT approach.

3. Mono-photon channel

For the mono-photon signal $e^+e^- \to \chi\overline{\chi}\gamma$, the χ's will contribute to the missing transverse energy at the detector. The dominant irreducible SM background to this process comes from neutrino pair production with an associated ISR photon, i.e. $e^+e^- \to \nu\overline{\nu}\gamma$. Since neutrinos are practically indistinguishable from DMs on an event-by-event basis, the majority of this background survives the event selection cuts. However, as we will show later, this background is highly polarization-dependent, and therefore, can be significantly reduced by the proper choice of polarized beams, without affecting the signal much.

Apart from the neutrino background, any SM process with a single photon in the final state can contribute to the total background if all other visible particles escape detected. The SM processes containing either jets or charged particles are relatively easy to distinguish from a DM event, so their contribution to the total background is negligible.[58] The only exception is the *Bhabha scattering* process associated with an extra photon (either from initial or final state radiation), i.e., $e^+e^- \to e^+e^-\gamma$, which has a large cross section, is polarization-independent, and can significantly contribute to the total background whenever the final-state electrons and positrons go undetected, e.g. along beam pipes. In our following analysis, we consider both neutrino and radiative Bhabha backgrounds.

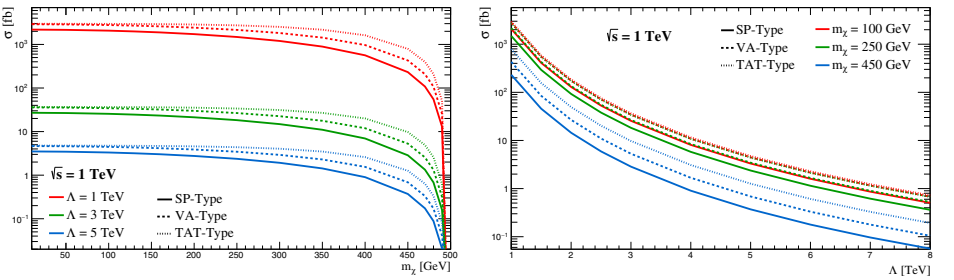

Fig. 1. Variation of mono-photon signal cross-section with the DM mass (left) and the cut-off scale (right) at $\sqrt{s} = 1$ TeV ILC. The solid, dashed and dotted lines are for the SP, VA and TAT-type operators respectively. In the left panel, the red, green and blue curves respectively correspond to different values of the cut-off scale $\Lambda = 1$ TeV, 3 TeV and 5 TeV, while in the right panel, they correspond to different values of the DM mass $m_\chi = 100$ GeV, 250 GeV and 450 GeV.

3.1. *Cross-sections*

The cross-sections for the mono-photon signal $e^+e^- \to \chi\overline{\chi}\gamma$ and the radiative neutrino background $e^+e^- \to \nu\overline{\nu}\gamma$ at $\sqrt{s} = 1$ TeV ILC are estimated using `CalcHEP`[75] with proper implementation of ISR and beamsstrahlung effects, which significantly affect the width and position of the neutrino Z-resonance. For this purpose, the EFT Lagrangian (1) is implemented in `FeynRules`[76] to generate the CHO library required for `CalcHEP`. To avoid collinear and infrared divergences, we limit the phase space in the event generation with the following cuts on the outgoing photon energy E_γ and its polar angle θ_γ:

$$8 \text{ GeV} < E_\gamma < 500 \text{ GeV}, \quad |\cos\theta_\gamma| \leq 0.995\,. \tag{3}$$

The *radiative* Bhabha scattering events are generated using `WHIZARD`[77] (to better handle the singularities) with the same set of cuts as in Eq. (3) to the matrix element photon (i.e., excluding the ISR and beamsstrahlung photons). Also, some additional cuts are implemented for the Bhabha process to take care of the soft and collinear divergences:

$$M_{e^\pm_{\rm in},e^\pm_{\rm out}} < 2m_e,\ M_{e^\pm_{\rm out},e^\pm_{\rm out}} < 5 \text{ GeV},\ P_T^\gamma > 1 \text{ GeV},\ \Delta R_{e^\pm,\gamma} > 0.2,\ \Delta R_{e^\pm,e^\pm} > 0.4. \tag{4}$$

After generating the signal and background events, we perform a fast detector simulation of the `SiD` detector of ILC[78] using `Delphes3`[79] with the configuration card validated in Ref.[80]. The variations of the unpolarized signal cross section as a function of the DM mass and the cut-off scale are shown in Figure 1 left and right panels respectively for all three operator types, namely, SP (solid), VA (dashed) and TAT (dotted)-type. We find that the cross-section is the smallest (largest) for the SP (TAT)-type operator at any given DM mass. In the left panel, the sudden drop in the cross-section as m_χ approaches $\sqrt{s}/2$ is due to phase-space suppression. Otherwise, for smaller DM masses, the cross-section for a given operator type and

Table 1. Comparison of the SM backgrounds and signal cross sections for the mono-photon channel with different choices of beam polarization at $\sqrt{s} = 1$ TeV. For the signal, we have chosen benchmark values of $m_\chi = 100$ GeV and $\Lambda = 3$ TeV. The numbers in bold highlight the optimal polarization choice for a given operator type.

		$(80, 30)$	**45.2**	27.7	27.7	45.2

a given cut-off scale is almost independent of the DM mass. In the right panel, we see that for a given DM mass the cross-section drops as Λ^{-4}, as expected.

As for the background, we find that the neutrino background cross section at $\sqrt{s} = 1$ TeV is 4.8 pb, while the radiative Bhabha background is 68.4 pb (though it is substantially reduced after the baseline selection). On the other hand, the DM signal cross section is found to be much smaller, as shown in Table 1 for a benchmark DM mass of $m_\chi = 100$ GeV and the cut-off scale $\Lambda = 3$ TeV.

3.2. *Effect of polarization*

One important advantage of lepton colliders is that the incoming beams can be polarized. This helps to reduce the neutrino background considerably, as shown in Table 1. To utilize the full advantage of the beam polarization, we investigate the effect of different choices of polarization on the signal and background. At the ILC, the baseline design foresees at least 80% electron beam polarization at the interaction point, whereas the positron beam can be polarized up to 30% for the undulator positron source (up to 60% may be possible with the addition of a photon collimator).[68] For comparison, we show our results for three different nominal absolute values of polarization: $|P(e^-, e^+)| = (80, 0)$, (80,20) and (80,30). In each case, we can also have four different polarization configurations, namely, $\text{sign}(P(e^-), P(e^+)) = (+,+)$, $(+,-)$, $(-,+)$ and $(-,-)$, where $+$ and $-$ denote the right- and left-handed helicities respectively.

In Table 1, we show the effect of different schemes of polarizations and helicity orientations on the mono-photon signal and background cross-sections. It is clear that the radiative Bhabha background remains almost unchanged. On the other

hand, electron beam polarization is very effective in reducing the neutrino background, as a 80% *right-handed* electron beam can reduce the neutrino background to 23% of the unpolarized case, even without any polarization on the positron beam. The effect is further enhanced by a *left-handed* positron beam. We see that for 20% and 30% left-handed positron beam polarization, the neutrino background is reduced to 20% and 18% of its unpolarized value, respectively.

The signals are also affected to some extent by beam polarization and the optimal helicity configuration depends on the operator type. For SP- and TAT-type operators we see no effect of electron-beam polarization, but a 20% (30%) *right-handed* positron beam can enhance the signal by 16% (24%). The VA-type signal, on the other hand, prefers the $(+,-)$ helicity configuration – the same choice for which the neutrino background is minimized. With the $(+80\%, -30\%)$ configuration, the VA-type signal is enhanced by a factor of 2.3, whereas the $(+80\%, +30\%)$ configuration enhances it by a modest 26%.

Overall, although the $(+80\%, -30\%)$ configuration minimizes the background the most, looking at the different signal to background ratio, we find that the $(+80\%, +30\%)$ configuration is the best for the SP- and TAT-type operators. For direct comparison between the results for different operators, we choose to work with the $(+80\%, +30\%)$ configuration democratically for all the operator types, unless otherwise specified.

3.3. *Cut-based analysis*

Now we analyze various kinematic distributions and perform a cut-based analysis to optimize the signal-to-background ratio. This of course depends on the DM mass, so in Table 2, we list three benchmark points (BPs) with $m_\chi = 100$ GeV, 250 GeV and 350 GeV respectively, and present the corresponding selection cuts optimized for each case. Here we fix $\Lambda = 3$ TeV for illustration, but in the next subsection, we will vary both m_χ and Λ to obtain the 3σ sensitivity limits. As for the choice of the DM mass values, since it was seen from Figure 1 that the signal cross-sections are barely sensitive to the DM mass up to around 100 GeV, our BP1 essentially captures the light DM scenario. Similarly, our BP3 is chosen moderately close to the kinematic limit of $\sqrt{s}/2$ (going too close to $\sqrt{s}/2$ will result in cross-section values too low too low to give sizable event counts after all the selection cuts). The BP2 is chosen for an intermediate mass DM in between BP1 and BP2.

We define our mono-photon signals by those events that pass through the baseline selection criteria as defined below, in addition to the cuts given in Eq. (3):

$$E_\gamma > 10 \text{ GeV}, \;\; |\eta_\gamma| < 2.45 \;\; \text{and} \;\; P_T^{\text{miss}} > 10 \text{ GeV}\,, \tag{5}$$

where the hardest photon in an event is considered as the signal photon. For the radiative Bhabha background, we define the selection criteria for electrons as $P_{T,e} > 10$ GeV, $|\eta_e| < 2.5$, and have kept only those events which contain no electrons (and positrons) passing these criteria, which means they have escaped detection.

Table 2. Mono-photon selection cuts for different BPs across all operator types.

	BP1	**BP2**	**BP3**
Definition	$m_\chi = 100$ GeV, $\Lambda = 3$ TeV	$m_\chi = 250$ GeV, $\Lambda = 3$ TeV	$m_\chi = 350$ GeV, $\Lambda = 3$ TeV
Baseline selection	$E_\gamma > 10$ GeV, $\|\eta_\gamma\| < 2.45$, $P_T^{\rm miss} > 10$ GeV		
SP-type			
Cut-1	$E_\gamma < 450$ GeV	$E_\gamma < 340$ GeV	$E_\gamma < 250$ GeV
Cut-2	$\|\eta_\gamma\| < 1.6$		
Cut-3	$P_T^{\rm miss} < 450$ GeV	$P_T^{\rm miss} < 340$ GeV	$P_T^{\rm miss} < 240$ GeV
Cut-4	$P_T^{\rm frac} < 1.3$		
Cut-5	$1.1 < \Delta R_{\gamma,\rm MET} < 4.5$		
VA-type			
Cut-1	$E_\gamma < 440$ GeV	$E_\gamma < 350$ GeV	$E_\gamma < 250$ GeV
Cut-2	$\|\eta_\gamma\| < 1.7$		
Cut-3	$P_T^{\rm miss} < 400$ GeV	$P_T^{\rm miss} < 340$ GeV	$P_T^{\rm miss} < 250$ GeV
Cut-4	$P_T^{\rm frac} < 1.2$		
Cut-5	$1.1 < \Delta R_{\gamma,\rm MET} < 4.5$		
TAT-type			
Cut-1	$E_\gamma < 460$ GeV	$E_\gamma < 360$ GeV	$E_\gamma < 230$ GeV
Cut-2	$\|\eta_\gamma\| < 1.7$		
Cut-3	$P_T^{\rm miss} < 450$ GeV	$P_T^{\rm miss} < 350$ GeV	$P_T^{\rm miss} < 230$ GeV
Cut-4	$P_T^{\rm frac} < 1.2$		
Cut-5	$1.1 < \Delta R_{\gamma,\rm MET} < 4.4$		

After implementing these baseline selection cuts, we find that the signal and the neutrino background are reduced to about 60% of their original values in Table 1. Similarly, the actual Bhabha-induced background relevant for our signal is found to be only about 13% of its original value quoted in Table 1 after the baseline selection cuts, taking into account only the missed electron events. To further enhance our signal-to-background ratio, we then examine the signal versus background distributions of some relevant kinematic variables and devise further cuts, which are dynamic with respect to different BPs, as summarized in Table 2. See Ref.[1] for details.

Even after implementing the baseline and analysis cuts 1 through 5, the neutrino background can only be reduced to about 40% of its original value in Table 1. Similarly, the radiative Bhabha background, although substantially reduced to about 4% of its original value in Table 1 after the baseline selection and analysis cuts, still remains sizable and comparable to the neutrino background. However, an electromagnetic calorimeter in the very forward direction of the beamline (BeamCal)[81] can further suppress the Bhabha background to the per mille level. To properly incorporate the effect of BeamCal, we have used the selection efficiencies obtained from a full detector simulation performed in Ref.[61] by modeling the complete instrumented region in a realistic way. According to this analysis, the selection efficiency of the Bhabha background after the BeamCal veto only is 2.7%, while that of the neutrino background is between 98% and 99.6%. As for the DM signal, we expect it to be

Table 3. Signal significance in the mono-photon channel for the three BPs at $\sqrt{s} = 1$ TeV with $\mathcal{L}_{\rm int} = 1000$ fb^{-1} integrated luminosity. The values in the parenthesis denote the significances with a 1% background systematic uncertainty.

Operator type	**Signal significance for $\mathcal{L}_{\rm int} = 1000\,{\rm fb}^{-1}$**					
	Unpolarized beams			Polarized beams		
	BP-1	BP-2	BP-3	BP-1	BP-2	BP-3
SP-type	8.1 (0.6)	5.8 (0.4)	3.5 (0.3)	18.1 (2.4)	13.0 (1.7)	7.8 (1.0)
VA-type	10.9 (0.8)	8.5 (0.6)	5.6 (0.4)	24.9 (3.2)	19.4 (2.5)	12.9 (1.7)
TAT-type	11.8 (0.8)	10.8 (0.8)	8.5 (0.6)	26.2 (3.5)	24.1 (3.2)	19.2 (2.6)

basically unaffected (just like the neutrino background) by the BealCal veto, as it does not contain highly energetic charged particles in the longitudinal direction.

For the polarized case, after the baseline selection cuts, the Bhabha background remains almost same as in the unpolarized case. The neutrino background, on the other hand, is significantly reduced in the polarized case to about 28% of its unpolarized value. The other cut efficiencies are also slightly better for the neutrino background in the polarized case.

As for the signals, from Table 1, we see that the TAT-type operator has the largest cross section to start with, both for the unpolarized as well as for the $(+80\%, +30\%)$ polarized cases. Even after the baseline selection and the specialized cuts discussed above, the TAT-type signal retains the largest efficiency among the three types. This will be reflected in our signal significance results below.

3.4. *Signal significance*

After implementing all the cuts mentioned above, we calculate the final signal significance for our benchmark scenarios using the definition

$$\text{Sig} = \frac{S}{\sqrt{S + B + (\epsilon B)^2}}\,, \tag{6}$$

where S and B are the number of signal and total background events respectively for a given integrated luminosity, and ϵ is the background systematic uncertainty. Our results are given in Table 3 for the three BPs. We show the numbers for an ideal case with zero systematics and also for a more realistic case with 1% systematics, i.e. with $\epsilon = 0.01$ (in parentheses). The results are significantly weakened in the latter case because of the relatively large background compared to the signal.

From Table 3, we see that the significance enhances as we go to lower DM mass regions, as expected because of kinematic reasons. Operator-wise we see that TAT and VA-type operators perform better than the SP-type. We also find substantial (around 50%) increase in significance on application of optimal beam polarization.

Going beyond the three BPs, we now vary the DM mass and calculate the signal significance following the same cut-based analysis procedure outlined above. Our results for the 3σ sensitivity contours in the (m_χ, Λ) plane are shown in Figure 2 for all the operator types. The solid (dashed) contours are for the unpolarized (optimally

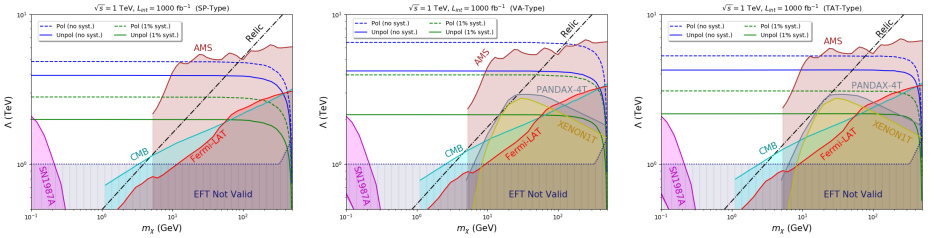

Fig. 2. 3σ sensitivity contours in the mono-photon channel for the SP (left), VA (middle) and TAT (right)-type operators with *unpolarized* (solid lines) and *polarized* (dashed lines) e^+e^- beams at $\sqrt{s} = 1$ TeV center-of-mass energy and with $\mathcal{L}_{\rm int} = 1000$ fb^{-1} integrated luminosity. The blue (green) contours are assuming zero (1%) background systematics. The various shaded regions are excluded by direct detection (XENON1T, PANDAX-4T), indirect detection (Fermi-LAT, AMS), astrophysics (SN1987A) and cosmology (CMB) constraints. In the shaded region below $\Lambda = \max\{\sqrt{s}/2, 3m_\chi\}$, our EFT framework is not valid. Along the dot-dashed line, the observed DM relic density is reproduced for a thermal DM assuming only DM-electron effective coupling.

polarized) case, and the blue (green) contours are assuming zero (1%) background systematics. The shaded regions are excluded by various constraints. First of all, for $\Lambda < \max\{\sqrt{s}/2, 3m_\chi\}$, our EFT framework is not valid (cf. Section 2). This is shown by the navy blue-shaded regions in Figure 2. For $\sqrt{s} = 1$ TeV as considered here, this EFT validity limit supersedes the previous LEP limit.[42]

The same effective operator given in Eq. (1) also gives rise to DM scattering with electrons $\chi e^- \to \chi e^-$. The exact analytic expressions for these cross sections in our EFT framework can be found in Appendix C of Ref.[82] for all the operator types. Comparing these with the experimental upper limits on $\sigma_{\chi e}$ from dedicated direct detection experiments,[32,33] we can derive a *lower* limit on the cut-off scale Λ as a function of the DM mass m_χ. However, the current best limit on $\sigma_{\chi e}$ from XENON1T is at the level of $\mathcal{O}(10^{-39})$ cm^2,[33] which translates into a very weak bound on Λ and is not relevant for our study. Even the future ambitious proposals like DARKSPHERE can only reach up to $\mathcal{O}(10^{-42})$cm^2,[83] still 5 orders of magnitude weaker than that needed to probe a TeV-scale Λ value.

However, more stringent limits can be derived from DM-nucleon scattering searches. Even for an LDM as in our case, DM-nucleon couplings are necessarily induced at loop level from photon exchange between virtual leptons and the quarks. In fact, as shown in Ref.[37], the loop-induced DM-nucleon scattering almost always dominates over the DM-electron scattering. The analytic expressions for the one and two-loop DM-nucleon scattering cross sections can be found in Ref.[37]. We have translated the experimental upper limits from XENON1T[84] and PANDAX-4T[85] onto the (m_χ, Λ) plane, as shown by the yellow and grey-shaded regions respectively in Figure 2. Note that these limits are only applicable for the vector and tensor lepton currents, i.e. $\Gamma_\ell = \gamma_\mu,\ \sigma_{\mu\nu}$ in Eq. (1). For the scalar lepton current, $\Gamma_\ell = 1$, the one-loop DM-nucleon coupling vanishes, and one has to go to two loops

which is suppressed by $\alpha_{\rm em}^2$ for the S-S type coupling and $\alpha_{\rm em}^2 v^2$ (where $v \sim 10^{-3}$ is the DM velocity) for the P-S type coupling. In contrast, for pseudo-scalar and axial-vector lepton currents, i.e. $\Gamma_\ell = \gamma_5,\ \gamma_\mu\gamma_5$, the DM-nucleon coupling vanishes to all orders. Therefore, we have not shown the XENON1T and PANDAX-4T limits for the SP-type operator on the top left panel of Figure 2.

The same effective operator given in Eq. (1) also enables DM annihilation into electrons $\chi\overline{\chi} \to e^+e^-$. The exact analytic expressions for these cross sections in our EFT framework can be found in Appendix C of Ref.[82] for all the operator types. Using these, we calculate the thermal-averaged cross section times relative velocity $\langle\sigma v\rangle$ which goes as m_χ^2/Λ^4 and compare it with the existing indirect detection upper limits on $\langle\sigma v\rangle$ in the e^+e^- channel to put a lower bound on Λ as a function of the DM mass. This is shown in Figure 2 by the red and brown-shaded regions respectively for the Fermi-LAT[86] and AMS-02[53] constraints on $\langle\sigma v\rangle$. Similar constraints on $\langle\sigma v\rangle$ can be derived using CMB anisotropies,[86] which is shown by the cyan-shaded region in Figure 2, assuming an s-wave annihilation (for p-wave annihilation, the CMB bound will be much weaker).

Along the dot-dashed line in Figure 2, the observed relic density can be reproduced for a DM. In principle, the region to the left and above of this line is disfavored for a thermal DM, because in this region $\langle\sigma v\rangle$ is smaller than the observed value of $\sim (2-5)\times 10^{-26}{\rm cm}^3{\rm sec}^{-1}$ (depending on the DM mass[87]), which leads to an overabundance of DM, since $\Omega_\chi h^2 \propto 1/\langle\sigma v\rangle$. However, this problem can be circumvented by either opening up additional leptonic annihilation channels (like $\mu^+\mu^-$, $\tau^+\tau^-$ and $\nu\bar{\nu}$) or even going beyond the DM paradigm and invoking e.g., the freeze-in mechanism.[88] This will not affect our main results, since the collider phenomenology discussed here only depends on the DM coupling to electrons.

Also shown in Figure 2 is the supernova constraint, which excludes the magenta-shaded region from consideration of energy-loss and optical depth criteria from the observation of SN1987A.[82] Here we have used an average supernova core temperature of 30 MeV. Note that the supernova bound is only applicable for DM mass below $\sim$ 200 MeV or so, and for a certain range of Λ values, above which the DM particles cannot be efficiently produced in the supernova core, and below which they will no longer free-stream.

From Figure 2, we find that in spite of a large irreducible background, the accessible range of the cut-off scale Λ at $\sqrt{s} = 1$ TeV ILC looks quite promising in the mono-photon channel, especially for low mass DM, where the collider sensitivity is almost flat, whereas the existing direct and indirect detection constraints are much weaker. This complementarity makes the collider searches for DM very promising. With unpolarized beams, the 3σ-reach for the SP-type operator can be up to 3.9 TeV, while for the VA and TAT-type operators, it can be up to 4.2 TeV. With optimally polarized beams, i.e. with $(+80\%, +30\%)$ for the SP and TAT-types and $(+80\%, -30\%)$ for the VA type, the sensitivity reaches can be extended to 4.8 TeV (SP), 6.5 TeV (VA) and 5.3 TeV (TAT), as shown in Figure 2.

4. Mono-Z channel

In addition to the mono-photon channel discussed in the previous section, another useful channel for LDM search at lepton colliders is the mono-Z channel, where the Z-boson is emitted from one of the initial states. Depending on the subsequent decay of the Z-boson to either leptonic or hadronic final states, we perform a dedicated cut-based signal and background analysis, as discussed below.

4.1. *Leptonic mode*

For the leptonic decay of the Z-boson, we examine the process $e^+e^- \to \chi\overline{\chi}Z(\to \ell^-\ell^+)$. We will only consider $\ell = e, \mu$ for simplicity and use the lepton pair as the visible particles for tagging. The main SM background for this channel is $e^+e^- \to \nu\overline{\nu}\,\ell^+\ell^-$, and it is polarization-dependent.

4.1.1. *Unpolarized and polarized cross-sections*

For the signal and background simulation, we generated the UFO library for our EFT framework using `FeynRules`[76] and then generated events for both signal and background using `MadGraph 5`[89] with the following basic baseline cuts:

$$P_T(\ell) > 10 \text{ GeV}, \quad |\eta_\ell| \leq 2.5, \quad \Delta R_{\ell\ell} \geq 0.4\,. \tag{7}$$

For the signal, the Z-bosons are decayed into the charged lepton pairs via the `MadSpin`[90,91] package which is implemented in `MadGraph 5`, to take care of the spin-correlation effects of the lepton pairs. A fast detector simulation to these events is done using `Delphes 3`[79] with the same configuration card[80] as in Section 3.1.

With unpolarized beams, we find that the neutrino background cross section at $\sqrt{s} = 1$ TeV is 420.5 fb, whereas the DM signal cross section is much smaller, as shown in Table 4 for a benchmark DM mass of $m_\chi = 100$ GeV and the cut-off scale $\Lambda = 3$ TeV. Similar to the mono-photon case, we also examine the effect of polarization on the signal and background cross-sections, as shown in Table 4. The neutrino background can be reduced to 28% of its original value by making the electron beam +80% polarized, and further reduced to 21% of its original value by additionally making the positron beam −30% polarized. The $(+80\%, -30\%)$ polarization configuration also enhances the VA-type signal by a factor of 2.4. However, the $(+80\%, +30\%)$ configuration is better for the SP and TAT-type signals. For ease of comparison between different operator types, we choose to work with the $(+80\%, +30\%)$ configuration democratically for all operator types, as well as for the background, unless otherwise specified.

4.1.2. *Cut-based analysis*

We define our signals by those events that pass through the baseline selection criteria as defined below: $P_{T,\ell} > 20$ GeV, $|\eta_\ell| < 2.45$, where the Z-boson is reconstructed

Table 4. Comparison of the leptonic mono-Z background and signal cross-sections for different choices of beam polarization for $m_\chi = 100$ GeV and $\Lambda = 3$ TeV at $\sqrt{s} = 1$ TeV ILC. The numbers in bold highlight the optimal polarization choice for a given operator type.

Process type	**Unpolarized cross-section (fb)**	**Polarization $P(e^-, e^+)$**	**Polarized cross-section (fb)**			
			$(+,+)$	$(+,-)$	$(-,+)$	$(-,-)$
$\nu\bar{\nu}\ell^-\ell^+$	420	$(80, 0)$	116	116	723	723

		(80,20)	0.72	0.52	0.52	0.72
		(80, 30)	**0.77**	0.47	0.47	0.77

by the condition that all final state lepton-pairs are oppositely charged and of same flavor (OSSF). Other selection criteria are dynamic with respect to different BPs. We have taken the same three BPs as in the mono-photon case to probe different regions of the parameter space, namely, BP1 essentially represents all light DM region, BP3 represents the region close to the kinematic limit of $\sqrt{s}/2 - m_Z$, whereas BP2 captures the intermediate DM mass region.

After implementing the baseline selection cuts, we find that the background is reduced to about 40% of its original value in Table 4 for the unpolarized (polarized) case, whereas the signals are reduced to about 60%-70% of their original values. We then consider various kinematic distributions for the signal and background, and devise some specialized selection cuts.[1] We find that after applying all these cuts, we can still retain about 35%-45% of the signal, whereas the background is reduced to below percent level of the original values given in Table 4.

4.1.3. *Results*

After implementing all these cuts, we calculate the final signal significance for the three BPs using Eq. (6). Our results are given in Table 5 for an integrated luminosity of $\mathcal{L}_{\rm int} = 1000$ fb^{-1}. We see that as we go higher up in the DM mass the signal significance drops. We also find that the best-performing operator type is the TAT-type, for which more than 97% of the background events are removed after all the selection cuts. For the signal we retain $58\% - 61\%$ of the events, although for BP3 only 48% remains. The SP-type operator also gives good results, where we retain $50\% - 66\%$ of the signal across BPs and polarization choices, while removing more than 96% of the background events. Even for VA-type we retain more than 50% of the signal events and are able to cut down the background event yields to 11%. We also notice the positive effect of the beam polarization by which we achieve an enhancement of signal significance by more than 2 times compared to the ones with

Table 5. Signal significance in the mono-Z leptonic channel at $\sqrt{s} = 1$ TeV and $\mathcal{L}_{\rm int} = 1000\,{\rm fb}^{-1}$. The values in the parenthesis correspond to 1% background systematic uncertainty.

Operator type	**Signal significance for $\mathcal{L}_{\rm int} = 1000\,{\rm fb}^{-1}$**					
	Unpolarized beams			Polarized beams		
	BP-1	BP-2	BP-3	BP-1	BP-2	BP-3
SP-type	1.7 (1.3)	0.7 (0.5)	0.1 (0.1)	3.8 (3.6)	1.7 (1.5)	0.3 (0.3)

unpolarized beams. For VA-type though the significance can be further increased for the polarized beam case by choosing the left-handed positron beams as is evident from Table 4.

Going beyond the three BPs, we now vary the DM mass and present the 3σ sensitivity reach for this channel in Figure 3 for all the operators. The labels and shaded regions are the same as in the mono-photon case (cf. Figure 2). We see that the accessible range of the cut-off scale Λ for the unpolarized beams can reach up to 3.2 TeV for the TAT-type operator, whereas for the SP and VA-type, it can reach up to 2.6 TeV and 1.6 TeV respectively. But with the application of optimally polarized beams as discussed earlier, we see an increase by about 25% of the 3σ reach on the Λ scale, up to 3.2 TeV, 2.5 TeV and 4 TeV for the for SP, VA and TAT-type operators, respectively.

4.2. *Hadronic mode*

Next we study $e^+e^- \to \chi\overline{\chi}Z(\to jj)$, where $j \equiv u, d, c, s, b$ quarks. The relevant SM background processes for this channel are $e^+e^- \to \nu\overline{\nu}jj$ and $e^+e^- \to jj\ell\nu$ (with one charged lepton escaping the detector) where the jets and leptons in the final state can come from any possible source (not necessarily from an on-shell Z).

4.2.1. *Unpolarized and polarized cross-sections*

We use the same UFO library as before which is implemented using `FeynRules`[76] and simulate the events for the signal and backgrounds via `MadGraph 5`[89] with the

Table 6. Comparison of the hadronic mono-Z background and signal cross-sections for different choices of beam polarization with $m_\chi = 100$ GeV and $\Lambda = 3$ TeV at $\sqrt{s} = 1$ TeV ILC. The numbers in bold highlight the optimal polarization choice for a given operator type.

		$(80,20)$	7.23	5.23	5.24	7.21
		$(80,30)$	**7.72**	4.73	4.73	7.69

following basic cuts to the parameter space:

$$P_T(j,\ell) > 10 \text{ GeV}, \quad |\eta_j| \leq 3.0, \;\; |\eta_\ell| \leq 2.5, \;\; \Delta R_{jj,\ell j} \geq 0.4\,. \tag{8}$$

For the signals, as in the leptonic case, the on-shell Z-bosons are decayed into the pairs of jets using the `MadSpin` package,[90,91] implemented in `MadGraph 5`. Both the signal and background samples are hadronized using `Pythia8.2`[92] and then the final state jets are reconstructed with with `anti-`kT[93] clustering algorithm with a minimum P_T of 10 GeV and a cone radius (R) of 0.4 using the `FastJet`[94] package. The fast detector simulation to these events are done using `Delphes 3`[79] with the same configuration card[80] as discussed in Section 3.1.

With unpolarized beams, we find the neutrino-pair background is 798 fb, whereas the $jj\ell\nu$ background is 1186 fb. On the other hand, the DM signal is only at a few fb level, as shown in Table 6 for a benchmark DM mass of $m_\chi = 100$ GeV and the cut-off scale $\Lambda = 3$ TeV. We then examine different choices of beam-polarization on both the event samples for this channel, as shown in Table 6. We find that both backgrounds are polarization-dependent and fall off significantly for right-handed electron beam and with increasing degree of polarization. We choose the polarization configuration $P(e^-, e^+) = (+80\%, +30\%)$ democratically over all the operator types.

4.2.2. *Cut-based analysis*

After obtaining the signal and background cross-sections as reported in Table 6, we proceed with our cut-based analysis to optimize the signal significance. We select the events that contain at least two jets with the following transverse momentum and pseudorapidity requirements: $P_{T,j} > 20$ GeV, $|\eta_j| < 2.45$. The hardest two jets

Table 7. Signal significances of the mono-Z hadronic channel at $\sqrt{s} = 1$ TeV and $\mathcal{L}_{\rm int} = 1000$ fb^{-1}. The values in the parenthesis denote the significance with a 1% background systematic uncertainty.

Operator types	**Signal significance for $\mathcal{L}_{\rm int} = 1000\,{\rm fb}^{-1}$**					
	Unpolarized beams			Polarized Beam		
	BP-1	BP-2	BP-3	BP-1	BP-2	BP-3
SP-type	4.7 (3.3)	1.5 (1.0)	0.3 (0.2)	10.3 (9.1)	3.6 (3.1)	0.8 (0.6)
VA-type	0.4 (0.2)	0.3 (0.1)	0.1 (0.1)	0.2 (0.1)	0.1 (0.1)	0.1 (0.04)
TAT-type	14.2 (10.4)	5.8 (3.7)	1.2 (0.7)	27.7 (25.6)	12.9 (11.1)	2.8 (2.3)

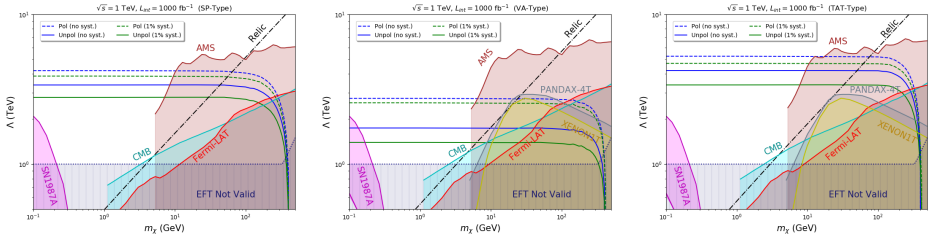

Fig. 4. 3σ sensitivity contours in the mono-Z hadronic channel. Labels are same as in Figure 2.

are required to reconstruct the Z-boson. Further selection cuts are applied some of which depend on the DM mass. So, as in the leptonic channel, we have taken the same three BPs with varying DM mass and impose dynamic cuts.[1]

4.2.3. *Results*

The signal significances calculated using Eq. (6) are tabulated in Table 7. We see similar behavior for the different BPs as in the previously discussed channels, i.e. enhanced signal significance with decreasing mass of the DM. The selection cuts are most efficient for SP- and TAT-type operators. For BP-1 we remove more than 98% of the background events while keeping at least 21% of the signal events for the two operator types, yielding a large signal significance especially for the TAT-type operator with polarized beams.

Varying the DM mass, we display the 3σ sensitivity contours for all three operators in Figure 4. It is clear that the TAT-type operator has the best sensitivity, which reaches up to 4.2 TeV with unpolarized beams and 5.2 TeV with optimally polarized beams. The SP-type operator also has a sensitivity comparable to the mono-photon channel, and can reach up to 3.4 (4.2) TeV with unpolarized (polarized) beams. The VA-type operator has a modest sensitivity in this channel, only up to 1.7 (2.7) TeV with unpolarized (polarized) beams.

5. Conclusion

We have explored the physics potential of the future e^+e^- colliders in probing such *leptophilic* DM in a model-independent way. As a case study, we have taken the

Table 8. Summary of our results for the 3σ sensitivity reach of the cut-off scale Λ in the three different channels discussed in the text. Here we have fixed the DM mass at 1 GeV. The numbers in parentheses are with 1% background systematics. The numbers in bold show the highest Λ value that can be probed for a given operator.

Process type	**Beam configuration**	**3σ sensitivity reach of Λ (TeV)**		
		SP	VA	TAT
Mono-γ	Unpolarized	3.91 (1.99)	4.19 (2.14)	4.25 (2.17)
	Polarized	**4.84** (2.81)	**6.49 (3.94)**	**5.28** (3.08)
Mono-Z leptonic	Unpolarized	2.62 (2.42)	1.57 (1.36)	3.22 (3.00)
	Polarized	3.24 (3.16)	2.47 (2.39)	4.02 (3.93)
Mono-Z hadronic	Unpolarized	3.38 (2.79)	1.74 (1.39)	4.22 (3.38)
	Polarized	4.21 (**3.87**)	2.75 (2.57)	5.25 (**4.71**)

$\sqrt{s} = 1$ TeV ILC with an integrated luminosity of 1000 fb^{-1} and have analyzed the pair-production of fermionic DM using leptophilic dimension-6 operators of all possible bilinear structures, namely, scalar-pseudoscalar, vector-axialvector and tensor-axialtensor. We have performed a detailed cut-based analysis for each of these operators in three different channels based on the tagged particle, namely, mono-photon, mono-Z leptonic and hadronic.

We have taken into account one of the most important and powerful features of lepton colliders, i.e., the possibility of beam-polarization with different degrees of polarization and helicity orientations. We find that the sign$(P(e^-), P(e^+)) = (+,+)$ beam configuration is optimal for the SP and TAT-type operators, while the $(+,-)$ configuration is better for probing the VA-type operators. The maximum value of the cut-off scale Λ that can be probed in each channel at 3σ is given in Table 8. We find that without any systematics, the mono-photon channel provides the best sensitivity across all operator types, while in presence of background systematic effects, the mono-Z hadronic channel provides better sensitivity for the SP and TAT-type operators.

We also demonstrate the complementarity of our lepton collider study with other existing direct and indirect detection searches for LDM (cf. Figures 2, 3 and 4). In particular, we show that lepton colliders will be able to provide the best-ever sensitivity in the still unexplored light DM regime.

INFN, Laboratori Nazionali del Gran Sasso, 67010 Assergi, AQ, Italy
E-mail: zurab.berezhiani@lngs.infn.it

Keywords: Dark matter; direct detection; rare processes.

This session has been dedicated to several topics of Dark Matter (DM) and Rare Processes (RP) field. Some talks have review character while others present some specific experimental results and developments. Mainly the contributions refer to Dark Matter (DM) topics while the last contribution discusses a specific rare process.

The first talk presented by M. Ricci (INFN-LNF) discusses the indirect signatures of DM from Space Satellite missions. Among the indirect searches for DM (complementary to the direct ones), the speaker has reviewed the possibilities of observing the DM signatures in the Cosmic Rays and in the gamma-ray sector, considering space missions like PAMELA, AMS, FERMI, DAMPE and the planned projects like GAPS (on stratospheric balloon) and HERD. An exhaustive overview on the current status and on the perspective of this field has been given.

The second talk presented by P. Belli (INFN-Roma Tor Vergata) is instead related to a direct detection on DM present at galactic scale. In fact, P. Belli has presented a detailed overview of the results of DAMA/LIBRA experiment and new results of two additional annual cycles, which further confirm the evidence of a signal that meets all the requirements of the model-independent DM annual modulation signature, at very high C.L.

A. Messina (INFN-Roma La Sapienza) in his talk discussed in details the known impact of the Migdal effect on the DM detection, mainly for candidates with GeV range masses, and pointed to some new ideas how one could measure such an effect with detectors based on Time Projection Chamber exposed to high neutron flux.

Talk by V. Caracciolo, (INFN-Roma Tor Vergata) was focused on the directionality approach which holds for DM candidates inducing just nuclear recoils. This approach is based on the study of the correlation between the nuclear recoils direction

and the Earth motion in the galactic rest frame. Several experimental techniques to explore the directionality approach have been proposed. In this talk, a review of such experimental approaches have been addressed with particular regard to the ADAMO project based on the use of anisotropic scintillators.

Talk of A. D'Angelo (INFN-Roma Tor Vergata) described the Heavy Photon Search (HPS) experiment which searches for an electro-produced dark photon using an electron beam provided by the CEBAF accelerator at the Thomas Jefferson National Accelerator Facility. It has been shown in some details that HPS looks for dark photons through two distinct methods, a resonance search in the e+e- invariant mass distribution above the large QED background (large dark photon-SM particles coupling region) and a displaced vertex search for long-lived dark photons (small coupling region). HPS employs a compact spectrometer, matched to the forward kinematic characteristics of A' electro- production. Three data taking periods took place in 2015, 2016 and 2019, while a fourth run has been scheduled in summer 2021. Results from the available data have been presented together with future projects.

The talk by A. Addazi (Sichuan University) has been focused in some details on the investigation in the laboratory and in the sky of the Mirror Dark Matter candidates. In particular, he discussed prospectives of laboratory search of the neutron to mirror neutron oscillations and its astrophysical implications, in particular for the neutron stars.

A. Zhitnitsky (University of British Columbia) discussed the Axion Quark Nugget Dark Matter Model, suggesting possible explanation of Telescope Array anomaly and for the positive dark matter signal of DAMA/LIBRA via the neutrons produced by quark nuggets in the rock. P. Belli has commented that already existing results disfavour such a hypothesis. It seems that other efforts will be pursued on that model.

B. Dev (Washington University in St. Louis) presented a detailed discussion on the possibilities to detect Leptophillic Dark Matter (LDM) at Linear Colliders. Such candidates could naturally arise in many beyond the Standard Model scenarios and might address certain experimental anomalies. Thus, some collider constraints on the LDM effective couplings with the Standard Model sector, considering its production at a future electron-positron linear collider (with polarized and unpolarized beam options) in the mono-photon and mono-Z channels.

Finally, C Curceanu (INFN-LNF) discussed experiment testing quantum mechanics in the Gran Sasso National Laboratories (LNGS): collapse models and spin-statistics. She has reported that they are experimentally investigating possible departures from the standard quantum mechanics' predictions, and - in particular - with radiation detectors they are searching signals predicted by the collapse models (spontaneous emission of radiation) which were proposed to solve the "measurement problem" in quantum physics and signals coming from a possible violation of the Pauli Exclusion Principle. Recent results published in Nature Physics under the title "Underground test of gravity-related wave function collapse", where they ruled out the parameter-free version of the gravity-related collapse model. More generic

results on testing Continuous Spontaneous Localization collapse models have been mentioned and future perspectives discussed. Finally, the VIP experiment looking for possible violations of the Pauli Exclusion Principle by searching for forbidden atomic transitions has been discussed.

This session was held in two subsequent afternoons and in both days the talks have been very interesting, the discussions were constructive and proceeded in exciting and serene atmosphere. The merit goes to the speakers and listeners and we give an account here. Finally, we remind that all the presentations are available on Youtube and that in most cases they refer to previously existing publications. Only some of the participants have sent the written contribution; we thank them.

Primordial black holes as dark matter candidates in the Galactic halo

Gravitational microlensing is a powerful method to constrain the abundance of massive dark objects in the Milky Way halo. We calculate the optical depth and the microlensing rate for events caused by Primordial Black Holes (PBHs) eventually distributed in the Milky Way halo, towards some selected directions of observation, as the Galactic bulge, the Large and the Small Magellanic Clouds and the M31 galaxy. The capability of the Euclid space telescope to constraint the abundance of PBHs with mass $\geq 10^{-7}\ M_{\odot}$ in observation towards the Galactic bulge is also discussed.

Keywords: Primordial black holes; Gravitational microlensing; Galactic halo.

1. Introduction

Primordial black holes (PBHs) are a hypothetical type of black holes that formed soon after the Big Bang. Their existence was proposed in 1966 by Zel'dovich and Novikov[1] and by Stephen Hawking[2] in 1971 who studied in depth their origins. In the early universe, high densities and heterogeneous conditions could have led sufficiently dense regions to undergo gravitational collapse, forming black holes. There are several mechanisms able to produce such inhomogeneities. For all of these, the increased cosmological energy density at early times plays a major role, yielding a rough connection between the PBH mass and the formation time t (see Ref. 3):

$$M_{PBH} \simeq \frac{c^3 t}{G} \simeq 10^{15} \left(\frac{t}{10^{-23}\,s}\right) g \simeq 10^5 \left(\frac{t}{1\,s}\right) M_{\odot}. \tag{1}$$

Hence PBHs could span an enormous mass range: those formed at the Planck time ($10^{-43}s$) would have the Planck mass 10^{-5} g, whereas those formed at 1 s would be as large as 10^5 $M_{\odot}$, comparable to the mass of the holes thought to reside in galactic nuclei. By contrast, black holes forming at the present epoch (e.g. in the final stages of stellar evolution) could never be smaller than about $1M_{\odot}$.

Then, depending on the PBH formation epoch, black holes of different masses can form in the early universe.

However, primordial black holes originally having mass below about $10^{-18}\ M_\odot$ would not have survived to the present due to Hawking radiation, which causes complete evaporation in a time shorter than the age of the Universe.[3] Hawking thought that PBHs would have formed before the electroweak phase transition, which occurred at $t \simeq 10^{-12}$ s. In this case one finds $M_{PHB} \leq 10^{-7}\, M_\odot$. However, there is no reason in principle which forbids the formation of PBHs later on. In this case, the PBH mass can rise of orders of magnitude, even up to $\sim 10^5\, M_\odot$ or so. Certainly, only observations might be able to settle this open issue.

PBHs might lead to various interesting astrophysical consequences, such as providing seeds for supermassive black holes in galactic nuclei,[4,5] influence the generation of large-scale structure through Poisson fluctuations[6] and cause important effects on the thermal and ionization history of the Universe.[7] But, perhaps, the most exciting possibility is that they could provide a non-negligible fraction of the dark matter, which is known to constitute about 25% of the critical density of the Universe.[8]

There are some observational conundra that may be explained by PBHs. They are associated with lensing,[9] accretion,[10] dynamical[11] and gravitational wave (GW) effects.[12] Various constraints on their abundance allowed to conclude that PBHs in three ranges of masses could provide the dark matter:[13] the asteroid mass range ($10^{-17} - 10^{-16}\ M_\odot$), the sublunar mass range ($10^{-13} - 10^{-9}\ M_\odot$) and what is sometimes called the intermediate-mass black hole (IMBH) range ($10 - 10^3\ M_\odot$). In general, constraints from these observables have been computed under the assumption that all PBHs have the same mass, assuming a single Dirac delta function. However, an extended (non-monochromatic) mass function, which will correctly combine constraints across all masses, is necessary.

Concerning the mass-fraction f of PBHs in the Galactic halo, the currently available limits are summarized in Fig. 1 of Carr & Kuhnel.[14] The main constraints are derived from PBH evaporation, different gravitational-lensing experiments, numerous dynamical effects and PBH accretion. Even if many different methods have been proposed in the literature for detecting and constraining PBHs (see, e.g. Refs. [8, 15] and references therein)[a], gravitational microlensing offers the most powerful and robust method of constraining PBHs. By the Kepler microlensing observations of Galactic sources[17] a limit in the planetary mass range: $f < 0.3$ for $2 \times 10^{-9} M_\odot < M < 10^{-7} M_\odot$ was found, while the MACHO project established that $f \sim 0.1$ in the $[0.1, 1] M_\odot$ mass range.[18]

Recently, Niikura *et al.*,[9] using the largest sample of microlensing events for stars in the Galactic bulge (2622 microlensing data) obtained from the 5-years OGLE observation, provided that PBHs constitute about 1% of the DM in the MW. Moreover, from a seven hour lasting observation with the Subaru Hyper Suprime-Cam (HSC) towards the $M31$ galaxy, a single candidate event was identified, which

[a]In addition to the methods discussed in that paper we also mention that lensing by fast radio bursts (FRBs) can allow constraining PBHs with mass larger than about $2\, M_\odot$.[16]

translates into a rather stringent upper bounds on the abundance of PBHs in the mass range[19] $[10^{-11} \div 10^{-6}]\ M_{\odot}$.

Gravitational microlensing is the best method to detect objects that do not emit light since this phenomenon may occur when a compact object (lens) passes close enough to the line of sight toward a source star.

In the simplest case, when both the lens and the source are considered as the point-object[b], individual images cannot be resolved (the image separation is the order of $\mu arcsec$), but the total brightness of the images increases with respect to that of the unlensed source, leading to a specific time-dependent amplification of the source star brightness, that is

$$A = \frac{2 + u^2}{u\sqrt{4 + u^2}}. \tag{2}$$

Here, $u(t)$ is the distance, in units of the Einstein radius, between the source star and the lens at an observation epoch t, and is given by

$$u(t) = \sqrt{u_0^2 + \left(\frac{t - t_0}{t_E}\right)^2}, \tag{3}$$

where t_0 is the peak time of the event (at the time of closest approach) and u_0 is the impact parameter, whereas $t_E = R_E/v_T$ is the Einstein timescale, which is defined as the time required for the lens to transit the Einstein radius. The Einstein radius is the radius of the ring image formed when the observer, lens and source are perfectly aligned. It is given by, $R_E = \sqrt{\frac{4GMD_S}{c^2}x(1-x)}$, where M is the mass of the lens and $x = D_L/D_S$ is the normalized lens distance, whereas D_S and D_L are the source-observer and lens-observer distances, respectively. We also note that v_T is the relative transverse velocity between the lens and the source. During a microlensing event, when the source position projected in the lens plane encounters the Einstein ring, the projected separation is $u_T = 1$ and the source threshold amplification is $A_T = 1.34$ (a microlensing event occurs when the source trajectory crosses the Einstein ring). The event amplification takes the maximum value for the smallest separation between the source and lens, $u = u_0$. By photometric measurements of the event lightcurve, three parameters can be defined: t_0, t_E and u_0. However, among these parameters, only t_E contains information about the lens and this gives rise to the so-called parameter degeneracy problem, which does not allow to infer the lens parameters uniquely. To break this degeneracy, second-order effects, as the finite source effects[21] and the parallax effect,[22] can be considered. Also, it is well known that a gravitational microlensing event gives rise to an astrometric shift of the source,[23] which may be extremely useful to break, at least partially, the parameter degeneracy problem in microlensing observations.[24]

[b]In our analysis we also assume that the relative motion among the observer, lens, and source is uniform (with constant velocity) and linear (on a straight line). See the discussion on this issue in Ref. 20 and references therein.

The goal of this work is to trace the PBHs in Galactic halo (if PBHs contribute to the Galactic halo DM) via microlensing observations. For this purpose we selected four directions (Galactic bulge, LMC, SMC and $M31$) and calculate the optical depth and microlensing rate towards them considering a wide range of possible masses for the PBHs. Moreover, we forecast the number of events caused by PBHs and observable by the Euclid telescope. It is a Medium Class mission of the ESA (European Space Agency), scheduled to be launched in 2022 at the L2 Lagrangian point. For it an additional survey is planned towards Galactic bulge, although not definitely approved as yet.[25] The photometric error of Euclid is expected to be less then[26] $\sim 0.1\%$, so the threshold amplification turns out to be $A_T \simeq 1.001$ and from Eq. (2) one can find $u_T \simeq 6.54$.

Until now, several microlensing surveys have been undertaken towards the Galactic bulge (in particular MOA and $OGLE$), $M31$ ($MEGA$,[27] $AGAPE$,[28] $WeCAPP$,[29] $PLAN$[30]) and the Large and the Small Magellanic Clouds (in particular $MACHO$, $EROS$,[31] $SuperMACHO$[32]). However, due to the way these surveys were designed, they were not able to give reliable constraints on PBHs with mass $\leq 10^{-6}\ M_\odot$ in the Galactic halo.

The plan of the paper is as follows: in Section 2, we review the models used in our analysis, for PBHs in Galactic halo and for the source stars in the MW bulge, LMC, SMC and M31. In Section 3 we give some basics for microlensing quantities. In Section 4 we present and discuss the results obtained for the optical depth and microlening rate towards four selected targets and Euclid field of view. Finally, our conclusions are drawn in Section 5.

2. MODEL

The microlensing quantities, the optical depth, the microlensing rate and Einstein timescale depend on the underlying astrophysical model. Below we provide some details for the mass density of the halo dark matter in our Galaxy[c] and the distribution of the stellar components in some favorable directions as the MW bulge, LMC, SMC and the $M31$ galaxy.

2.1. *Distribution of dark matter in Galactic halo*

For the DM in the MW halo region we assume the standard halo model (S), which consists of a cored isothermal sphere with dark matter density given by:

$$\rho_{DM}(r) = \rho_0 \frac{r_c^2 + r_0^2}{r_c^2 + r^2}, \tag{4}$$

[c]Since we are interested in microlensing observations with sources in our Galaxy we neglect[30] the presence of dark matter associated to the targets. In the case of the M31 galaxy this choice, of course, will results in a lower limit of the optical depth, microlensing rate and expected number of events.

where r is the galactocentric radius, $\rho_0 \simeq 0.0079\, M_\odot\, pc^{-3}$ is the local dark matter density, $r_c \simeq 5.6$ kpc is the halo dark matter core radius and $r_0 \simeq 8.5$ kpc is the galactocentric distance of the Sun.[33] Considering a scenario in which PBHs constitute some mass-fraction f of the DM, the PBH mass density distribution is $\rho_{PHB}(r) = f\rho_{DM}(r)$.

2.2. *Source star distributions*

To trace the microlensing events caused by PBHs in Galactic halo we selected some favorable directions for such observations, as the MW bulge, LMC, SMC and the $M31$ galaxy.

2.2.1. *Sources in Galactic bulge*

For the mass density distribution of the stellar population in the Galactic bulge we use the triaxial bulge model given by

$$\rho_b = \frac{M_b}{8\pi abc} exp\left(-\frac{s^2}{2}\right). \tag{5}$$

Here $s^4 = (x^2/a^2 + y^2/b^2)^2 + z^4/c^4$, the scale length values are $a = 1.49$ kpc, $b = 0.58$ kpc and $c = 0.40$ kpc (we remind that the coordinates x and y span the galactic disk plane, whereas z is perpendicular to it) and the bulge mass is $M_b \approx 2 \times 10^{10}\, M_\odot$.[34]

2.2.2. *Sources in the LMC*

The source star distribution in the LMC is generally described as a luminous disk and a bar.[35] The distance between the center of the LMC and the observer is $D_{LMC} \simeq 50$ kpc and the stellar disk is modeled with a double exponential profile:

$$\rho_{disk} = \frac{M_d}{4\pi z_d R_d^2} \exp(-R/R_d - |z|/z_d), \tag{6}$$

where $R = \sqrt{x^2 + y^2}$. $R_d \simeq 1.6$ kpc is the radial scale length, $z_d \simeq 0.3$ kpc is the vertical scale height and $M_d = [2.4, 4.8] \times 10^9\, M_\odot$ is the LMC disk mass. The galactic coordinates for the center of the LMC disk are $l = 297.7°$, $b = -33.5°$. The LMC disk is inclined by an angle $i = 30°$ with respect to our line of sight and its position angle is $\phi = 170°$. In addition to the disk, the LMC possess a stellar bar described by a triaxial Gaussian density profile:

$$\rho_{bar} = \frac{M_{bar}}{(2\pi)^{3/2} x_b y_b z_b} \exp\left(-\frac{1}{2}\left[\left(\frac{x}{x_b}\right)^2 + \left(\frac{y}{y_b}\right)^2 + \left(\frac{z}{z_b}\right)^2\right]\right), \tag{7}$$

where x, y, z are coordinates along the principal axes of the bar. Here, $x_b = 1.0$ kpc, $y_b = 0.3$ kpc, $z_b = 0.3$ kpc are the scale lengths along the three axes and $M_{bar} = [0.6, 1.2] \times 10^9 M_\odot$ is the total mass of the bar. The bar is inclined by an angle $i = 30°$ and has a position angle $\phi = 120°$. The galactic coordinates for the center of the LMC stellar bar are $l = 280.5°, b = -32.8°$.

2.2.3. *Sources in the SMC*

Accordingly to the star formation history of the SMC, two stellar components can be distinguished: an old star (OS) and a young star (YS) population (see Ref. 36). For the YS mass distribution, we adopt a spheroidal model with a fully Gaussian profile:

$$\rho_{SMC}^{(YS)} = \rho_0^{(YS)} \exp\left(-\frac{1}{2}\left[\left(\frac{\xi}{\xi_{YS}}\right)^2 + \left(\frac{\eta}{\eta_{YS}}\right)^2 + \left(\frac{\zeta}{\zeta_{YS}}\right)^2\right]\right). \tag{8}$$

As far as the OS mass distribution is concerned, we keep the Gaussian profile along the line of sight, and a smoother exponential profile in the orthogonal plane:

$$\rho_{SMC}^{(OS)} = \rho_0^{(OS)} \exp\left[-\sqrt{\left(\frac{\Xi}{\Xi_{OS}}\right)^2 + \left(\frac{\Upsilon}{\Upsilon_{OS}}\right)^2}\right] \exp\left[-\frac{1}{2}\left(\frac{Z}{Z_{OS}}\right)^2\right]. \tag{9}$$

The central density values for the YS and OS population are $\rho_0^{(YS)} = 8.5 \times 10^6\, M_\odot\, kpc^{-3}$ and $\rho_0^{(OS)} = 3.9 \times 10^7\, M_\odot\, kpc^{-3}$, respectively. The value of the position angle, with respect to the north direction, is fixed at $\phi_{YS} = 66°$ and $\phi_{OS} = 83°$ for the YS and OS populations, respectively. The reference frames (ξ, η, ζ) and (Ξ, Υ, Z) are directed along the principal axes of the YS and OS spheroid, respectively. For the YS population, we fix $(\xi_{YS}, \eta_{YS}, \zeta_{YS}) = (0.8, 3.5, 1.8)$ kpc and for the OS population, $Z_{OS} = 2.1$ kpc, $(\Xi_{OS}, \Upsilon_{OS}) = (0.8, 2.1)$ kpc. The galactic coordinates for the SMC are $l = 307°, b = -46°$. The YS population is inclined by the angle $i = 74°$, while the OS population is not inclined. The OS and YS populations have a relative distance shift between them, since the centre of the YS population is at a distance of about 2 kpc behind that of the OS component, which is at a distance of $\simeq 63.5$ kpc from the Earth.

2.2.4. *Sources in the M31 galaxy*

The morphology of M31 is similar to that of the Milky Way, with a central bulge and a disc. The distance between the center of the M31 and the observer is $D_{M31} \simeq 778$ kpc. The M31 bulge is parameterized by a flattened power law of the form

$$\rho_B(R, z) = \rho_B(0)\left[1 + \left(\frac{R}{a}\right)^2 + q^{-2}\left(\frac{z}{a}\right)^2\right]^{-s/2}, \tag{10}$$

where the coordinates x and y span the M31 disk plane (z is perpendicular to it), $\rho_B(0) \simeq 4.5 \times 10^9 M_\odot kpc^{-3}$, $q \simeq 0.6$ is the ratio of the minor to major axes, $a \simeq 1.0$ kpc is the core radius and $s = 3.8$ is the power-law index.[37] The mass density of the M31 disk stars adopting the parameters of the Reference model in Ref. 38 is described by a sech-squared profile as follows:

$$\rho_D(R, z) = \rho_D(0) \exp(-R/h) \operatorname{sech}^2(z/H), \tag{11}$$

where R is the distance to the center of the M31 disk, $H \simeq 0.3$ kpc and $h \simeq 6.4$ kpc are, respectively, the scale height and scale lengths of the disk and $\rho_D(0) \simeq 3.5 \times 10^8\, M_\odot kpc^{-3}$ is the central mass density. The M31 disk is inclined by the angle $i = 77^\circ$ to our line of sight and has position angle $\phi = 38.6^\circ$.

3. Microlensing events by PBHs

The microlensing events are unpredictable phenomena, and to quantify their rarity we present the optical depth and the microlensing rate.

3.1. *The optical depth*

The microlensing optical depth τ is the probability that any given star is being significantly lensed at any given time by a foreground compact object. For a star and a given model of the lens density distribution one can calculate τ through the equation

$$\tau = \int_0^{D_S} n(D_l)\pi u_T^2 R_E^2 dD_l \tag{12}$$

which is just the probability that a lens object is inside the microlensing tube (see, e.g., Refs. 39 and 40). Here, $n = \rho/M$ is the number density of the lenses (ρ is their mass density) and M is the lens mass. Since $R_E^2 \propto M$, it turns out that the optical depth is simply a geometrical quantity and does not depend on the lens mass.

The sources are not all at the same distance D_S, but are distributed along the line of sight, so we define the average optical depth as:[41]

$$< \tau >= \left[\int_{D_{S,min}}^{D_{S,max}} dD_S n(D_S) D_S^2\right]^{-1} \int_{D_{S,min}}^{D_{S,max}} dD_S n(D_S) D_S^2 \tau(D_S) \tag{13}$$

where $D_{S,min}$ and $D_{S,max}$ are the minimum and maximum distances (up to the boundary of the observation region) from the observer's position and $n(D_S)$ is the number density distribution of source stars. Considering the above mentioned scenario, that PBHs constitutes some mass fraction f of the halo DM in the MW halo region, where $f = \frac{\Omega_{PHB}}{\Omega_{DM}} = \frac{\rho_{PHB}}{\rho_{DM}}$, the optical depth due to the PBHs can be written in the form $< \tau >_{PBH} = f < \tau >_{DM}$.

3.2. *The microlensing rate*

The event rate is the rate at which a given background star undergoes a microlensing event due to a foreground lensing object. The microlensing event rate for any given source is extremely small, but it can be maximized toward regions with a high surface density of sources, as the Galactic bulge, LMC, SMC and the $M31$ galaxy.

In order to define the microlensing rate, we consider the geometry and variables defined in Fig. 4 of Griest,[39] which gives the differential event rate ($d\Gamma$) of a lensing

object entering a volume element along the line-of-sight, where the lens causes a microlensing with magnification above a certain threshold value. Integrating it along the line of sight to the source, the microlensing rate per background star is defined as

$$\Gamma = \int d\Gamma = \int \frac{n(D_l) f(\vec{v}) d^3x d^3v}{dt}, \tag{14}$$

where $n(D_l)$ is the number density of the lenses, $f(\vec{v})$ is the lens velocity distribution, $d^3x = v_\perp cos(\theta) dt R_E u_T d\alpha d(D_l)$ is the volume element and $d^3v = d^2v_\perp dv_\parallel$ the velocity element (see the Ref. 35 for details). The perpendicular component of the velocity element in cylindrical coordinates can be then written as $d^2v_\perp = v_\perp dv_\perp d\theta$. Therefore, Eq. (14) can be rewritten as:

$$d\Gamma = \frac{\rho}{M} u_T R_E dD_l f(v_\perp, v_\parallel) d^2v_\perp dv_\perp d\theta \cos(\theta) d\alpha dv_\parallel. \tag{15}$$

We note that the parameters $\theta, \alpha, v_\perp$ in the equation above vary in the range $[-\pi/2, \pi/2]$, $[0, 2\pi]$ and $[0, \infty)$, respectively. Considering the velocity distribution of the lenses and source to be a Maxwellian distribution with dispersion velocity σ_l and σ_s and including the transverse velocity of the microlensing tube $v_{t\perp}$ one gets

$$\begin{aligned}\Gamma(D_S) = \frac{2u_T D_S}{M} \int_0^1 dx \rho(x) R_E(x) \times \int_0^\infty \frac{v_{s\perp}}{\pi\sigma_s^2} exp(-\frac{v_{s\perp}^2}{\sigma_s^2}) dv_{s\perp} \\ \times \int_0^\infty \frac{v_\perp^2}{\pi\sigma_l^2} exp(-\frac{v_\perp^2 + v_{t\perp}^2}{\sigma_l^2}) dv_{l\perp} \times \int_0^{2\pi} exp(-\frac{2v_\perp v_{t\perp} cos\beta}{\sigma_l^2}) d\beta \times \int_0^{2\pi} d\phi.\end{aligned} \tag{16}$$

Using the variables $y = v_{l\perp}/\sigma_l$, $\eta = v_{t\perp}/\sigma_l$ and $z = v_{s\perp}/\sigma_s$, the microlensing rate is

$$\begin{aligned}\Gamma(D_S) = 4u_T D_S \sqrt{\frac{4GMD_s}{c^2}} \frac{\sigma_l}{\pi M} \int_0^1 dx \rho(x) \sqrt{x(1-x)} \times \int_0^\infty z exp(-z^2) dz \\ \times \int_0^\infty y^2 exp(-y^2 - \eta^2) dy \times \int_0^{2\pi} exp(-2y\eta cos\beta) d\beta.\end{aligned} \tag{17}$$

Finally, the average microlensing rate per star can be rewritten as (see, e.g.,[41] for further details)

$$< \Gamma >= \left[\int_{D_{S,min}}^{D_{S,min}} dD_S n(D_S) D_S^2 \right]^{-1} \int_{D_{S,min}}^{D_{S,min}} dD_S n(D_S) D_S^2 \Gamma(D_S), \tag{18}$$

In the same way, the microlensing rate due to the PBHs can be written in the form $< \Gamma >_{PBH} = f < \Gamma >_{DM}$.

The median microlensing timescale is related to the optical depth and the microlensing rate[40] through the relation

$$t_E = \frac{2}{\pi} \frac{\tau}{\Gamma}. \tag{19}$$

Since τ does not depend on the lens mass and Γ scales with the PBH mass as $M^{-1/2}$, the microlensing timescale t_E turns out to be proportional to the square root of the PBHs mass.

4. Model results

Let us now consider that a mass-fraction f of the Galactic halo DM is in the form of PBHs, assumed to have a mass density distribution exactly as that of the halo DM.

First, we consider a monochromatic mass distribution for the PBHs, so we assume that all PBHs have the same mass. We calculate the optical depth and the microlensing rate for this model, varying masses in the range $10^{-14}\,M_\odot \leq M \leq 10^2\,M_\odot$ (see, e.g. Ref. 42 and references therein). Using the Galactic celestial coordinate variables (l, b), an object at the distance d from the observer (Sun's position) is at a distance $r = \sqrt{r_0^2 - 2r_0 d\cos l\cos b + d^2}$ from the Galactic center, where $r_0 \simeq 8.5$ kpc is the distance between the Sun and Galactic center, $d = \sqrt{x'^2 + y'^2 + z'^2}$ and $x' = d\cos b\cos l$, $y' = d\cos b\sin l$, $z' = d\sin b$. In the Cartesian coordinate system (x', y', z'), the observer is at the coordinate origin. Since we are interested in estimating the optical depth and microlensing rate due to the PBHs in the Galactic halo towards three nearby galaxies, i.e. LMC, SMC and $M31$, we introduce the coordinate system (x_0, y_0, z_0), which has the origin in the center of these galaxies at (l_0, b_0, D_0) and has the $z_0 - axis$ directed toward the observer: the $x_0 - axis$ is assumed to be anti parallel to the galactic longitude axis and the $y_0 - axis$ parallel to the galactic latitude axis. For an object at distance D from the observer, a point with galactic coordinates (l, b) can be defined through the coordinates (x_0, y_0, z_0) as:

$$\begin{aligned} x_0 &= -D\cos b\sin(l - l_0) \\ y_0 &= D\sin b\cos b_0 - D\cos b\sin b_0\cos(l - l_0) \\ z_0 &= D_0 - D\cos b\cos b_0\cos(l - l_0) - D\sin b\sin b_0 \end{aligned} \tag{20}$$

Therefore, in order to find the coordinates (x, y, z) according to the selected systems, in the case of LMC and M31 they are obtained by rotating around $z_0 - axis$ with position angle ϕ counterclockwise and around the new $x - axis$ with the inclination angle i clockwise. In the case of SMC, the coordinates (Ξ, Υ, Z) for the OS population and (ξ, η, ζ) for the YS population are obtained by rotating around $z_0 - axis$ with the position angle ϕ counterclockwise and around the new $x - axis$ with the inclination angle i counterclockwise.

In particular, the optical depth depends uniquely on the lens (and source) population spatial density, whereas the microlensing rate depends also on the lens mass function and the lens–source relative velocity.

4.1. *Optical depth*

Based on Eq. (13) we estimate the average optical depth due to the PBHs towards the Galactic bulge, LMC, SMC and the M31 galaxy. In Table 1 are given the values of the optical depth towards the Galactic bulge, LMC, SMC and M31 galaxy. The galactic coordinate are: $(l_0, b_0) = (0^\circ, 0^\circ)$ for the Galactic bulge, $(l_0, b_0) = (280.5^\circ, -32.8^\circ)$ for LMC, $(l_0, b_0) = (307^\circ, -46^\circ)$ for SMC and $(l_0, b_0) = (121.17^\circ, -21.57^\circ)$ for M31. For definiteness, the values are given for $f_{PBH} = 1$ and $u_T = 1$. In case of other values, the rescaling is obviously a multiplication by f_{PBH} and by u_T^2.

As one can see from Table 1, the largest values of the optical depth are found towards M31 ($\tau \sim 10^{-6}$), with a factor about 20 times larger than those towards the Galactic bulge. This can be certainly attributed to the enormous volume and large mass content between the Earth and M31.

Table 1. The average optical depth, microlensing rate (per source per year) and the Einstein timescale due to PBHs in Galactic halo. From top to bottom, the values are given towards the MW bulge, LMC disk and bar, SMC young and old stellar populations and M31 bulge and disk. For the microlening rate and microlensing timescale t_E are selected two values of the PBH mass M, i.e. $M = 10^{-14}\, M_\odot$ and $M = 10^2\, M_\odot$.

	$<\tau>$ ($\times 10^{-7}$)	$<\Gamma>(10^{-14}\, M_\odot)$	$<\Gamma>(10^2\, M_\odot)$ ($\times 10^{-8}$)	$t_E(10^{-14}\, M_\odot)$ (s)	$t_E(10^2\, M_\odot)$ (year)
MW_{bulge}	1.30	8.14	8.14	0.32	1.02
LMC_{disk}	4.84	9.96	9.96	0.98	3.10
LMC_{bar}	4.84	9.97	9.97	0.98	3.09
SMC_{YS}	7.26	15.7	15.7	0.93	2.95
SMC_{OS}	7.11	16.4	16.4	0.87	2.76
$M31_{bulge}$	14.25	20.64	20.64	1.39	4.40
$M31_{disk}$	14.25	20.35	20.35	1.41	4.46

One can also remark that the optical depth towards SMC is significantly larger than that towards LMC. This has to be attributed mainly to the larger value of the SMC center longitude with respect to the corresponding value of LMC, but also to its larger distance. The ratio of the optical depth towards SMC and LMC turns out to be $<\tau>_{SMC} \simeq 1.4\ <\tau>_{LMC}$, consistent with the results to Ref. 43. The LMC optical depth is about 5×10^{-7}, in agreement to the result in Ref. 39, in which the adopted values of the model parameters are slightly different.

We also remark that the optical depth towards the Galactic bulge is compatible with the results obtained in Ref. 9 (see e.g., Table I).

Concerning SMC, there is a more visible difference between the role of the two star populations, mainly due to the fact that their centers are shifted by about 2 kpc one with respect to the other.

4.2. *Microlensing rate*

Based on Eq. (18), we estimate the average microlensing rate varying the PBH masses in the range $10^{-14}\,M_\odot \leq M \leq 10^2\,M_\odot$ considering the same conditions as in the previous section. Concerning the transverse velocity dispersion, we keep the value $\sigma_l = 210$ km/s as it is considered for the lenses in the MW halo.[35] For the source star populations in the MW bulge, the velocity dispersion is assumed to be $\sigma = 156$ km/s, whereas in the case of the M31 galaxy, we consider[37] $\sigma_{bulge} = 100$ km/s and $\sigma_{disk} = 30$ km/s. For LMC, we have $\sigma_{disk} = 20.2$ km/s and $\sigma_{bar} = 24.7$ km/s, while for SMC,[44] $\sigma_{YS} = 20$ km/s and $\sigma_{OS} = 30$ km/s.

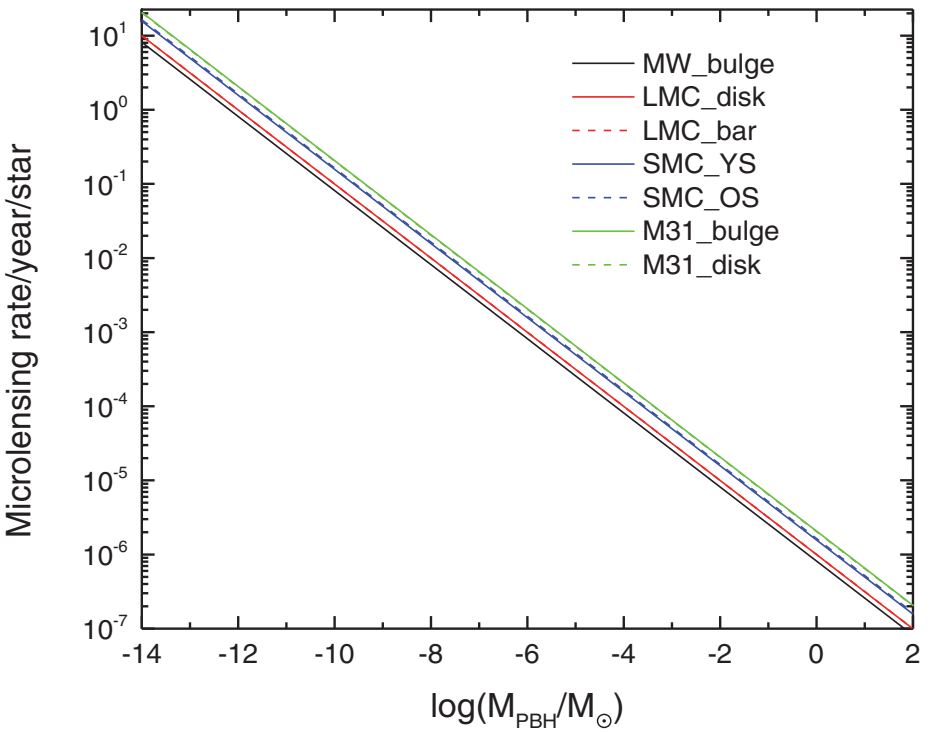

Fig. 1. The microlensing rate caused by our Galactic halo PBHs to the stars in MW bulge (black line), LMC (red line), SMC (blue line), and M31 (green line) is plotted as a function of the PBH mass.

In Fig. 1 we plot the PBH microlensing rate per star per year towards the MW bulge, LMC, SMC and M31 as a function of the PBH mass. We also remind that the plots are given for $f_{PBH} = 1$ and $u_T = 1$. In case of other values, the rescaling is obviously obtained with a multiplication by f_{PBH} and u_T. As one can see, the value of the microlensing rate vary from 10^{-7} for $M \simeq 10^2\,M_\odot$ up to

10^1 for $M \simeq 10^{-14}\, M_\odot$. The highest value of the microlensing rate is obtained in the case of observations towards the M31 galaxy, this has to be attributed to the dark matter distribution function as a cored isothermal sphere. Indeed, microlensing observations towards M31 are able to allow a full map of the Galactic halo, whereas the other considered targets are immersed within the Galactic halo.

Based on the Eq. (19) we define the microlensing timescale of the events caused by the PBHs in Galactic halo towards four selected targets. In Table 1 we present the Einstein timescale for events caused by PBHs towards the center of the MW bulge, LMC, SMC and M31 for two extremal cases of $M = 10^{-14}\, M_\odot$ and $M = 10^2\, M_\odot$ of the PBH mass. As expected, due to the wide mass interval in consideration, the t_E values vary by several orders of magnitude, from a fraction of a second up to several years. For that reason, since a sufficiently high image sampling is requested in order to recognize a microlensing event (let's say at least 5-10 images within t_E are necessary for that aim), different observing strategies and facilities are needed in order to probe the full PBH mass range.

4.3. *PBHs by Euclid*

Since an additional survey of the Euclid telescope, although not definitely approved as yet, is to observe for a few months the Galactic bulge, we devote a special attention to its survey towards the Galactic bulge.[25] Based on the galactic coordinates of the line of sight $(l, b) = (1.1^\circ, -1.7^\circ)$ and the distributions of the PBHs and bulge stars we find the optical depth to be $< \tau > \simeq 1.30 \times 10^{-7}$ and the microlensing rate per stars per year to be $< \Gamma > = 8.12 \times 10^{-7}$ for the PBH mass, $M = 1\, M_\odot$. Based on the magnitude limit of the Euclid telescope, which is foreseen to be $m = 24$, the mass-luminosity relation $\frac{L}{L_\odot} = (\frac{M}{M_\odot})^{3.5}$ and considering the middle point 8.5 kpc away from us, we find the lowest value $M_{min} = 0.31 M_\odot$ of the star's mass to be detected by this telescope. Using a Salpeter mass function $\frac{dN}{dM} \propto M^{-2.4}$, for stars in the Galactic bulge, we calculate their mean mass value $< M > = 0.97\, M_\odot$. Considering the distance of the bulge stars to be within the range $[7, 10]$ kpc with mass density distribution given by Eq. (5) and since the Euclid's field of view is 0.54 square degree we obtain that the number N_{ED} of detectable source stars in the Euclid microlensing observations is $N_{ED} = 6.45 \times 10^7$. By multiplying $< \Gamma > N_{ED} t_{obs}$, where t_{obs} is the observation timescale in years, we find about 340 microlensing events per year (for $f_{PBH} = 1$ and $u_T = 6.54$), with a microlensing timescale $t_E \sim 8$ months in the case of a PBH mass of $1\, M_\odot$. In Fig. 2 we plot the PBH microlensing rate and microlensing timescale towards the Euclid field of view as a function of the PHB mass. We remind that the plot of the microlensing rate is given for $f_{PBH} = 1$, $u_T = 6.54$ and the microlensing timescale for $u_T = 6.54$, the last one is independent of f_{PBH}.

Considering a cadence of 20 minutes[25] and no less than 5 points within t_E, we find that Euclid could detect PBHs down to $M = 10^{-7} M_\odot$.

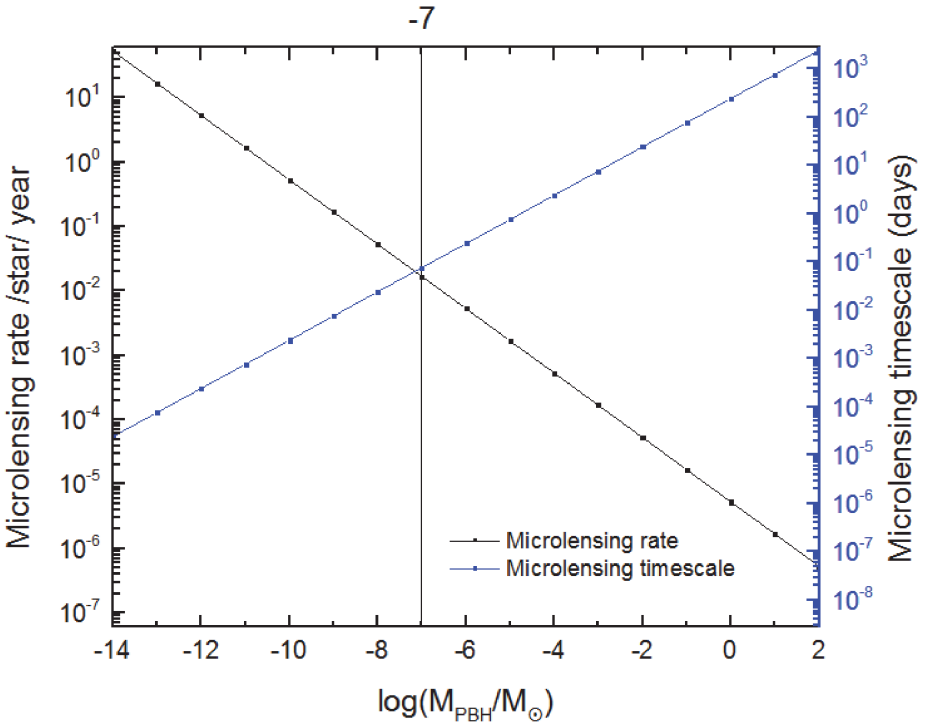

Fig. 2. The microlensing rate (black line) and the microlensing timescale (blue line) caused by our Galactic halo PBHs to the stars in Euclid field view as a function of the PBH mass. The vertical line at $M_{PBH} = 10^{-7}\ M_{\odot}$ represents the lower mass limit for observations towards the Galactic bulge by the Euclid telescope.

5. Conclusions

To obtain valuable information about the mass function and the spatial distribution of PBHs, if they contribute to a high enough fraction of the Galactic halo dark matter, the gravitational microlensing is the best method. We use this method to investigate the traces of MW halo's PBHs towards four selected targets: the MW bulge, Large and Small Magellanic Clouds and the M31 galaxy.

We estimate the optical depth and the microlensing rate towards these targets, assuming for PBHs a standard halo model and for the target sources, their mass density distributions. The largest values of both the optical depth and the microlensing rate are found for observations towards the M31 galaxy, due to its larger distance.

We calculate and discuss the microlensing timescale, which changes by many orders of magnitude, for the reason of the high mass range $[10^{-14}, 10^{2}]M_{\odot}$ of PBHs, taken into consideration. It varies from less than 1 seconds up to about 4.5 years. Therefore, completely different observation strategies are necessary in order to

detect PBHs in different bins of masses. We also mention that the present paper is a summary of a more detailed work.[45]

As far as the Euclid observations towards the Galactic bulge is concerned, and based on its features, we define that it will observe and will detect about 340 microlensing events per year (for mass-fraction $f_{PBH} = 1$ and $u_T = 6.54$), with a microlensing timescale $t_E \sim 8$ months in the case of a PBH mass of $1\,M_\odot$. Also, we find that it could detect PBHs with mass down to $M = 10^{-7} M_\odot$. Below this mass limit, the expected number of points in the lightcurve is insufficient to perform a reliable analysis. For PBH masses around this value we estimated a number of about 10^6 events per year, since the microlensing rate varies as $1/\sqrt{M}$.

Since a confusing element in the observed stars is the stellar intrisic variability, it needs a special attention. In fact, this can be avoided by carefully looking at different bands: gravitational microlensing is an achromatic effect, while stellar variability appears different in different spectral bands.

Recently, a diffuse γ-rays emission in the energy range 1-100 GeV has been detected around M31, that extends up to 120-200 kpc from its center. Such extended emission is difficult to be explained in the typical scenario of cosmic rays produced in the galactic disk or in the galactic center (GC) and diffusing in the galactic halo. We show that a cosmic ray origin, either hadronic or leptonic, of the emission is viable if non-standard cosmic ray transport scenarios are considered, or if particles are accelerated directly in the galactic halo (*in situ* acceleration). The cosmic ray halo can be powered by the accretion of intergalactic gas or by the activity of galaxy's central black hole. If giant cosmic ray halos are common around galaxies, the interactions of cosmic ray protons and nuclei with the circumgalactic gas surrounding Milky Way could explain the isotropic diffuse flux of neutrinos observed by Icecube.

Keywords: Galaxies: halos; cosmic rays; gamma rays; neutrinos.

1. Introduction

The Andromeda Galaxy (M31) and the Milky Way (MW) present many similarities. Both have a bulge, a disk, an extended gaseous halo, a central supermassive black hole and a dark matter halo with a radial extension of $200 - 300$ kpc and a total mass of $\sim 10^{12} M_{\odot}$.[1] The integrated $\gamma-$ray luminosity of the Andromeda galaxy,

as reported by *Fermi*-LAT,[2,3] above 100 MeV is of $\sim 6.6 \times 10^{41}$ erg s^{-1}, less than a factor ~ 2 that of the MW.[2] Fermi Bubbles-like structure emanating from the central region of M31 may also exist, as recently reported.[4] However, while in the MW the $\gamma-$ray emission correlates spatially with the gaseous disk, in M31 it appears to be concentrated within the inner ~ 5 kpc region.[3]

Recently the *Fermi*-LAT data have been analyzed in detail in Ref. 1, from a region that corresponds to a projected radius of ~ 200 kpc from the center of M31 and found an excess that extends up to $\sim 120 - 200$ kpc. The analysis was performed with an accurate modeling of the MW foreground emission and considering a spherically symmetric template, centered on M31 and including three regions:

- the inner galaxy (IG)
  a ~ 5.5 kpc radius region that contains the emission from the inner galaxy[3]
- the spherical halo (SH)
  a ring of $\sim 5.5 - 120$ kpc
- the outer halo (OH)
  a ring of $\sim 120 - 200$ kpc.

For each region the authors provide the $\gamma-$ray spectra. Moreover, given the contamination from the MW disk emission, especially relevant for the northern part of the OH, the spectra for the southern and northern part of the SH and OH are also reported. The north/south regions' spectra are quite similar for the SH, while they exhibit relevant differences for the OH, where the spectrum of the northern part shows a bumpy profile likely associated to a contamination from the MW. Thus, the authors concluded that, while the excess from the SH region is likely associated to the halo of M31, the origin of the emission from the OH is much less clear and may be rather related to the MW, or to something else. Here we focus on the SH region.

Two possible spectral fits for the SH region are reported by Ref. 1, one with a power-law plus exponential cut-off parametrization given by

$$I_{SH} \approx 9.8 \times 10^{-11}\, E_{\rm GeV}^{-1.9}\, e^{-E_{\rm GeV}/11.6} {\rm MeV}^{-1}\, {\rm cm}^{-2} {\rm s}^{-1}\, {\rm sr}^{-1} \qquad (1)$$

and one with pure power-law, as shown in Fig. 1. Here $E_{\rm GeV}$ is the photon energy in GeV. The total γ-ray luminosity (northern plus southern part) of SH is:

$$L_\gamma \approx 1.7 - 1.9 \times 10^{39} {\rm erg/s}\ . \qquad (2)$$

where the lower(upper) value corresponds to the power law plus cutoff(pure power law) fit to data. Based on the large extension of $\gamma-$ray halo, on the intensity and spectrum of the various components, the authors of Ref. 1 suggest a dark matter interpretation for such emission[5] and, based on typical CR propagation scenarios,

conclude that it is unlikely that a major fraction of the emission is due to cosmic rays (CR) in the halo of M31.

Instead, we illustrate that the $\sim 100 - 200$ kpc extended emission from Andromeda could be naturally explained as the result of CR interactions in the halo provided that: *i)* a non-standard mechanism of CR transport into galactic halos, by means of buoyant bubbles, is considered; *ii)* particles are directly accelerated in the galaxy's halo. In what follows we summarize our results reported in Ref. 6 and we refer the reader to that paper for more details.

Interestingly, if the MW is surrounded by a halo similar to that reported for M31, it could be possible to explain the diffuse Icecube neutrino flux, as previously proposed by Ref. 7. Moreover, such large halo around M31 was previously proposed by Ref. 8, which showed that it could contribute to the isotropic gamma-ray background.

2. Hadronic and leptonic origin of the M31 γ-ray halo: Energetics

2.1. *Leptonic scenario*

In this scenario the γ-ray emission from the SH is the result of inverse Compton scattering (ICS) of relativistic electrons off the interstellar radiation field (IRF). At the distances from the disk of the SH region, the IRF is dominated by CMB photons and the galactic magnetic field is likely below $\sim 1\,\mu$G, so that synchrotron losses are probably negligible compared to ICS losses. Thus, $\gamma-$rays in the range $\sim 1 - 100$ GeV would be produced by electrons of energy $\sim 0.6 - 6$ TeV, and the cutoff at $E_\gamma = 11.6$ GeV would correspond to electrons of energy $E_{max,e} \approx 1.9$ TeV. The lepton energy loss time in the CMB field is given by (see Ref. 6 and references therein)

$$\tau_{CMB} \sim 1.3 \times 10^6 E_{\rm TeV}^{-1} \text{ yr}, \tag{3}$$

where $E_{\rm TeV}$ is the particle energy in TeV.

Such short timescale implies that, for any realistic interstellar CR diffusion, electrons coming from the disk/GC would lose all their energy before reaching traveling a few kpc in the halo. Thus, if the SH emission of M31 is produced by electrons they have to be directly accelerated in that region. The minimal energy requirement is obtained in the assumption that the $\gamma-$ray production takes place in a calorimetric regime (namely the ICS timescale is shorter than any other relevant dynamical scale). In this regime the observed γ-ray luminosity (Eq. 2) equals the electron luminosity:

$$L_e = L_\gamma \approx 1.7 - 1.9 \times 10^{39} \text{erg/s}. \tag{4}$$

Notice that this luminosity refers only to electrons in the energy band $\approx 0.6 - 6$ TeV, and is of the same order than the total estimated power of CR electrons in the disk of the MW.[9]

2.2. *Hadronic scenario*

In this scenario $\gamma-$rays are produced in proton-proton interactions between CRs and the ambient gas, where photons of energy E_γ are generated by CR protons of $E_p \approx 10\, E_\gamma$. In order to account for the observed γ-ray luminosity L_γ, the required CR proton luminosity reads:[6,7]

$$L_p = 3\, L_\gamma / f, \quad f = 1 - e^{-\tau_{res}/\tau_{pp}}, \tag{5}$$

where τ_{res} is the residence time of CRs in the halo and τ_{pp} is the timescale for pp interactions. The latter depends on the density of the ambient medium and is given by

$$\tau_{pp} \sim 7.1 \times 10^{10} n_{H,-3}^{-1} \text{ yr} \tag{6}$$

where $n_{H,-3}$ is the halo hydrogen density in units of 10^{-3} cm^{-3}. At a distance of ~ 100 kpc from the Galactic disk, the gas density of the MW halo is probably of the order $\sim 10^{-4} - 10^{-3}$cm^{-3} (see Ref. 6 and references therein), for which the loss time is larger than the age of the Universe. Given the similarities with M31, we may expect that a similar gaseous halo is also present around Andromeda. Taking a reference value of $\tau_{res} = 10^9 \tau_{res,9}$ yr for the CR residence time, the CR proton luminosity reads:

$$L_p \approx 1.8 \times 10^{41}\, \tau_{res,9}^{-1}\, n_{H,-3}^{-1} \text{erg/s}\,. \tag{7}$$

Notice that for $\tau_{res,9} \gtrsim 1$ and $n_{H,-3} \sim 1$, such luminosity is of the same order of that invoked to explain the population of CR protons observed in the disk of the MW.[9]

3. Origin of the radiating particles

The most popular hypothesis for the origin of Galactic CRs is that particles are accelerated in sources located in the disk (e.g. supernova remnants, pulsars, stellar winds, the GC) and escape form the Galaxy undergoing a diffusive-advective transport, the former due to the scattering of CRs on magnetic inhomogeneities and the latter to the possible presence of a galactic wind.[9] A similar situation is likely present also in M31 and one may wonder whether the emission from the SH results from the transport of particles from the disk/GC of Andromeda. However this hypothesis is very problematic. Indeed, for typical values of the interstellar CR diffusion coefficient, TeV electrons would lose energy due to ICS and sychrotron emission before reaching distances of few kpc from the disk. As for protons, typical models of diffusive-advective propagation from the disk/GC predict a substantial decrease of the CR density with the distance from the disk. Moreover, also the halo gas density decreases moving away from the disk, with a density of $\approx 1\,\text{cm}^{-3}$ in the disk and $\approx 10^{-4} - 10^{-3}\,\text{cm}^{-3}$ at a distance of ~ 100 kpc. This imply that, in order to fit the γ-ray flux observed from the SH, the CR proton intensity in the disk of M31 should be large, which would result in a bright γ-ray emission from the disk,

which is not observed. In particular, the observed ratio between the average $\gamma-$ray emissivity of the IG and SH regions is

$$\frac{\langle \epsilon_{SH} \rangle}{\langle \epsilon_{IG} \rangle} \sim 10^{-3}. \tag{8}$$

while in standard CR propagation scenarios would be (see Ref. 6 for a detailed discussion)

$$\frac{\langle \epsilon_{SH} \rangle}{\langle \epsilon_{IG} \rangle} \lesssim 10^{-5} \frac{n_{SH,-3}}{n_{IG,0}}, \tag{9}$$

where we assumed a typical gas density of $n_{IG} \sim 1\,\mathrm{cm}^{-3}$ and $n_{SH} \sim 10^{-3}\,\mathrm{cm}^{-3}$ for the IG and SH region respectively.

3.1. *Cosmic ray transport by means of buoyant bubbles*

The Fermi Bubbles[10] in the MW are probably the result of past nuclear activity of the GC, and similar structures are possibly present also in the M31.[4] Motivated by these observations, we envisage a scenario in which CR protons produced in periodic episodes of nuclear activity are transported into the SH within buoyant bubbles.

Buoyant bubbles are often observed in the central regions of galaxy clusters,[11,12] but also in galaxies.[13] Such bubbles are generally found to rise at a speed of the order of a fraction of the sound speed (≈ 100 km/s in the hot diffuse circumgalactic gas[14]), before being disrupted due to plasma instabilities. Their lifetime could reach order of $\sim 10^9$ yrs if the possible stabilizing action of a magnetic field (see Ref. 14 and references therein).

Let us assume that bubbles are generated at a rate of $\nu_B = 10^{-2}\nu_{B,-2}\mathrm{Myr}^{-1}$. The effective rate at which CR protons may be injected into the halo is $L_p = \eta E_B \nu_B \sim 3.2 \times 10^{41} \eta E_{B,57} \nu_{B,-2}\mathrm{erg/s}$, where $E_{B,57} = E_B/10^{57}$ erg[15,16] and η is a CR conversion efficiency that also accounts for possible adiabatic energy losses due to the bubble expansion during its rise in the halo. Comparing this expression with the energy requirement in Eq. 7 one finds

$$\eta \approx 0.56\ \tau_{res,9}^{-1} n_{H,-3}^{-1} E_{B,57}^{-1} \nu_{B,-2}^{-1}. \tag{10}$$

CRs can be transported into the galactic halo within such bubbles before the bubble is disrupted. When the bubble is disrupted CRs are released in the SH and spread diffusively to fill a region of ≈ 100 kpc radius. If the contributions of several bubbles overlap in the SH, a quasi-stationary CR population can be established in this region, while in the IG, an intermittent Fermi Bubble like structure could be observed. In this way, it is possible to populate the SH with CRs without having a large CR density in the IG and in the disk, contrary to the case in which CRs diffuse/advect directly from the galactic disk or the GC.

If the CR diffusion coefficient in the SH increases with the particle energy, similarly to what happens in the near-disk region of the MW, a quasi-stationary CR population can be maintained in the SH for energies such that the diffusion

time $\tau_{res} \sim R_{SH}^2/(6\ D)$ over a region of size $R_{SH} \sim 100$ kpc is shorter than the typical time between episodes of nuclear activity $1/\nu_B$. At large enough energy, this condition is no longer valid and protons will populate the halo intermittently, which would result in a spectral cut-off at the particle energy, E_c, such that $D(E_c) = 5 \times 10^{30}\ R_{100}^2 \nu_{B,-2}$ cm^2/s. This would explain the power law plus cut-off fit to $\gamma-$ray data (black points in Fig. 1), provided that $E_c \approx 100$ GeV (see Ref. 6 and references therein).

Instead, the pure power law fit to the data (see Fig. 1) could be explained in the case in which the diffusion coefficient is rather flat in energy, and/or if CRs injected during the entire lifetime of M31 are confined in the SH remain confined in the SH.

3.2. *In situ acceleration*

In the case of a leptonic origin, the acceleration of CRs have to take place directly in the SH. Thus, let us assume that a giant spherical shock of radius R_s (whose possible origin is discussed below) is present in the SH. The maximum energy $E_{max,e}$ of accelerated electrons can be estimated: *i*) by assuming that the energy losses due to ICS are the most relevant limitation to the acceleration; *ii*) the particle acceleration at shocks is accompanied by an amplification of the magnetic field. Under such assumptions, he maximum energy reads (see Ref. 6 for the details)

$$E_{max,e} \approx 24\ u_{s,3}^3 n_{0,-4}^{1/4} \left(\frac{\xi_B}{0.035}\right)^{1/4} \text{TeV}, \tag{11}$$

where $n_0 = 10^{-4} n_{0,-4}$ cm^{-3} is the number density of the intergalactic gas, $u_s = 10^3 u_{s,3}$ km/s is the velocity at which matter flows into the shock, $\xi_B \approx 3.5\%$ of the shock ram pressure is converted into magnetic field energy.

Given that the observed γ-ray spectrum extends up to at least a photon energy $E_\gamma \approx 10$ GeV, the electron spectrum should extend at least up to an energy $E_{max,e} \approx 2$ TeV, which requires a shock speed

$$u_{s,3} \gtrsim 0.43\ n_{0,-4}^{-1/12} \left(\frac{\xi_B}{0.035}\right)^{-1/12}. \tag{12}$$

The possible origin of such a shock can be envisaged by noticing that the radius of the SH, $R_{SH} = 100 R_{SH,2}$ kpc, is of the same order of the virial radius of the galaxy. Moreover, the shock velocity inferred above is close to the free fall velocity at the edge of the SH $v_{ff} \sim 0.29 \times 10^3 M_{12}^{1/2} R_{SH,2}^{-1/2}$ km/s, where $M = 10^{12} M_{12} M_\odot$ is the total mass of M31. Thus, it is possible to speculate that particles are accelerated at a spherical accretion shock. However it is important to remark that the existence of accretion shocks around galaxies is matter of debate.[6] The energy flow across the shock would be approximately:

$$L_s \approx (4\pi R_{SH}^2) \frac{\varrho_0 v_{ff}^3}{2} \sim 3.4 \times 10^{42} R_{SH}^{1/2} n_{0,-4} M_{12}^{3/2} \text{erg/s} \tag{13}$$

which could accommodate the energy requirement given by Eq. 4.

A giant spherical shock may also be formed as a result of the GC nuclear activity. In this case an estimate of the shock velocity v_s for a shock radius $R_s \sim R_{SH}$ and a overall duration of the nuclear activity of $\tau_{GC} = 10^9 \tau_{GC,9}$ is given by (see Ref. 6 and references therein)

$$u_s \approx 0.2 \times 10^3 \; L_{GC,43}^{1/5} n_{0,-4}^{-1/5} \tau_{GC,9}^{-2/5} \mathrm{km/s}, \tag{14}$$

where $L_{GC} = 10^{43} L_{GC,43}$ erg/s is the time averaged rate of energy injection due to galactic nuclear activity. Interestingly, a typical value of 10^{43} erg/s for the energy injection rate is much smaller than the Eddington luminosity of the central supermassive black hole of mass M_{BH}, $L_{Edd} \sim 1.3 \times 10^{46} \left(\frac{M_{BH}}{10^8 \; M_\odot}\right)$ erg/s.

In both scenarios for the origin of the shock, the CR electron luminosity needed to explain observations (Eq. 4) can be explained with an acceleration efficiency of the order of $\eta \approx 10^{-4}$.

From the study of Galactic CRs[9] it emerges that interstellar shocks, together with electrons, also accelerate protons, likely with a much larger efficiency. In this case, the maximum energy $E_{max,p}$ is most likely limited either by the age of the system, $\tau_s = 10^9 \tau_{s,9}$ yr, since in the dilute medium that form the SH the proton-proton loss time is typically larger than the age of the Universe (see Eq. 6), either by the particle confinement time in the accelerator, namely the diffusion length at energy $E_{max,p}$ should be smaller than the size of the accelerator ($\sim R_{SH}$). The two conditions provides similar values of $E_{max,p}$, so we consider here the former, which gives $E_{max,p} \approx 4.6 \times 10^2 \; u_{s,3}^3 \tau_{s,9} n_{0,-4}^{1/2} \left(\frac{\xi_B}{0.035}\right)^{1/2}$ PeV. Thus, the acceleration of CR protons can proceed well beyond the $\sim$ 10-100 TeV needed to explain the γ-ray observations. The latter can be accounted for by an acceleration efficiency at the level of $\approx 1\%$.

4. A giant CR halo around the MW and the origin of Icecube neutrinos

The possible existence of a $\sim 100 - 200$ kpc CR halo surrounding the MW was proposed by Ref. 7 for explaining the diffuse flux of multi-TeV neutrinos detected by Icecube. The differential isotropic flux of astrophysical neutrinos (all flavors, neutrinos plus antineutrinos) measured at Earth can be fitted with a power law[17]

$$\Phi_\nu^{IC}(E_\nu) \sim 6.37 \times 10^{-18} \left(\frac{E_\nu}{100 \text{ TeV}}\right)^{-2.87} \mathrm{GeV^{-1} cm^{-2} s^{-1} sr^{-1}}. \tag{15}$$

The integrated isotropic flux is

$$F_\nu(> 100 \text{ TeV}) \sim 1.2 \times 10^{-10} \, \mathrm{erg/cm^2/s/sr}. \tag{16}$$

Let us assume that such neutrino flux is produced in the MW halo due proton-proton interactions at a typical distance of $R_H = 10^2 R_{H,2}$ kpc. The corresponding

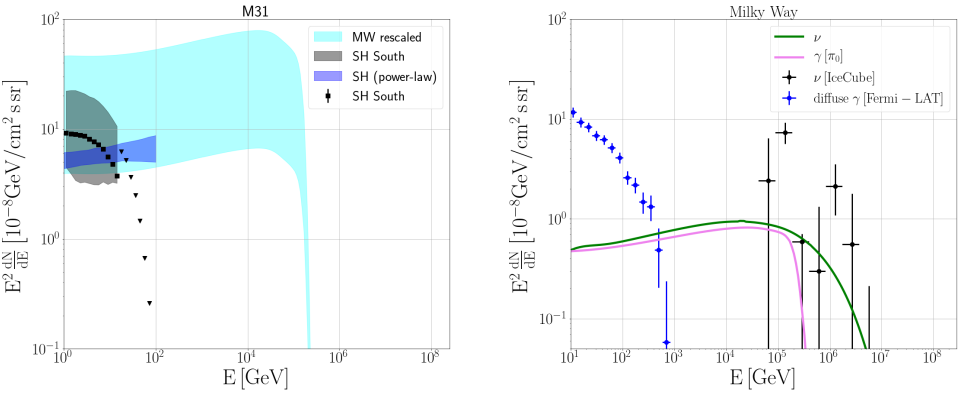

Fig. 1. *left:* Expected γ-ray emission from M31 (shaded cyan region) obtained re-scaling the predictions for the halo of the Milky Way. The black data points and the shaded gray region show *Fermi*-LAT observations of M31[1] *right:* Isotropic diffuse neutrino and γ-ray emission observed by Icecube[17] (black) and *Fermi*-LAT[18] (blue data points). Solid lines are predictions for the neutrino (green) and γ-ray (pink) resulting from the interactions of CR protons with ambient gas in a ~ 100 kpc halo surrounding the MW.

differential neutrino emissivity from the entire MW would be

$$Q_\nu^{MW}(E_\nu) = (4\pi)^2 \Phi_\nu^{IC}(E_\nu) R_H^2. \tag{17}$$

Then, a neutrino luminosity $L_\nu^{MW}(> 100 \text{ TeV}) \approx 1.8 \times 10^{39} R_{H,2}^2 \text{erg/s}$ is expected, together with an isotropic diffuse γ-ray emission above ~ 100 TeV with a similar luminosity.

The isotropic diffuse fluxes of γ-rays and neutrinos measured by *Fermi*-LAT[18] and Icecube,[17] respectively, are shown in Fig. 1, together with the predictions from the γ-ray and neutrino emission from CR proton-proton interactions in the MW halo, estimated assuming a proton spectrum $\propto E_p^{-2} \exp(-E_p/20 \text{ PeV})$ normalized in such a way to contain a total energy equal to $W_p \sim 4.6 \times 10^{57} R_{H,2}^2 n_{H,-3}^{-1}$ erg. A cutoff in the γ-ray spectrum appears due to the absorption of very high energy photons by pair production in the CMB.

Since the MW and M31 are quite similar galaxies, and the gas density in their halos are inferred from observations to be comparable (see e.g. Refs. 19, 20), it appears natural to compare the MW halo origin proposed for the Icecube neutrino flux and the M31 γ-ray SH emission. In the proposed scenarios the CR proton density in the halo would scale linearly with the central SMBH mass (if CR protons are powered by the galactic nuclear activity) or with the total mass of the galaxy to the power 3/2 (if CRs are accelerated at an accretion shock). The ratio between the mass of M31 and of the MW is ~ 2, while the ratio between the SMBH masses is ~ 33 (see Ref. 6 and references therein), which means that, if the CR confinement time in the halo is similar for the two galaxies (order of Gyr), one may suppose that the γ-ray and neutrino luminosities of M31 are a factor of $\approx 2.8 - 33$ than those of

the MW. In Fig. 1 we show the rescaled MW neutrino flux together with the $\gamma-$ray spectrum of M31 observed by *Fermi*-LAT for a power law plus exponential cutoff modeling of data (black points and shaded gray region) and for a power law model (blue line and shaded region).[1]

Remarkably, in the absence of a cutoff/steepening in the γ-ray spectrum of M31, we find a good agreement of our predictions and *Fermi*-LAT data, that suggests a possible common origin of the GeV γ-ray emission from the halo of M31 and the neutrino emission from the halo of the MW.

5. Conclusions

Recently, *Fermi*-LAT discovered a giant γ-ray halo of size $\sim$ 100-200 kpc around M31. We investigated a possible CR origin of the emission and we concluded that it could be explained by CR protons interacting with the circumgalactic gas. Particles can be accelerated directly in the SH of M31, or may be produced in the GC of M31 and then transported into the halo by means of buoyant bubbles. The morphology of the emission is expected to be spherically symmetric in the former case and similar to that of Fermi Bubbles, but much more extended, in the latter case. If CR protons can be confined for long times in the SH of M31 (order of gigayears), the emission measured by *Fermi*-LAT could be explained with a time averaged luminosity of CRs injected in the halo of the order of $\gtrsim 10^{40} - 10^{41}$ erg/s, comparable to the estimated luminosity of CR sources in the Galactic disk. Such luminosity can be accounted for by the galaxy nuclear activity or by an accretion shock.

Moreover, if a similar giant CR halo is present also around the MW, which appears plausible given the similarities between the MW and M31 and the observational evidence of similar extended gaseous halos around both galaxies, also the isotropic diffuse neutrino emission observed by Icecube could be explained as originating from the halo of our own Galaxy (as proposed by Ref. 7).

If gaseous halos are a common feature of MW and M31-like galaxies they might all emit both γ-rays and neutrinos, which however are beyond the capabilities of current instruments for distances significantly larger than M31 (see Ref. 6 for a discussion).

Alternatively, the M31 $\gamma-$ray emission could be of leptonic origin, namely the result of ICS of electrons on the CMB. In this case the particles have to be accelerated directly in the SH and no neutrinos would be expected from M31.

A nearly complete census of intergalactic gas using the kinematic Sunyaev-Zel'dovich effect

Chaves-Montero, Jonás

Donostia International Physics Centre, Paseo Manuel de Lardizabal 4, 20018 Donostia-San Sebastian, Spain
E-mail: jonas.chaves@dipc.org
Webpage: https://jchavesmontero.github.io/jchavesmontero/

A complete census of baryons in the late universe is a long-standing challenge due to the intermediate temperate and rarefied character of the majority of cosmic gas. To gain insight into this problem, we extract measurements of the kinematic Sunyaev-Zel'dovich (kSZ) effect from the cross-correlation of angular redshift fluctuations maps, which contain precise information about the cosmic density and velocity fields, and CMB maps high-pass filtered using aperture photometry; we refer to this technique as ARF-kSZ tomography. Remarkably, we detect significant cross-correlation for a wide range of redshifts and filter apertures using 6dF galaxies, BOSS galaxies, and SDSS quasars as tracers, yielding a 11 sigma detection of the kSZ effect. We then leverage these measurements to set constraints on the location, density, and abundance of gas inducing the kSZ effect, finding that this gas resides outside dark matter haloes, presents densities ranging from 10 to 250 times the cosmic average, and comprises half of cosmic baryons. Taken together, these findings indicate that ARF-kSZ tomography provides a nearly complete census of intergalactic gas from $z = 0$ to 5. This contribution is a summary of the work already published in Ref. 1.

Keywords: Diffuse radiation; cosmic background radiation; large-scale structure of Universe; cosmology: observations; cosmology: theory

1. Introduction

Over the last decades, precise observations of primordial CMB anisotropies[2] and Big Bang nucleosynthesis studies[3] have set strict constraints on the abundance and distribution of baryons in the early universe. However, a complete census of baryons at late times remains elusive; this is principally due to the intermediate temperature and rarefied character of nearly all cosmic gas, which hinders the detection of baryons outside high-density regions and leaves invisible the majority of cosmological volume. Such is the case that until recently, low redshift studies only detected 70% of the expected amount of baryons.[4–6]

Nonetheless, recent studies have successfully detected baryons outside high-density areas conducting kinematic Sunyaev-Zel'dovich (kSZ) effect observations,[7,8] thermal Sunyaev-Zel'dovich (tSZ) studies,[9,10] low-redshift Lyman-α surveys,[11] and deep X-ray campaigns.[12,13] Despite their success, these works only set constraints on the distribution of baryons at either a few specific redshifts or across a reduced

number of line-of-sights, failing to provide a complete picture of cosmic gas in the late universe.

Of the different strategies listed above, throughout this work we set constraints on the properties of intergalactic gas using measurements of the kSZ effect, which refers to the Doppler boosting of CMB photons as these scatter off free electrons moving relative to the CMB rest frame.[14,15] The motivation of using these measurements is that the kSZ effect is sensitive to free electrons independently of the temperature and density of the medium in which these reside, and thus it is uniquely suited to study the large-scale distribution of baryons at low redshift.

Even though the kSZ effect presents significant advantages to observe cosmic gas, it is challenging to extract this signal from observations because the amplitude of kSZ fluctuations is approximately two orders of magnitude smaller than that of primordial CMB fluctuations and the spectral shape of both signals is practically the same. Furthermore, most extraction methods require estimating the peculiar velocity field of intervening matter,[16,17] which is also challenging and adds notable uncertainties. Other approaches circumvent such estimation but require either using cosmological simulations for calibration or modelling and subtracting other effects,[8,18–20] which also introduces substantial uncertainties.

In this scenario, the cross-correlation of angular redshift fluctuations (ARF),[21] which encode precise information about the cosmic density and velocity fields, and CMB observations provides a clean window towards a tomographic detection of the kSZ effect given that systematic uncertainties affecting either of these observables do not present significant correlation. This approach, which we refer to as ARF-kSZ tomography, requires redshift information from either spectroscopic or spectro-photometric surveys as well as theoretical predictions for the large-scale cross-correlation between ARF and the kSZ effect.

2. Results

To extract measurements of the kSZ effect, we start by generating ARF using galaxies from the 6dF Galaxy Survey (6dF),[22] galaxies from the Baryon Oscillation Spectroscopic Survey (BOSS),[23,24] and quasars from the extended Baryon Oscillation Spectroscopic survey (eBOSS)[25] selected at 16 different redshift shells between $z = 0$ and 5. Then, we high-pass filter foreground-reduced *Planck* maps by applying aperture photometry filters of different sizes on the positions given by the aforementioned galaxies and quasars, thereby extracting kSZ signal induced by gas surrounding these sources. This technique also reduces contamination from primordial CMB anisotropies as aperture photometry removes signals that are constant over the size of the aperture. Then, we cross-correlate these maps, finding significant correlation for a wide range of redshifts and filter apertures. After accounting for

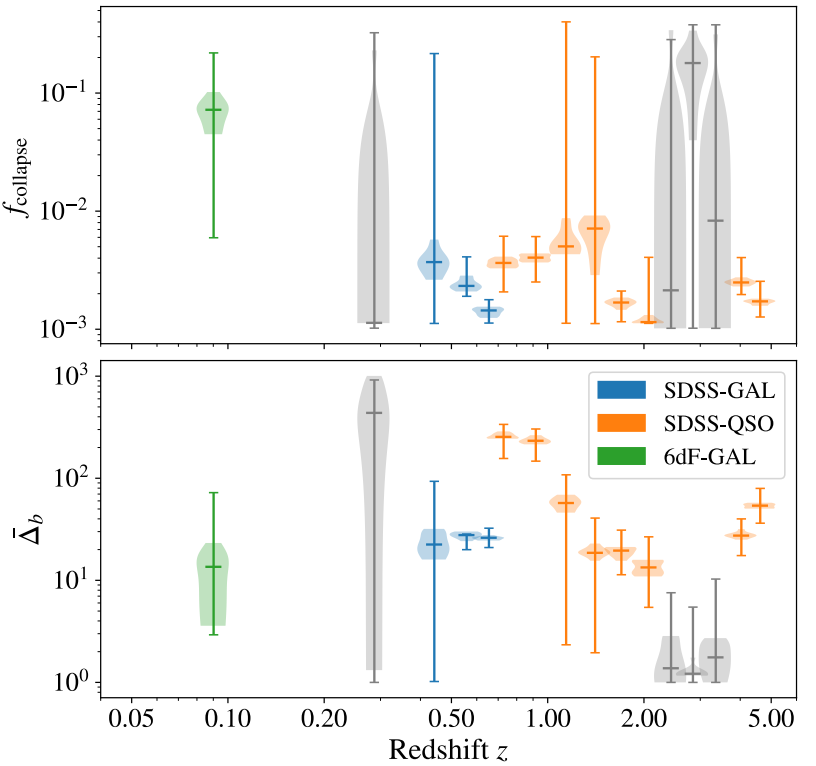

Fig. 1. Fraction of kSZ gas to within dark matter haloes (top panel) and average density of kSZ gas outside these structures (bottom panel). The horizontal bar and size of the shaded regions indicate the average and scatter of results computed using different *Planck* foreground-reduced maps, respectively; green, blue, and orange colours indicate the results for shells containing 6dF galaxies, BOSS galaxies, and SDSS quasars; grey colours denote shells with no significant detection of the kSZ effect; and error bars show 1σ uncertainties for *Planck* COMMANDER map. We find that more than 99% of kSZ gas resides outside haloes and that the density of this gas ranges from 10 to 250 times the cosmic baryon density, which is in agreement with the density of the intergalactic medium according to hydrodynamical simulations.

correlations between different measurements, we find that our measurements yield an 11σ detection of the kSZ effect, which is the highest significance detection of the kSZ effect up to date.

We leverage these measurements to set constraints on the location, density, and abundance of kSZ gas from redshift $z = 0$ to 5. In Fig. 1, we show that more than 99% of kSZ gas resides outside haloes and that the density of this gas ranges from 10 to 250 times the cosmic average, which is in agreement with the density of the gas in filaments and sheets according to hydrodynamical simulations. Then, in Fig. 2 we show that our kSZ measurements are compatible with detecting 50% of

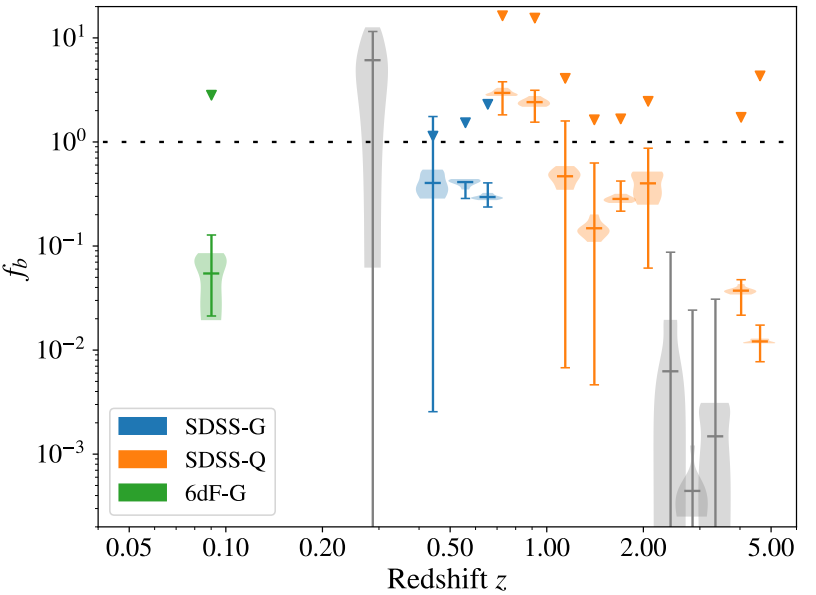

Fig. 2. Fraction of the total abundance of cosmic baryons detected at different redshifts. We use the same coding as Fig. 1. Remarkably, ARF-kSZ tomography is sensitive to approximately 50% of cosmic baryons, which highlights the efficiency of this technique detecting intergalactic gas. The results are well below 50% for the first and last two shells because the number density of sources at these redshifts is very low; in fact, forecasts for f_b when considering an infinite number density of sources (triangles) are compatible among all shells.

cosmic baryons. Taken together, these findings indicate that ARF-kSZ tomography provides a nearly complete census of intergalactic gas from $z = 0$ to 5.

Department of Mathematics and Physics "Ennio De Giorgi", University of Salento, Via per Arnesano, I-73100, Italy, INFN, Sezione di Lecce, Via per Arnesano, I-73100, Italy

**E-mail: antonio.franco@le.infn.it*

Intermediate Mass Black Holes (IMBHs) are a class of black holes with masses in the range $10^2 \div 10^5\ M_\odot$, which cannot directly derive from stellar evolution. Looking for these objects and estimating their abundance is important not only for a deeper understanding of their origin but also for unveiling the nature and distribution of the dark matter in the galactic halo. Since February 2018 to January 2020, the Large and Small Magellanic Cloud have been intensively monitored by the DECAM instrument, installed on the 4m V. Blanco Telescope (CTIO, Chile) with the main objective to discover microlensing events possibly due to IMBHs.

Here we outline the developed data analysis pipeline. We have tested it versus known variable sources finding many not previously known variables objects. A few sources show a light curve similar to that expected for a microlensing event, but further analysis is required to confirm the microlensing nature of these events.

For these sources, and in particular for the uncatalogued variable stars, we try to determine if they are periodic or not via a periodogram analysis.

Keywords: Intermediate Mass Black Holes, ISIS Subtraction package, Large Magellanic Cloud, Small Magellanic Cloud, DECAM, Microlensing, Variable stars.

1. Introduction

During the last years of XVIII century, the English pastor John Michell and the mathematician Pierre Simon de Laplace imagined the existence of some dark objects, which were called *dark stars*.[1] The given name derived from the fact that if the radius of an object with mass M turns out to be $R = 2GM/c^2$ (where G is Newton's gravitational constant and c is the light speed), it cannot be visible from outside and therefore it would "appear" as *dark*.

The first actual mathematical description was provided in 1916 by Karl Schwarzschild with his solution of Einstein's field equations, representing the gravitational field around a non-rotating, spherical, and electrically neutral mass.

Half a century later, in 1967, John Wheeler coined the term *black hole* (BH) to indicate an object whose gravitational field is so large that does not let anything, even light, escape from its gravitational attraction. Unlike the classical formalization, General Relativity predicts the existence of an event horizon located at $r = r_S = 2GM/c^2$, which is called the Schwarzschild radius.

2. Black Holes Classification

There are three main kinds of black holes: stellar, intermediate, and supermassive BHs. The most common ones are stellar and supermassive BHs: the first one, with a mass less than $30\,M_{\odot}$, are produced by stellar death, when very massive stars with $M > 25 - 30\,M_{\odot}$ reach the and of their lives.

Supermassive BHs, with $M \simeq 10^5 \div 10^{10}\,M_{\odot}$, are located at the center of almost every galaxy in the Universe and are also responsible for the AGN activity.

The most unknown and mysterious intermediate-mass black holes (IMBHs) have a hypothetical mass in the range $30 \div 10^5\,M_{\odot}$ and might provide the Galactic Halo's dark matter contribution. Their formation and evolution are not well known as we are not able to observe many of these objects. There are four main possible mechanisms for IMBHs[a] formation[11]:

- Evolution of Population III stars
- Stellar collisions in dense star clusters
- Primordial Black Holes[12–17]

3. Gravitational Microlensing

Gravitational microlensing may offer an efficient way to detect BHs if they populate the Galactic Halo. This phenomenon shows up when an object (the lens) stands in the way between the observer and a faraway source. Photons coming from the source are deflected by the gravitational field of the lens (see Ref. 18 for a review). Depending on the phenomenon geometry, we might observe virtual images of the source. If the images are separated by large enough angles, as happens in the case of lensed quasars, one can detect double or multiple images of the same source. In the case of unresolved images, we have a microlensing event. It might be possible to observe the luminosity variation of the source, that is called *amplification*, which follows the *Paczyński law*[19]:

$$\mu(t) = \frac{u(t)^2 + 2}{u(t)\sqrt{u(t)^2 + 4}} \tag{1}$$

where $u(t) = \beta(t)/\theta_E$ is the Lens-Source angular separation ($\beta(t)$) in Einstein's angle (θ_E) unit.

4. Searching for Intermediate Mass Black Holes with DECAM

Searching for IMBHs might be important to obtain significant information regarding the evolution of black holes and constrain their contribution to the halo dark

[a]Searches for IMBHs have been attempted recently in dwarf spheroidal galaxies (dSph) where these objects are expected to form (see, e.g., Ref. 2–9). In fact, extrapolating the fundamental M_{BH} - M_{Bulge} relation (see, e.g., Ref. 10, for the supermassive BHs case) down to typical dSph masses, black holes in the typical IMBH mass range arise.

matter. This study could give major contributions about PBHs as dark matter candidates.[20,21] This study can be carried out using the microlensing phenomenon and monitoring some regions in the sky with a very high stellar density, such as the Magellanic Clouds.

The microlensing rate toward the Large Magellanic Cloud (LMC in the following) is estimated to be[22]:

$$\Gamma \approx \frac{1.66 \times 10^{-6}}{(M/M_{\odot})^{1/2}} \text{ event/year} \tag{2}$$

and, given $N_0 \approx 10^7$ the number of LMC stars, the number of expected microlensing events for solar mass lenses is:

$$N_{ev} = N_0\, \Gamma(\mathrm{M})\, t_{exp}\, \varepsilon(\mathrm{M}) \approx 50 \text{ events} \tag{3}$$

where $t_{exp} \simeq 2$ years is the duration of the survey and $\varepsilon \approx 0.1$ is the detection efficiency. Taking into account microlensing events with a duration up to two years, is possible to estimate the detectable mass limit that is $\lesssim 300\, M_{\odot}$: we can therefore observe lenses in the IMBH mass range.

4.1. *DECAM instrument*

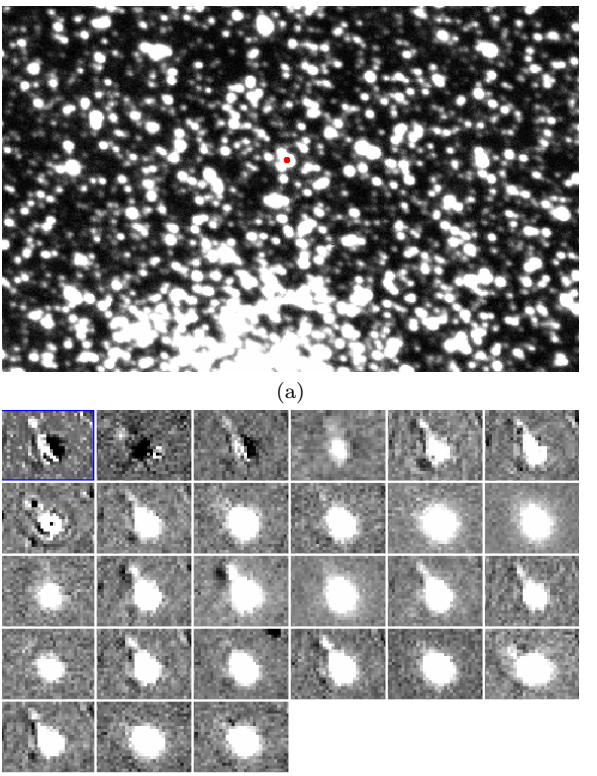
DECAM[23] (Dark Energy CAMera) is a high-performance, wide-field CCD imager mounted at the prime focus of the Victor M. Blanco 4m Telescope (CTIO, Chile). This camera consists of a grid of 62 CCDs (2048×4096 Pixels) which cover a field of view of $\sim 3\,\mathrm{deg}^2$ (~ 2.2 degree wide) with 0.263 arcsecond/pixel resolution. It uses a set of filters similar to those employed in the Sloan Digital Sky Survey (g,r,i,z,Y filters). It is active since September 2012 on behalf of the Dark Energy Survey (DES), finished in January 2019.

4.2. *Blanco/DECAM survey*

The proposal considered for this work, whose Principal Investigator is William Dawson, is related to the current rate of LIGO events that favors such a large abundance that IMBHs would make up the majority of dark matter. A Blanco/DECAM microlensing survey is useful to search for similar IMBHs in our Milky Way.[24] The survey was designed to intensively observe the Magellanic Clouds for two years, from February 2018 to January 2020, acquiring several images toward 23 LMC fields and 6 SMC fields. In particular, the LMC survey, currently under study, has continuously monitored a portion of sky with $4\mathrm{h}\,40\mathrm{m} < \alpha < 6\mathrm{h}\,20\mathrm{m}$ and $-73° < \delta < -65°$. The images have been acquired with a sampling of 7-10 days between each observation night, and a sub-sampling of few hours, acquiring 3-4 images during the same night. The final result is about 40 images acquired for each field and for each filter used (mainly in g and r bands, with just few images obtained in the i band).

In particular, for our aim, we have used 36 resampled images (bias, flat and dark subtracted) in the g band acquired toward the Large Magellanic Cloud.

4.3. *Detection method*



(a)

(b)

Fig. 1. (a) Small frame within the observed field of view toward LMC. The red dot indicates an identified microlensing candidate at coordinates $\alpha = 84.126\,738°, \delta = -68.797\,069°$. (b) Differential luminosity over time for the microlensing candidate event.

In order to search for microlensing events, it is essential the detection of variable sources in the images. This goal can be achieved using the ISIS 2.2 subtraction package.[25,26] The ISIS software, developed by Christophe Alard since the last years of the 90s, allows to perform the photometry of different objects through images difference, especially in very crowded field like LMC and SMC. The software works in multiple steps:

- Interpolation: images alignment;
- Creation of a reference image (from N selected "good" images from the hole sample) to compute the subtraction process;
- Subtraction between the reference image and each image of the sample, highlighting the brightness difference for variables;
- Detection of variable sources;
- Execution of the photometry for these objects.

Once a variable and potentially interesting source is identified, we use the Schwarzenberg-Czerny algorithm,[27] providing the phased light curve, and attempting an estimate of the period of the source. This algorithm gives more reliable results, in particular for high signal/noise ratio values, where the Lomb-Scargle algorithm is not efficient enough.[28]

4.4. *Microlensing candidate analysis*

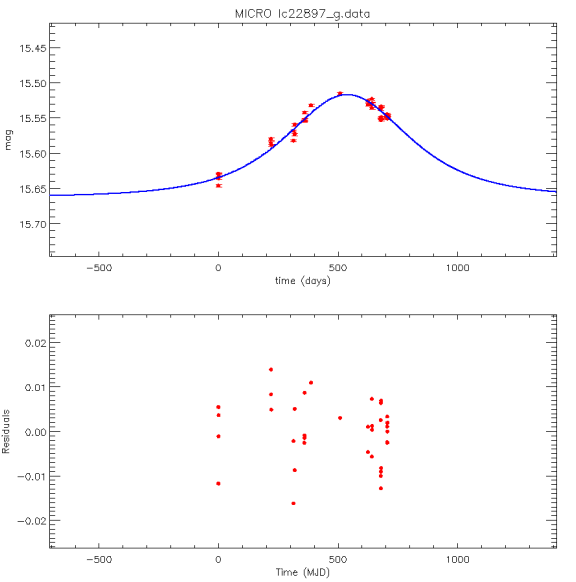


Fig. 2. The upper box shows the magnitude of the variable sources over two years of data (red dots) and the fitted Paczyński curve. The bottom box shows the residuals.

One of the most interesting variable sources detected so far is a microlensing like curve that seems to be associated with an object in the direction of LMC ($\alpha = 84.126\,738°, \delta = -68.797\,069°$). The field of view containing this source is shown in Fig. 1(a).

Using the ISIS software it appears that this source is clearly variable, as shown in Fig. 1(b). The corresponding light curve is shown in Fig. 2 from which it is apparent a Paczynski-like behavior, typical of a microlensing event. The fit and the residuals are shown in the upper and lower panels of Fig. 2, respectively.

The fit returns an estimate of the event Einstein time $t_E = (246.4 \pm 31.7)$ days and the baseline magnitude $m_0 = 15.66 \pm 0.01$. We note that the indicated magnitude represents the instrumental magnitude of the camera, without any photometric correction. In addition, it is important to understand the geometry of the phenomenon in order to estimate the lens mass. For these reasons new images toward

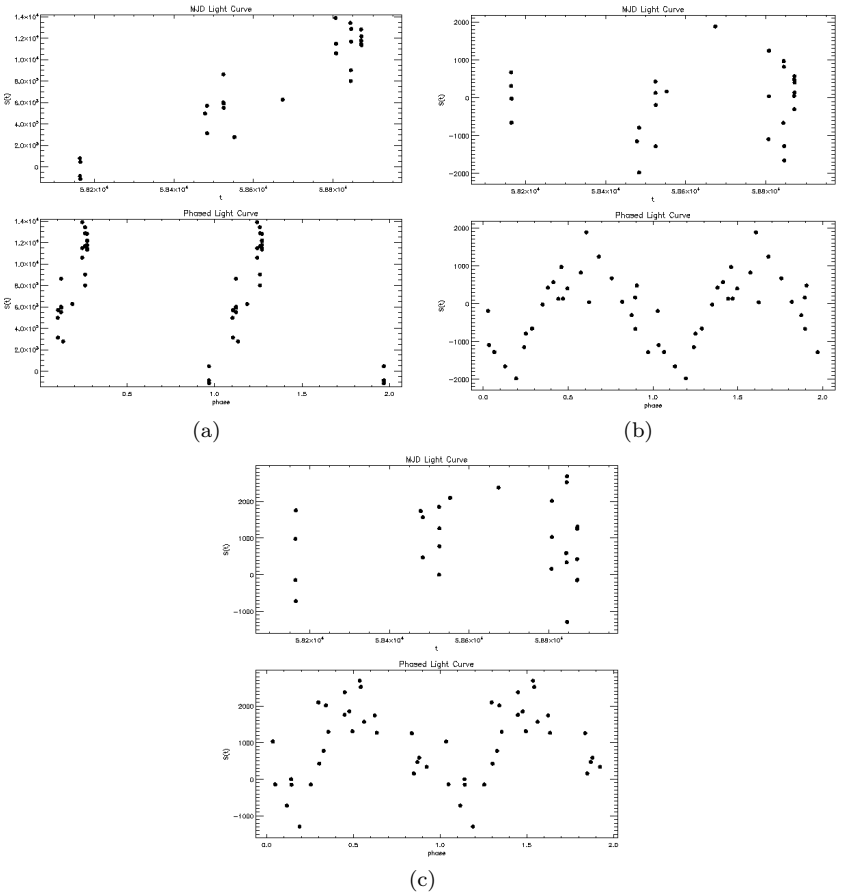

Fig. 3. The MJD light curves (upper panel) and phased light curve (lower panel) for three different variable sources. (a) Non-periodic variable and (b), (c) eclipsing binary candidates.

the particularly interesting fields will be acquired in the next future in order to provide a better and complete results, that will be published after completion of the work.

4.5. *Periodic variable sources candidate analysis*

ISIS 2.2 and the Schwarzenberg-Czerny algorithm enable the recognition of a few periodic variables and allow to obtain an estimate of their period. This can be used both to confirm previously observed sources and to detect new ones. The observed data for three variable sources toward the LMC are shown in Fig. 3. Panel (a) shows the light curve for non-periodic variable source, at coordinates $\alpha_a = 84.530\,329°, \delta_a = -68.791\,993°$, displaying the increasing flux over time and highlighting the absence of a particular periodicity in the phased light curve. Panels (b)

and (c) show two sources, at coordinates $\alpha_b = 84.486\,772°, \delta_b = -68.799\,780°$ and $\alpha_c = 84.303\,917°, \delta_c = -68.741\,760°$, displaying the variation of the flux with respect to the time (upper) and over two phases (bottom), enabling the estimate of the period that is $P_b \simeq 1.69$ days and $P_c \simeq 0.31$ days.

5. Conclusions

The detection of periodic and non-periodic variable sources has allowed confirming the goodness of the developed pipeline. In particular, the two years time window, the sampling and the efficiency of the DECAM instrument have shown the possibility to detect microlensing events. So far, many known variable sources have been identified in four DECAM fields of view - toward LMC - and some unknown variables are waiting to be studied more deeply. A few possible microlensing event candidates (e.g. that shown in Fig. 2), which wait for confirmation, have been also found in the data.

The contents presented in this paper will be discussed in more details in the the paper "*Searching for galactic halo Intermediate Mass Black Holes through gravitational microlensing*", by A. Franco et al., currently under preparation.

The asymmetry in the cosmic microwave background (CMB) towards several nearby galaxies detected by *Planck* data is probably due to the rotation of "cold gas" clouds present in the galactic halos. In 1995 it had been proposed that galactic halos are populated by pure molecular hydrogen clouds which are in equillibrium with the CMB. More recently, it was shown that the equillibrium could be stable. Nevertheless, the cloud chemical composition is still a matter to be studied. To investigate this issue we need to trace the evolution of these virial cloud from the time of their formation to the present, and to confront the model with the observational data. The present paper is a short summary of a paper.[1] Here we only concentrate on the evolution of these clouds from the last scattering surface (LSS) *up to* the formation of first generation of stars (population-III stars).

Keywords: Dark matter; cosmic microwave background radiations; spiral galaxies; molecular clouds; galactic halos.

1. Introduction

The study of the nature of galactic halos and their dynamics is a task that is difficult to address. Here we present a summary of a more detailed analysis addressing this issue.[1]

The Λ cold dark matter (ΛCDM) model entails that $\sim 5\%$ of our Universe is made of baryonic matter,[2] of which $\sim 60\%$ is detected,[3–7] but $\sim 40\%$ is still undetected at present. This is the so-called "missing baryon problem".

In 1995 it was proposed that a fraction, f, of these missing baryons is present in the galactic halos in the form of *pure* molecular hydrogen (H_2) clouds which are in equillibrium with the CMB.[8] The difficutly was on the observation of such "chameleons" megerd with the background. One of the suggestions was, to look for a Doppler shift effect due to the rotation of galaxies, assuming that the rotation of these clouds is synchronized with the rotation of galactic halos, and hence they should be Doppler shifted, those clouds roatating towards us should give a blue-shift effect while those rotating away from us would give a red-shifted contribution.

In 2011 WMAP data was analyzed for M31. The analysis revelaed a temperature asymmetry in the CMB which was almost frequency independent,[10] which was a strong indication of the Doppler shift effect due to the galactic halo rotation. This opens up a window to observe these clouds and to study the baryonic content of the galactic halos.[11] Soon after WMAP, in 2014 *Planck* data towards M31 was analyzed and the asymmetry was seen at a more precise level.[12] A temperature asymmetry was also detected towards several nearby spiral galaxies.[13–16]

There was more than one item of evidence of the predicted Doppler shift effect, but observing that there is a Doppler shift due to the halo rotation does not reveal the true nature of the effect, i.e. if it is partially or fully due to the molecular clouds in the halos, or, if is there anything else that could give a masking or mimiking effect in the asymmetry. Another unanswered question is the chemical composition of these clouds: are they pure H_2 clouds, or there is some contamination of dust or heavier molecules in them? It is quite obvious that galactic halos contain a significant fraction of dust that *should* contaminate these clouds,[18] so one needs to model the clouds.

As these clouds should survive on acount of the virial theorem, they were called "virial clouds". These clouds were modeled and it was seen that at the current CMB temperature the centeral density of pure H_2 clouds was $\approx 1.60 \times 10^{-18}$kg m^{-3}, similarly the mass and radius were $\approx 1.93 \times 10^{-4} M_{\odot}$, and ≈ 0.032 pc.[19] The change in their physical parameters with the contamination of heavier molecules and dust were also estimated. It was seen that as the contamination of dust and hevier molecules were increased in the clouds, they became denser, and their mass and radius decreased.[19–21] An objection was raised on the stability of these clouds, as it was believed that molecular clouds can not be stable at this, very low, CMB temperature, as there would be no mode that could be excited by the photons and the cloud might collapse to form stars or other planetary objects,[22] but it was demonstrated that this equilibrium *does* arise on account of the translational mode, despite its extremely small probability, because of the size of the virial clouds and the time scales available for thermal equilibrium to be reached, so that the time required for thermalization is much less than that required for collapse.[19]

Modeling the virial clouds and estimating the change in physical parameters with the contamination of heavier molecules and dust, and observing the CMB temperature asymmetry by *Planck* data still does not answer the question on the nature of virial clouds and the exact cause of the observed asymmetry in the CMB. One has to run the clock back and trace the evolution of virial clouds when they were formed at the LSS to the present. This task needs to be done in two phases: (*i*) from LSS up to the formation of population-III stars; and (*ii*) from the formation and explosion of population-III stars to the present. Here we discuss the first part of evolution, as various qualitative changes took place during the formation of population-III stars.[23] Hence there will be significant changes during the second step, which will be studied more clearly and in more detail later.

2. First epoch of virial clouds evolution

Virial clouds would have formed at $z = 1100$, the last scattering time (LSS) and they evolved in their chemical composition and physical parameters, but in order to maintain their stability they survived the collapse and stayed in quasi-static equilibrium with the CMB since then. It is quite obvious that when they formed they should have had the primordial chemical composition, i.e. $\sim 75\%$ atomic hydrogen and $\sim 25\%$ helium. In addition to H and He there were other atoms and molecules like deuterium, helium-3, lithium and molecular hydrogen, which could have contributed to the virial clouds, but their fraction was negligilble as compared to H and He. Hence these molecules and atoms could not have any significant effect on the virial cloud physical parameters. As a result the ratio of atomic hydrogen and helium would remain the same and these would be the main component to form the virial clouds during the period, but there should be a fast change in their chemical composition after the formation and explosion of population-III stars.

2.1. *Hydrogen-Helium virial clouds*

Since virial clouds must be considered to be in thermal equilibrium because they are embedded in the heat bath of the CMB, we need to use the canonical distribution function for a fixed temperature and use the cooling of the heat bath to provide a quasi-equilibrium. Moreover, these clouds should start to form in the potential well of cold dark matter (CDM). As the clouds are thermalized the potential well will not cause them to collapse to form population-III stars,[24] but will modify the physical parameters of virial clouds.

To obtain a general expressions we consider a virial cloud composed of an arbitrary mixture of H and He, with mass fractions α and β. Then, we use the primordial cosmological fractions of H and He for the final computation. The total mass of the cloud is, obviously, $M_{cl}(r) = \alpha M_H(r) + \beta M_{He}(r)$, with the condition $\alpha + \beta = 1$. The density distribution for two fluids is given by[19]

$$\rho_{cl}(r) = \sqrt{\frac{64}{27}} \frac{(G\rho_{c_H}\rho_{c_{He}})^{3/2}}{(k_B T)^{9/2}} (m_H m_{He})^{5/2} \\ exp\left[-\frac{1}{2}\left(\frac{\alpha G M_H(r) m_H}{r k_B T} + \frac{\beta G M_{He}(r) m_{He}}{r k_B T}\right)\right]. \quad (1)$$

and the corresponding differential equation can be written as[19]

$$r\frac{d\rho_{cl}(r)}{dr} - r^2\left(\frac{2\pi G}{k_B T}\right)[\rho_{cl}(r)(\alpha\rho_{c_H} m_H \\ + \beta\rho_{c_{He}} m_{He})] - \rho_{cl}(r)\ln\left(\frac{\rho_{cl}(r)}{\tau}\right) = 0, \quad (2)$$

where, $\tau = (8/3\sqrt{3})[(G\rho_{c_H}\rho_{c_{He}})^{3/2}/(k_B T)^{9/2}][m_H m_{He}]^{5/2}$, ρ_{c_H} is the central density of H cloud, $\rho_{c_{He}}$ is the central density of He cloud, m_H, the mass of single atom of hydrogen, and m_{He}, the mass of single atom of helium.

We use eq. (2) to estimate the central density of the clouds. We estimated the central density, Jeans mass and radius of the two-fluid virial clouds with primordial fraction of H, and He, i.e. $\alpha = 0.75$, and $\beta = 0.25$. In order to solve eq. (1) numerically, we assumed a guess value of ρ_c, at a fixed temperature, and estimate where the density becomes *exactly* zero at the boundary. We then compare the Jeans radius with that central density with the value available to us. We adjust the central density so that the density becomes zero exactly at the Jeans radius. In this way we get a self-consistent solution of the differential equation subject to the given boundary conditions. Next, we decrease the temperature and repeat the process.

It was seen that with the decrease in temperature and redshift, the density of virial clouds increased, at $z = 1100$ these clouds were $\approx 8.53 \times 10^{-20} kgm^{-3}$ and at $z = 50$ the density of the clouds was $\approx 6.05 \times 10^{-19}$kg m^{-3}. On the other hand the mass decreased with the decrease in temperature and so as the radius of the clouds. These clouds were massive ≈ 50 pc, with a mass $\approx 3.05 \times 10^5 M_\odot$ at $z = 1100$, then at $z = 50$ the clouds were ≈ 3.54 pc with a mass of $\approx 7.54 \times 10^3 M_\odot$.

3. Results and discussion

The first stage of the virial cloud evolution turns out to be quite simple. We have seen that virial clouds became denser with time, and they lost mass and shrunk in size. The physics of the second stage of evolution will not be that simple since there will be cooling due to the formation of molecular hydrogen, turbulence and the angular momentum effects in the virial cloud after the formation and explosion of population-III stars. We need to consider all these things while tracing the second epoch of evolution, and this will be done in the later paper.

One could expect molecular hydrogen to be formed in the first epoch, but during the era of study in the current summarized paper any H_2 molecules formed in the clouds will be unstable and dissociate due to the radiation pressure at that time, since H_2 needs dust particles to remain stable. The molecular cooling of such clouds played a vital role after the recombination and thir cooling rate has been analyzed from $T \sim 120 - 3$ K.[25] Hence, we do not need to consider the effect of cooling from molecular hydrogen till population-III stars exploded. It may also be expected that the electronic transition mode in hydrogen and helium atoms by the CMB photons. One can check that most of the CMB photons at 3000 K do not have enough energy to excite the electrons of a hydrogen atom from its ground state, but the higher energy tail does have sufficient energy to do so. The percentage of such photons is 0.016, which is quite low. Hence, there will be a negligible effect of this mode, but these effects will be more significant in the later stage of evolution.

Testing Weyl-modified gravity on M31 and Milky Way

Muhammad Bilal* and Asghar Qadir†

Abdus Salam School of Mathematical Sciences, 68-B Model Town, Government College University, Pakistan

**Email: bilalchughtai799@gmail.com*

†*Email: asgharqadir46@gmil.com*

Lee and Qadir,[1] on the basis of various arguments, suggested using a gravitational Lagrangian with a coupling between the Weyl tensor and two copies of the stress-energy tensor, without testing the suggestion for any actual galaxy. As a first step, they used a constant density in their analysis. However unrealistic the constant density approximation is, here we follow up their first step by using their calculations to obtain the coupling constant for the extra term that fits for M31 and the Milky Way, to check if they are consistent within the crude approximation of the model.

Keywords: Dark matter; flat rotation curves; Weyl-induced gravity.

1. Introduction

While the cosmological constant explains the so-called "dark energy problem",[2] providing the Λ of the standard model of cosmology (SMC), the ΛCDM model, The standard model of particle physics (SMPP) ceased to explain the dark matter required to explain the observed dynamics of galaxies. Various suggestions to modify the law of gravity had emerged since the observations of Vera Rubin,[3] but all needed many parameters to solve a single problem, which is no use. Qadir, Lee and Kim[4] had suggested a modification of the Einstein-Hilbert Lagrangian to include an explicit interaction term, RT, on the grounds that it might also solve the problem of quantum gravity. However, the gravitational field is given by the Weyl tensor, $C^{\mu}{}_{\nu\rho\pi}$ and not the Ricci scalar, which gives the mass-energy.

Lee and Qadir[1] suggested a modification of the Lagrangian by including the interaction term, $\lambda C_{\mu\nu\rho\pi}T^{\mu\rho}T^{\nu\pi}$. They obtained the rotational velocity of particles at arbitrary distances from the centre if the density is known as a function of the radial distance. They went on to approximate it as a constant function as a first step, to simplify the calculation. The idea had been that the same interaction coupling must explain the dark matter for all galaxies and systems, or clusters, of galaxies, and manage to avoid the problem of a non-renormalizable theory of quantum gravity. There had been no basis for the latter, just a pious hope. For the former, on the other hand, it should reasonably work out. The calculations were not applied to any specific galaxy. In this brief note, we compare the results for the value of λ required to obtain the rotational curves for M31 and the Milky Way.

The model takes the Schwarzschild interior metric

$$ds^2 = -e^{\nu(r)}c^2dt^2 + e^{\mu(r)}dr^2 + r^2d\Omega^2 \ , \tag{1}$$

where $d\Omega^2 = d\theta^2 + \sin^2\theta d\phi^2$. Since the rotation curves are obtained by seeing stars in the outer reaches of the galaxies, the relevant radius is the radius of the visible part of the galaxy, the mass is the total mass contained within that radius and the test particle mass, m, is the mass of a typical star. For definiteness, we take it to be a solar mass.

Using the field equations obtained from the modified Lagrangian[1] we get

$$\mu(r) = F(r) - \ln\left[\left\{\frac{r}{1-\lambda rc^4\rho\rho'}\left(\int\frac{e^{F(r)}}{r^2}dr - \kappa c^2\int\rho(r)e^{F(r)}dr\right)\right\}\right] \ , \tag{2}$$

where

$$F(r) = \frac{1}{2}\int\frac{4+\lambda rc^4\left(r\rho^2\nu'^2 - 2r\rho\rho'\nu' - 2r\rho'^2 - 2r\rho\rho'' - 8\nu'\rho\rho'\right)}{r\left(1-\lambda rc^4\rho\rho'\right)}dr \tag{3}$$

and

$$\nu'(r) = \frac{1+\sqrt{1+2\lambda\rho^2c^4\left(e^{\mu(r)}-1\right)}}{2r\lambda\rho^2c^4} \ . \tag{4}$$

The square of the rotational velocity is

$$v^2(r) = \frac{1+\sqrt{1+2\lambda\rho^2c^4\left(e^{\mu(r)}-1\right)}}{2\lambda\rho^2c^2} \ , \tag{5}$$

and hence,

$$\lambda = \frac{2\left(\frac{v}{c}\right)^2 + e^{\mu(r)} - 1}{2\rho^2v^4} \ . \tag{6}$$

Following[1] we assume a constant density. Thus

$$e^{\mu(r)} = \frac{e^{F_{const}(r)}}{r\left(\int\frac{e^{F_{const}(r)}}{r^2}dr - \kappa\rho c^2\int e^{F_{const}(r)}dr\right)} \ , \tag{7}$$

where,

$$F_{const}(r) = 2\ln\left(\frac{rc^2}{2GM(r)}\right) + \frac{\lambda\rho^2c^4}{2}\int r\nu'^2dr \ , \tag{8}$$

where, M(r) is the mass interior to the radius r. It is worth mentioning that in[1] an r is missing inside the integral which has been corrected here. The square of the rotational velocity is determined numerically, taking r to be the radius of the visible galaxy and thus $M(r)$ to be the mass of the visible galaxy. As required, for positive λ, the "gravitational force" is effectively enhanced.

For M31, the Andromeda galaxy,[5] the radius of the visible halo is $\sim 34.7\ kpc$, and the mass $\sim 3.43 \times 10^{11}\ M_\odot$. The constant density comes out to be $1.97 \times 10^{-3}\ M_\odot/pc^3$. For the Milky Way[6] the radius of the visible halo is $\sim 31.5\ kpc$ and the mass $\sim 6.06 \times 10^{10}\ M_\odot$, yielding a density $\sim 4.66 \times 10^{-4}\ M_\odot/pc^3$. The rotational velocity of the visible halo of M31 is $\sim 226\ km/s$ and of the Milky Way is $\sim 220\ km/s$.

The rotational velocity curve does not come out flat for either galaxies, see Fig. 1. This is due to the crude assumption of a constant density. However the curves for both galaxies match for $\lambda = 1.14 \times 10^{16}\ km^2 s^4/kg^2$, thus verifying that both require the same interaction coupling.

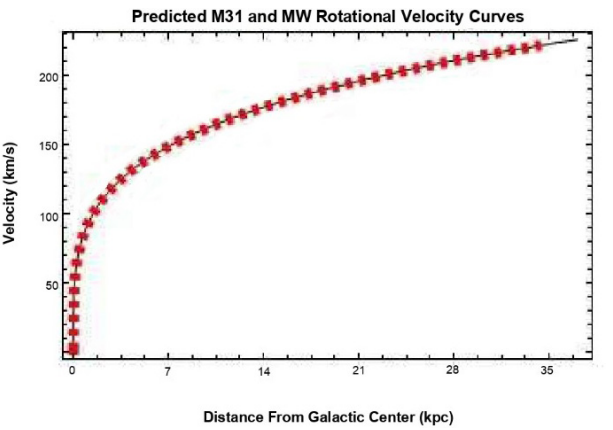

Fig. 1. The black line gives the predicted rotation curve for M31, and the red dotted line the predicted rotation curve for the Milky Way, for $\lambda = 1.14 \times 10^{16}\ km^2 s^4/kg^2$, having taken the rotational velocity at the edge of M31 and the Milky Way as 226 km/s, 220 km/s respectively.

For the purpose of checking that the proposal of the Weyl-interaction modification of gravity is viable, it would be necessary to check the proposal for a more realistic model (variable density) for a number of different galaxies, taking into account the baryonic dark matter in that region and distinguishing between the density for the disc matter and the bulge matter.

THE MARCEL GROSSMANN MEETINGS

Series Editor: REMO RUFFINI

Publications in the Series of Proceedings

Proceedings of the Sixteenth Marcel Grossmann Meeting on General Relativity
(Virtual Meeting, 2021)
Edited by G. Vereshchagin, R. Ruffini
World Scientific, 2022

Proceedings of the Fifteenth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2018)
Edited by E.S. Battistelli, R.T. Jantzen, R. Ruffini
World Scientific, 2022

Proceedings of the Fourteenth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2015)
Edited by M. Bianchi, R.T. Jantzen, R. Ruffini
World Scientific, 2017

Proceedings of the Thirteenth Marcel Grossmann Meeting on General Relativity
(Stockholm, Sweden, 2012)
Edited by K. Rosquist, R.T. Jantzen, R. Ruffini
World Scientific, 2015

Proceedings of the Twelfth Marcel Grossmann Meeting on General Relativity
(Paris, France, 2009)
Edited by T. Damour, R.T. Jantzen, R. Ruffini
World Scientific, 2012

Proceedings of the Eleventh Marcel Grossmann Meeting on General Relativity
(Berlin, Germany, 2006)
Edited by H. Kleinert, R.T. Jantzen, R. Ruffini
World Scientific, 2007

Proceedings of the Tenth Marcel Grossmann Meeting on General Relativity
(Rio de Janiero, Brazil, 2003)
Edited by M. Novello, S. Perez-Bergliaffa, R. Ruffini
World Scientific, 2005

Proceedings of the Ninth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2000)
Edited by V.G. Gurzadyan, R.T. Jantzen, R. Ruffini
World Scientific, 2002

Proceedings of the Eighth Marcel Grossmann Meeting on General Relativity
(Jerusalem, Israel, 1997)
Edited by T. Piran
World Scientific, 1998

Proceedings of the Seventh Marcel Grossmann Meeting on General Relativity
(Stanford, USA, 1994)
Edited by R.T. Jantzen and G.M. Keiser
World Scientific, 1996

Proceedings of the Sixth Marcel Grossmann Meeting on General Relativity
(Kyoto, Japan, 1991)
Edited by H. Sato and T. Nakamura
World Scientific, 1992

Proceedings of the Fifth Marcel Grossmann Meeting on General Relativity
(Perth, Australia, 1988)
Edited by D.G. Blair and M.J. Buckingham
World Scientific, 1989

Proceedings of the Fourth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 1985)
Edited by R. Ruffini
World Scientific, 1986

Proceedings of the Third Marcel Grossmann Meeting on General Relativity
(Shanghai, People's Republic of China, 1982)
Edited by Hu Ning
Science Press – Beijing and North-Holland Publishing Company, 1983

Proceedings of the Second Marcel Grossmann Meeting on General Relativity
(Trieste, Italy, 1979)
Edited by R. Ruffini
North-Holland Publishing Company, 1982

Proceedings of the First Marcel Grossmann Meeting on General Relativity
(Trieste, Italy, 1975)
Edited by R. Ruffini
North-Holland Publishing Company, 1977

FREEDOM OF MOVEMENT FOR SCIENTISTS

The Marcel Grossmann Meetings were founded with the premise that scientists of all nations have a right to meet to exchange knowledge independent of national borders.

ACKNOWLEDGEMENTS

We acknowledge the outstanding job done before, during and after the meeting by the ICRANet/ICRA administrative and secretarial staff: Cristina Adamo, Silvia Latorre, Elisabetta Natale, and Cinzia di Niccolo. Finally this meeting and its proceedings could not have functioned without the dedicated IT support of the ICRANet system manager Gabriele Brandolini, with some temporary assistance from Domenico La Selva and Damiano Verzulli. We would like to thank Linda Kwan from World Scientific for valuable assistance during preparation of these proceedings.

ORGANIZING BODIES OF THE SIXTEENTH MARCEL GROSSMANN MEETING

INTERNATIONAL ORGANIZING COMMITTEE

Blair David, Choquet Bruhat Yvonne, Damour Thibault, De Bernardis Paolo, Everitt C. W. Francis, Fryer Chris, Haensch Theodor, Henneaux Marc, Jones Christine, Kerr Roy, Kleinert Hagen, Kunz Jutta, Laemmerzahl Claus, Longair Malcolm, Mirabel Felix, Mirzoyan Razmik, Piran Tsvi, Rueda Jorge, Ruffini Remo (chair), Sasaki Misao, Sato Humitaka, Sunyaev Rashid, 't Hooft Gerard, Weinberg Steven, Yau Shing-Tung, Zhang Bing

LOCAL ORGANIZING COMMITTEE

Adamo Cristina, Bianco Carlo Luciano, Brandolini Gabriele A., di Niccolo Cinzia, Latorre Silvia, La Selva Domenico, Li Liang, Loppini Alessandro, Natale Elisabetta, Verzulli Damiano, Vereshchagin Gregory (chair), Wang Yu

INTERNATIONAL COORDINATING COMMITTEE

ALBANIA: Hafizi M. - ARGENTINA: Arguelles C., Scoccola C., Reula O., Romero G.E. - ARMENIA: Sahakyan N. - AUSTRALIA: Blair D., Ju L., Lun A., Manchester D., Melatos A., Quinn P., Scott S.M., Steele J.D. - AUSTRIA: Aichelburg P.C., Schindler S. - BELARUS: Kilin S., Prakapenia M., Siutsou I. - BELGIUM: Henneaux M. - BOLIVIA: Aguirre C.B. - BOSNIA: Pasic V. - BRAZIL: Barres de Almeida U., Coelho Goulart J., Dalmolin F.T., de Lima Rafael C.R., Guzzo M., Maia C., Malheiro M., Romero Filho C.A., Shellard R.C., Zen Vasconcellos C. - BULGARIA: Yazadjiev S. - CANADA: Singh D., Smolin L., Turok N. - CHILE: Bauer F., Bunster W.C., Giacomini A. - CHINA (MAINLAND): Cai R., Cai Y., Cao Z., Chang J., Chen J., Chen X., Dai Z., Feng L.-L., Han W., Jing Y., Li T.-P., Lin W., Lou Y.-Q., Luo J., Mei J., Tam T., Wang A., Wang Y., Wu X.-P., Wu Y.-L., Yuan Y.-F., Zhang B.-B., Zhang S.-N., Zhao G. - CHINA (TAIWAN): Chen Chiang-Mei, Chen Pisin, Lee Da-Shin, Lee Wo-Lung, Ni Wei-Tou - COLOMBIA: Bargueño de Retes P., Gonzalez G., Higuera Garzon M.A., Núñez L., Romano A.E., Valenzuela Toledo C.A., Zuluaga J.I. - CROATIA: Dominis Prester D., Karlica M., Milekovic M., Smolcic V., Smolic I., Suric T. - CUBA: Perez Martinez A., Pérez Rojas H. - CZECH REPUBLIC: Bicak J., Stuchlik Z. - DENMARK: Naselsky P. - ECUADOR: Contreras E. - EGYPT: Tawfik A.N., Wanas M.I. - ESTONIA: Einasto J., Saar E. - FINLAND: Poutanen J., Volovik G. - FRANCE: Brillet A., Buchert T., Chardonnet P., Coullet P., de Freitas Pacheco J.A., Deruelle N., Iliopoulos J., Lamanna G., Mignard F. - GEORGIA: Lavrelashvili George, Machabeli Giorgi - GERMANY: Biermann P., Blumlein J., Di Piazza A., Fritzsch H., Genzel R., Gilmozzi R., Hasinger G., Hehl F., Keitel C., Kiefer C., Mirzoyan R.,

MARCEL GROSSMANN AWARDS

Sixteenth Marcel Grossmann Meeting

Institutional Awards

"for the creation of the world's best X-ray map of the entire sky, for the discovery of millions of previously unknown accreting supermassive black holes at cosmological redshifts, for the detection of X-rays from tens of thousands of galaxy clusters, filled mainly with dark matter, and for permitting the detailed investigation of the growth of the large-scale structure of the universe during the era of dark energy dominance".

S.A. LAVOCHKIN ASSOCIATION
- presented to its Designer General **Alexander Shirshakov**

MAX PLANCK INSTITUTE FOR EXTRATERRESTRIAL PHYSICS (MPE)
- presented to Professor **Peter Predehl**, Principal Investigator of eROSITA

SPACE RESEARCH INSTITUTE (IKI) OF THE RUSSIAN ACADEMY OF SCIENCES
- presented to Professor **Rashid Sunyaev,** Principal Investigator of SRG Observatory in Russia

Individual Awards

DEMETRIOS CHRISTODOULOU
"For his many lasting contributions to the foundation of mathematical physics including the dynamics of relativistic gravitational fields. Notably for: contributing in 1971, at the age of 19, to derive with Remo Ruffini the mass-energy formula of black holes as a function of their angular momentum, charge and irreducible mass. Christodoulou turned then to the study of partial differential equations and mathematical physics, to which he remained dedicated for the rest of his career. Highlights in this area include the theoretical discovery of the nonlinear memory effect of gravitational waves (Phys. Rev. Letters 1991), the monograph (1993) in collaboration with Sergiu Klainerman on the global nonlinear stability of the Minkowski spacetime, the monograph (2009) on the formation of black holes in pure general relativity by imploding gravitational waves, and the monographs (2007 and 2019) on the formation and further development of shocks in fluids."

GERARD 't HOOFT
"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon".

TSVI PIRAN
"for extending Relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory".

STEVEN WEINBERG
"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory".

Each recipient is presented with a silver casting of the TEST sculpture by the artist A. Pierelli. The original casting was presented to His Holiness Pope John Paul II on the first occasion of the Marcel Grossmann Awards.

15th Marcel Grossmann Meeting
July 2018, Rome, Italy

Institutional Awards

PLANCK SCIENTIFIC COLLABORATION (ESA)
"for obtaining important constraints on the models of inflationary stage of the Universe and level of primordial non-Gaussianity; measuring with unprecedented sensitivity gravitational lensing of Cosmic Microwave Background fluctuations by large-scale structure of the Universe and corresponding B-polarization of CMB, the imprint on the CMB of hot gas in galaxy clusters; getting unique information about the time of reionization of our Universe and distribution and properties of the dust and magnetic fields in our Galaxy"

- presented to Jean-Loup Puget, the Principal Investigator of the High Frequency Instrument (HFI)

HANSEN EXPERIMENTAL PHYSICS LABORATORY AT STANFORD UNIVERSITY
"to HEPL for having developed interdepartmental activities at Stanford University at the frontier of fundamental physics, astrophysics and technology"

- presented to Research Professor Leo Hollberg, HEPL Assistant Director

Individual Awards

LYMAN PAGE
"for his collaboration with David Wilkinson in realizing the NASA Explorer WMAP mission and as founding director of the Atacama Cosmology Telescope"

RASHID ALIEVICH SUNYAEV
"for the development of theoretical tools in the scrutinising, through the CMB, of the first observable electromagnetic appearance of our Universe"

SHING-TUNG YAU
"for the proof of the positivity of total mass in the theory of general relativity and perfecting as well the concept of quasi-local mass, for his proof of the Calabi conjecture, for his continuous inspiring role in the study of black holes physics"

14th Marcel Grossmann Meeting
July 2015, Rome, Italy

Institutional Award

EUROPEAN SPACE AGENCY (ESA)
"for the tremendous success of its scientific space missions in astronomy, astrophysics, cosmology and fundamental physics which have revolutionized our knowledge of the Universe and hugely benefited science and mankind"

- presented to its Director General Johann-Dietrich Woerner

Individual Awards

KEN'ICHI NOMOTO
"for heralding the role of binary systems in the evolution of massive stars"

MARTIN REES
"for fostering Research in black holes, gravitational waves and cosmology"

YAKOV G. SINAI
"for applying the mathematics of chaotic systems to physics and cosmology"

SACHIKO TSURUTA
"for pioneering the physics of hot neutron stars and their cooling"

FRANK C.N. YANG
"for deepening Einstein's geometrical approach to physics in the best tradition of Paul Dirac and Hermann Weyl"

T.D. LEE (award received by Yu-Qing Lou on behalf of Prof. T.D. Lee)
"for his work on white dwarfs motivating Enrico Fermi's return to astrophysics and guiding the basic understanding of neutron star matter and fields"

13th Marcel Grossmann Meeting
July 2012, Stockholm, Sweden

Institutional Award

ALBANOVA
for its innovative status as a joint institute established by Stockholm University and the Royal Institute of Technology and for fostering contributions to cosmology and astrophysics in the profound scientific tradition established by Oskar Klein.

- presented to the Rector of Stockholm University, Prof. Kåre Bremer.

Individual Awards

DAVID ARNETT
for exploring the nuclear physics and yet unsolved problems of the endpoint of thermonuclear evolution of stars, leading to new avenues of research in physics and astrophysics.

VLADIMIR BELINSKI and I.M. KHALATNIKOV
for the discovery of a general solution of the Einstein equations with a cosmological singularity of an oscillatory chaotic character known as the BKL singularity.

FILIPPO FRONTERA
for guiding the Gamma-ray Burst Monitor Project on board the BeppoSAX satellite, which led to the discovery of GRB X-ray afterglows, and to their optical identification.

12th Marcel Grossmann Meeting
July 2009, Paris, France

Institutional Award

INSTITUT DES HAUTES ÉSTUDES SCIENTIFIQUE (IHÉS)
for its outstanding contributions to mathematics and theoretical physics, and notably for having renewed basic geometrical concepts, and having developed new mathematical and physical aspects of spacetime.

- presented to Prof. Jean-Pierre Bourguignon

Individual Awards

JAAN EINASTO
for pioneering contributions in the discovery of dark matter and cosmic web and fostering research in the historical Tartu Observatory.

CHRISTINE JONES
for her fundamental contributions to the X-ray studies of galaxies and clusters tracing their formation and evolution and for her role in collaborations using clusters to study dark matter and in analyzing the effects of outbursts from supermassive black holes on the intracluster gas.

MICHAEL KRAMER
for his fundamental contributions to pulsar astrophysics, and notably for having first confirmed the existence of spin-orbit precession in binary pulsars.

11th Marcel Grossmann Meeting
July 2006, Berlin, Germany

Institutional Award

FREIE UNIVERSITÄT BERLIN
for the successful endeavor of re-establishing — in the spirit of the Humboldt tradition — freedom of thinking and teaching within a democratic society in a rapidly evolving cosmos

- presented to Dr. Dieter Lenzen, President of FUB

Individual Awards

ROY KERR
for his fundamental contribution to Einstein's theory of general relativity: "The gravitational field of a spinning mass as an example of algebraically special metrics."

GEORGE COYNE
for his committed support for the international development of relativistic astrophysics and for his dedication to fostering an enlightened relationship between science and religion.

JOACHIM TRUMPER
for his outstanding scientific contributions to the physics of compact astrophysical objects and for leading the highly successful ROSAT mission which discovered more than 200,000 galactic and extragalactic X-ray sources: a major step in the observational capabilities of X-ray astronomy and in the knowledge of our universe.

10th Marcel Grossmann Meeting
July 2003, Rio de Janeiro, Brazil

Institutional Award

CBPF (Brazilian Center for Research in Physics)
for its role as a teaching and research institution and as a place originating fundamental physics ideas in the exploration of the universe.

- presented to its founders Cesar Lattes, Josè Leite Lopez and Jayme Tiomno

Individual Awards

YVONNE CHOQUET-BRUHAT AND JAMES W. YORK, JR.
for separate as well as joint work in establishing the mathematical framework for proving the existence and uniqueness of solutions to Einstein's gravitational field equations.

YUVAL NE'EMAN
for his contributions to science, epistimology, mathematics and physics from subnuclear to space sciences.

9th Marcel Grossmann Meeting
July 2000, Rome, Italy

Institutional Award

SOLVAY INSTITUTES
for identifying and recording in discussions by the protagonists the crucial developments of physics and astrophysics in the twentieth century.

- presented to Jacques Solvay

Individual Awards

CECILLE AND BRYCE DEWITT
for promoting General Relativity and Mathematics research and inventing the "summer school" concept.

RICCARDO GIACCONI
for opening, five successive times, new highways for exploring the Universe.

ROGER PENROSE
for extending the mathematical and geometrical foundations of General Relativity.

8th Marcel Grossmann Meeting
June 1997, Jerusalem

Institutional Award

HEBREW UNIVERSITY
for its role as a cradle of Science and Humanities and for hosting the manuscripts of Albert Einstein.

- presented to M. Magidor, President of the Hebrew University of Jerusalem

Individual Awards

TULLIO REGGE
for his contributions to the interface between mathematics and physics leading to new fields of research of paramount importance in relativistic astrophysics and particle physics.

FRANCIS EVERITT
for leading the development of extremely precise space experiments utilizing superconducting technology to test General Relativity and the Equivalence Principle.

7th Marcel Grossmann Meeting
June 1994, Stanford, USA

Institutional Award

SPACE TELESCOPE SCIENCE INSTITUTE
for its critical role in the direction and operation of the Hubble Space Telescope, a truly unique international laboratory for the investigation and testing of general relativity in the context of modern astrophysics and cosmology.

- presented to Peter Stockman

Individual Awards

SUBRAHMANYAN CHANDRASEKHAR
for his contributions to the analysis of gravitational phenomena from Newton to Einstein and especially for leading the way to relativistic astrophysics with the concept of critical mass for gravitational collapse.

JIM WILSON
for having built on his experience in nuclear physics, thermonuclear reactions, and extensive numerical simulation to create a new testing ground for the novel concepts of relativistic astrophysics.

6th Marcel Grossmann Meeting
June 1991, Kyoto, Japan

Institutional Award

RITP
for keeping alive first in Hiroshima and them in Kyoto research in relativity, cosmology, and relativistic field theory and the development of a school of international acclaim.

- presented to Professor K. Tomita

Individual Awards

MINORU ODA
for participating in the pioneering work of the early sixties in X-ray astronomy and for his subsequent molding of an agile and diversified Japanese scientific space program investigating the deepest aspects of relativistic astrophysics.

STEPHEN HAWKING
for his contributions to the understanding of spacetime singularities and of the large scale structure of the Universe and of its quantum origins.

5th Marcel Grossmann Meeting
August 1988, Perth, Australia

Institutional Award

THE UNIVERSITY OF WESTERN AUSTRALIA
for its contributions to relativistic astrophysics.

- presented to the Vice Chancellor, Professor Robert Smith

Individual Awards

SATIO HAYAKAWA
for his contributions to research in gamma, X-ray and infrared radiation as well as cosmic rays.

JOHN ARCHIBALD WHEELER
for his contributions to geometrodynamics and Einstein's visions.

4th Marcel Grossmann Meeting
July 1985, Rome, Italy

Institutional Award

THE VATICAN OBSERVATORY
for its contributions to the origin and development of astrophysics.

- presented to His Holiness Pope John Paul II

Individual Awards

WILLIAM FAIRBANK
for his work in gravitation and low temperature physics.

ABDUS SALAM
for his work in unifying fundamental interactions.

Institutional Awards for the Spektrum-Roentgen-Gamma (SRG) mission

"for the creation of the world's best X-ray map of the entire sky, for the discovery of millions of previously unknown accreting supermassive black holes at cosmological redshifts, for the detection of X-rays from tens of thousands of galaxy clusters, filled mainly with dark matter, and for permitting the detailed investigation of the growth of the large-scale structure of the universe during the era of dark energy dominance".

S.A. LAVOCHKIN ASSOCIATION
- presented to its Designer General **Alexander Shirshakov**

MAX PLANCK INSTITUTE FOR EXTRATERRESTRIAL PHYSICS (MPE)
- presented to Professor **Peter Predehl**, Principal Investigator of eROSITA

SPACE RESEARCH INSTITUTE (IKI) OF THE RUSSIAN ACADEMY OF SCIENCES
- presented to Professor **Rashid Sunyaev,** Principal Investigator of SRG Observatory in Russia

Dr Alexander Shirshakov

S.A. Lavochkin Association created the Navigator space platform carrying German eRosita and Russian ART-XC X-Ray Telescopes, organized the launch of SRG Orbital X-Ray Observatory to the second Lagrangian point of the Sun-Earth system at a distance of 1.5 million km from the Earth and managed the observatory flight and the daily reception of its scientific data on Earth for 23.5 months.

Dr Alexander Shirshakov, Designer General of the S.A. Lavochkin Association, is specialized in design, manufacture, testing, launch and control of S/C for scientific purposes. Among those S/C launched, there are the «Radiostron» Astrophysical Observatory (2011) and the «Spektr-RG» space observatory (2019), while the planned S/C launches are «Luna-25» and «Exomars».

Dr Shirshakov started his career in 1973, working as an engineer of the State Unitary Enterprise «NPO named by S.A. Lavochkin» in Khimki (Russian Federation). Starting from 1989 he has played multiple roles within the Lavochkin Association, been appointed head of the group, head of the sector, head of department, deputy head of the complex, head of the branch, director of the center, deputy head of the Design Bureau, deputy General Designer and deputy General Director.

Dr Shirshakov is an editorial board Member of the reviewed edition of «Vestnik of Lavochkin Association». Since 2017, he is also member of the General Designer council. He has been awarded Honored Mechanical engineer of the Russian Federation as well as Agency-level award of the Russian Federal Space Agency.

MAX PLANCK INSTITUTE FOR EXTRATERRESTRIAL PHYSICS (MPE)
presented to Professor **Peter Predehl**, Principal Investigator of eROSITA

Professor Peter Predehl

eROSITA is the soft X-ray telescope on-board the Russian-German Spektr-RG mission which was successfully launched from Baikonur on July 13, 2019 and placed in a halo orbit around the L2 point. 30 years after ROSAT, eROSITA performs an all-sky survey with an unprecedented sensitivity, spectral and angular resolution. Clusters of galaxies are the largest collapsed objects in the Universe. Their formation and evolution is dominated by gravity, i.e. Dark Matter, while their large scale distribution and number density depends on the geometry of the Universe, i.e. Dark Energy. X-ray observations of clusters of galaxies provide information on the rate of expansion of the Universe, the fraction of mass in visible matter, and the amplitude of primordial fluctuations which are the origin of clusters of galaxies and the whole structure of the universe. eROSITA has been designed to detect at least 100.000 clusters of galaxies and to detect systematically more than 3 million obscured accreting Black Holes. eROSITA will also allow to study the physics of galactic X-ray source

populations, like pre-main sequence stars, supernova remnants and X-ray binaries. The eROSITA telescope consists of seven identical Wolter-1 mirror modules. A novel detector system has been developed by MPE on the basis of the successful XMM-Newton pn-CCD technology. MPE is the scientific lead institute of eROSITA, responsible for the development of the instrument, the operation, the analysis software and data archive. Peter Predehl led this development as Principal Investigator of eROSITA and German lead scientist of the SRG mission for more than 15 years until the completion of the first of eight surveys in 2020. At this time eROSITA has already discovered more than 1 million X-ray sources, more than all X-ray observatories of the last 50 years together. This demonstrates that the design goals of the mission will easily be fulfilled.

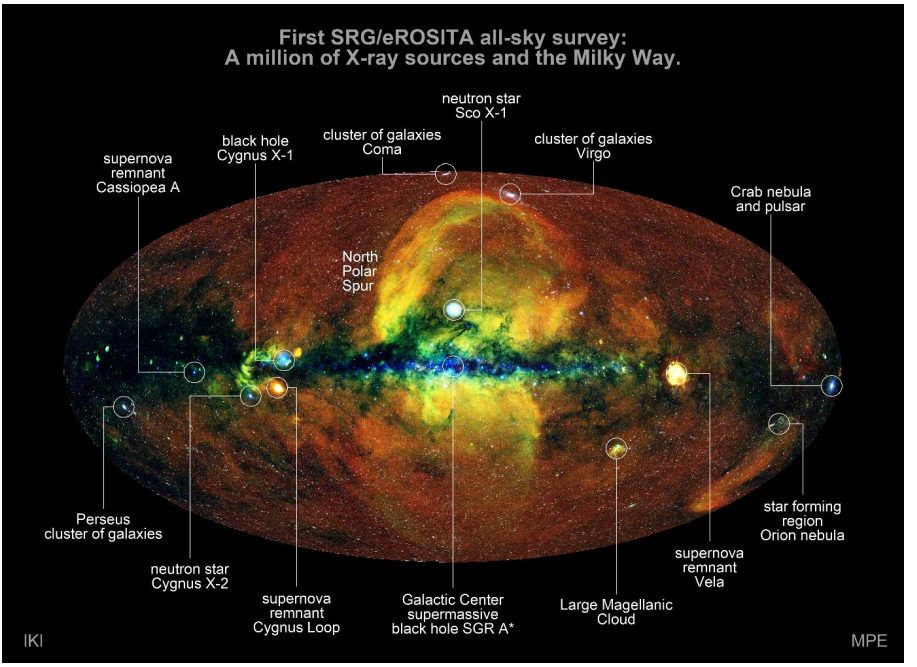
SPACE RESEARCH INSTITUTE (IKI) OF THE RUSSIAN ACADEMY OF SCIENCES
presented to Professor **Rashid Sunyaev**

Professor Rashid Sunyaev

Space Research Institute (IKI) of the Russian Academy of Sciences was responsible for developing the overall concept and scientific program of the SRG Orbital observatory and played a leading role in developing the ART-XC telescope and the entire SRG observatory as part of the Russian space science program carried out by Roskosmos Corporation in the interests of the Russian Academy of Sciences.

During the flight to the L2 point of the Sun-Earth system, SRG with German (eRosita) and Russian (ART-XC named after Mikhail Pavlinsky) X-ray Telescopes aboard performed calibrations and long duration Performance Verification observations of a dozen of targets and deep fields. Starting in the middle of December 2019, the SRG scanned the whole sky three times. During these scans, SRG discovered two million point X-ray sources: mainly quasars, stars with hot and bright coronae, and more than 30 thousand clusters of galaxies. There is a competition and synergy in the search for clusters of galaxies between SRG and the ground-based Atacama Cosmology and South Pole Telescopes, which are searching for clusters of galaxies in microwave spectral band using Sunyaev-Zeldovich effect. SRG provided the X-Ray map of the whole sky in hard and soft bands, the last is now the best among existing. The huge samples of the X-ray selected quasars at the redshifts up to z = 6.2 and clusters of galaxies will be used for well-known cosmological tests and detailed study of the growth of the large scale structure of the Universe during and after reionization. SRG/eRosita is discovering every day several extragalactic objects which increased or decreased their brightness more than 10 times during half of the year after the previous scan of the same one-degree wide strip on the sky. A significant part of these objects has observational properties similar to the Events of Tidal Disruption of a star orbiting in the vicinity of the supermassive black hole. ART-XC discovered a lot of bright galactic and extragalactic transients.

Rashid Sunyaev is the Principal Investigator of SRG mission in Russia, director-emeritus of the Max-Planck Institute for Astrophysics and Maureen and John Hendricks distinguished visiting professor of the Institute for Advanced Study, Princeton.



Individual Awards

Professor **DEMETRIOS CHRISTODOULOU**

"For his many lasting contributions to the foundation of mathematical physics including the dynamics of relativistic gravitational fields. Notably for: contributing in 1971, at the age of 19, to derive with Remo Ruffini the mass-energy formula of black holes as a function of their angular momentum, charge and irreducible mass. Christodoulou turned then to the study of partial differential equations and mathematical physics, to which he remained dedicated for the rest of his career. Highlights in this area include the theoretical discovery of the nonlinear memory effect of gravitational waves (Phys. Rev. Letters 1991), the monograph (1993) in collaboration with Sergiu Klainerman on the global nonlinear stability of the Minkowski spacetime, the monograph (2009) on the formation of black holes in pure general relativity by imploding gravitational waves, and the monographs (2007 and 2019) on the formation and further development of shocks in fluids."

Professor Demetrios Christodoulou

It was back in 1967 that Achille Papapetrou mentioned the case of the 16-year-old Demetrios Christodoulou to John Archibad Wheeler. Wheeler interviewed Demetrios in Paris and brought him immediately to Princeton where he was registered as an undergraduate at the university. After one year he entered the graduate school and started collaborating with me. At the time I was working with Wheeler on the effective potential approach to geodesics co-rotating and counter-rotating (see e.g. reference in The Classical Theory of Fields (Landau and Lifshitz, 1980) in the Kerr metric (later renamed as ISCO; see e.g. (Gravitation Misner, Thorne, Wheeler. 1973). In parallel, Frank Zerilli was working on the gravitational radiation emitted by the fall of a test particle in a Schwarzschild black hole (Zerilli 1970). From these limited conceptual arena Charles Misner and later Kip Thorne launched a program for the detection of gravitational waves on the Earth; see e.g. Misner 1974, Abbott et al. 2016, Abbott et al. 2017. See however Davis et al. 1972, Rodriguez et al. 2018 and J.A. Rueda et al. 2018.

A new approach started with the arrival of Demetrios: he was just creating mathematics following his needs. We identified the reversible and irreversible transformations of a Kerr black hole. Wheeler advanced a thermodynamic analogy. I addressed the need of identifying the concept of irreducible mass (from the Italian "irriducibile"), and was Demetrios's contribution to integrate, overnight, the differential equation for infinitesimal reversible transformations which led to the finite mass-energy formula of a Kerr black hole. That evening, while walking back home through IAS woods, I expressed to Wheeler the great relevance of the newly found formula by Demetrios and proposed to let Demetrios be the single author of this article, admiring his great mathematical talent. Wheeler agreed. The Editor of PRL objected since in that two pages article the Fig. 2 by Wheeler and myself was still unpublished. Actually that Fig. 2 followed a discussion I previously had with Penrose in Florence (Penrose 1961) which allowed us to present there, for the first time, a "Penrose Process". Some difficulties in achieving this process were obvious from the example in Fig. 2, which Roger later recognized himself (Penrose & Floyd 1971). The Editor finally agreed on our written request and the paper appeared on September 17, 1970 (Christodoulou, 1970). On January 1971 appeared my article with Johnny introducing the Black Hole (Ruffini & Wheeler, 1971), with the new physics we were developing in Princeton, including the concept of the "ergosphere". On march 1 1971 we submitted the mass formula of the Kerr Newmann metric, including the relation between the surface area of the horizon and the irreducible (Christodoulou & Ruffini, 1971). On March 11, 1971 the same results were independently confirmed by Steven Hawking, extending further the applicability of our equation (Hawking 1971).

The thesis was successfully discussed by a committee including Eugene Wigner (see Fig. 1), one of the closest collaborators of Albert Einstein and David Wilkinson (see Fig. 2), the head of the NASA WMAP mission, and Johnny and myself as supervisors. The new message was clear: Black Holes, far from being a sink of energy, were energy sources emitting "in principle" 50% of their mass energy, being extractable (Christodoulou & Ruffini, 1971).

Fig. 1 and Fig. 2: Demetrios during his thesis presentation with Eugene Wigner (Fig. 1) and David Wilkinson (Fig.2). Johnny and I were supervisors, ready to intervene in case of need, but no need of intervention was necessary! Wigner elaborated the aphorism of Niels Bohr "Interesting = wrong" in the most definite "very interesting if true = totally wrong".

Demetrios turned soon to the study of partial differential equations and mathematical physics, to which he dedicated for the rest of his career and results were published in four monographs: (Christodoulou and Klainerman 1994, Christodoulou 2007, Christodoulou 2009, Christodoulou 2019). In 1968, Johnny proposed to Demetrios the collapse of a "geon" composed of massless scalar field as a second topic for his thesis. It took almost forty years for him to solve this problem, extended by Demetrios to the focusing of gravitational waves leading to black hole formation (Christodoulou 2009).

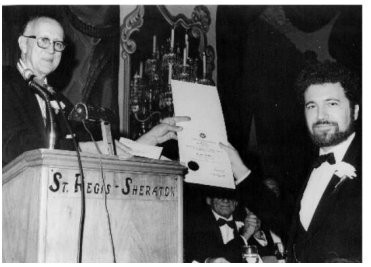


Fig. 3: Prof. Remo Ruffini receiving the Cressy Morrison Award of the New York Academy of Sciences, 1972 for the discovery of the first Black Hole in our galaxy Cygnus X1.

A "long march" started on 12 December 1970 with the launch of the Uhuru satellite by Riccardo Giacconi. Early in 1971 an almost daily conversation with him and Herb Gursky at the Smithsonian Astrophysical Observatory, leading to the discovery of binary X-ray sources. This was soon followedby the announcement of Cygnus X1 identified as the first black hole in our galaxy (Ruffini 1973); see e.g. Gursky & Ruffini 1975, which contained as well the first publicannouncement of the Discovery of Gamma Ray burst, as well as Giacconi & Ruffini 1980, 2009; see Figs. 3 and 4).

Fig. 4: In the second row, from left to right, there are, among others: E. T. Newman, S. Chandrasekhar (Nobel 1983), R. Giacconi (Nobel 2002), R. Ruffini, A. Treves, A. Hewish (Nobel 1974), D. Arnett, J.H. Taylor (Nobel 1993), J. Wilson, R. Penrose (Nobel 2020), as well as J. Bahcall, T. Damour, T. Piran et al.

Today, after fifty years, this "long march" has reached a definite result: through the grandest observational multi-wavelength effort in the history of mankind, from space, ground and underground observatories, we are finally finding evidence that black holes are "alive" and their "extractable energy" in our mass formula (Christodoulou & Ruffini, 1971), is the energy source of the most energetic cosmological sources: gamma ray bursts (GRBs),the active galactic nuclei (AGNs) as well as the ultra-high energy cosmic rays (UHECRs) (Ruffini et al. 2021 and references therein). Their "inner engine", has three independent components: 1) a Kerr black hole which is neither in a stationary state nor in vacuum, 2) a background magnetic field aligned with the black hole rotation axis, and 3) an extremely diluted fully ionized plasma (Moradi et al. 2021).There is no role in this inner engine for ISCO. Indeed a new electro dynamical field equations describe the synchrotron radiation emitted close to the black hole horizon, they point to a discrete and repetitive emission of "blackholic quanta" in the MeV and in the GeV. The magnitudes and the emission time scales of these quanta, for M87 and GRB 130427A, are expressed as a function of the above three parameters (Rueda & Ruffini, 2021). A long lasting GeV emission with a luminosity decreasing as a temporal power law, allows for the first time in GRBs, the determination of the black hole mass and spin as well as their time evolution perfectly fulfilling our mass energy formula (Christodoulou & Ruffini, 1971): a long lasting emission process profoundly different from the traditional process of continued gravitational contraction.

Remo Ruffini

Professor **GERARD 't HOOFT**

"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon".

Professor Gerard 't Hooft

Prof. Gerard 't Hooft has been a full Professor at the Utrecht University (the Netherlands), since 1977. Nowadays, he is an Emeritus Professor at that University. During his career, he has paid extended scientific visits to CERN (Geneva), Harvard, Stanford, Princeton and Duke University, NC. In 1999, together with M. Veltman, he received the Nobel Prize in Physics, awarded by The Royal Swedish Academy of Sciences, *"For elucidating the quantum structure of electroweak interactions in physics"*.

Prof. 't Hooft's main subjects of research includes:

– Gauge Theories for the sub-atomic particles and forces, various aspects and ingredients of what is now called "The Standard Model of the sub-atomic particles: renormalizability, topological features such as magnetic monopoles and instantons, 1/N expansions.

– Theories for the quantization of the gravitational force and black holes: producing models for the quantum properties of a black hole, as derived from Standard Model and General Relativity alone; its topological features such as antipodal identification.

– Fundamental theories underlying quantum mechanics, in particular returning determinism and reality to the dynamics of the tiniest material entities in his universe.

Prof. 't Hooft has been awarded the Wolf Prize of the State of Israel (1982), the Pius XI Medal (Vatican City, 1983), the Lorentz Medal (KNAW Amsterdam, 1986) as well as the Spinoza Premium (Netherlands Organization for Scientific Research NWO, 1995).

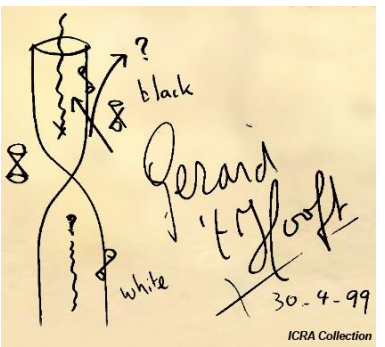

Fig. 2: The signature of Gerard 't Hooft on the wall of ICRA Room 301 (April 4, 1999).

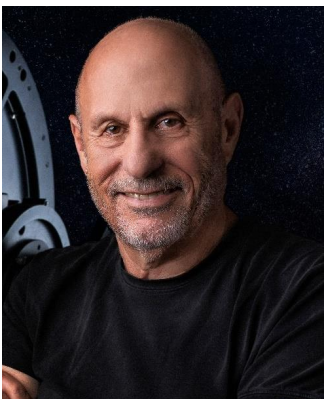
A special event took place at ICRA on April 30, 1999. Prof. Ruffini invited Gerard 't Hooft to Rome to discuss a boundary condition for a quantum field on the black hole horizon, a topic Prof. Ruffini discussed in a previous article "Black-hole evaporation in the Klein-Sauter-Heisenberg-Euler formalism" with Thibault Damour (Phys. Rev. D 14, 332, 1976), but which needed to be examined in more detail. Prof. Ruffini planned to direct Gerard's attention to some specific aspects of this problem. Because we have traditionally been very attentive in spending ICRA travel funds, ICRA offered Gerard to come to Rome on a reduced fare weekend ticket arriving Friday and departing Monday. He had a great relaxing weekend together with Prof. Ruffini following his seminar, which among other things allowed Gerard to sign the wall in our ICRA Room (see Fig. 2), and during this splendid Rome spring weekend he also was able to find a missing factor of 2 in a formula in Prof. Ruffini's 1971 paper with Demetri Christodoulou on the black hole mass formula. The following October, Gerard received the Nobel prize, which meant that we could no longer get away with bringing him to Rome on a cheap ticket! Ever since Gerard has been in our MG IOC helping us with the preparation of the meetings. We are very happy to announce this MG16 Award to Gerard 't Hooft with the motivating phrase *"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon"*.

Remo Ruffini

Professor **TSVI PIRAN**

"for extending relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory".



Professor Tsvi Piran

Tsvi Piran is the emeritus Schwartzmann professor at the Hebrew University of Jerusalem. He obtained his PhD in Physics, in 1976 from the Hebrew University working on the collisional Penrose process. Piran returned to the Hebrew University at 1981after being a post doc at Oxford and Texas and a long-term member at the IAS at Princeton. In 1982 he initiated and directed the first ever summer school on Gravitational Waves that took place at Les Houches. Piran was a visiting professor at Harvard, Columbia and New York and a Moore scholar at Caltech.

Piran's research deals with numerous aspects of relativistic astrophysics, ranging from the foundation of numerical relativity to modeling of observer relativistic phenomena and analytic work on the fate of gravitational collapse. Piran's research work focuses mostly on black holes and in particular on gamma-ray bursts. He was among the first to point out their cosmological origin and their association with merging neutron stars and heavy r-process nucleo synthesis. Piran's achievements were recognized in the 2019 EMET prize for Physics.

Professor **STEVEN WEINBERG**

"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory".

Professor Steven Weinberg. Photo courtesy of Matt Valentine.

Steven Weinberg is a member of the Physics and Astronomy Departments at The University of Texas at Austin. His research has covered a broad range of topics in quantum field theory, elementary particle physics and cosmology. He has been honored with numerous awards, including the Nobel Prize in Physics, the National Medal of Science, the Heinemann Prize in Mathematical Physics and in 2020, the Breakthrough Prize. He is a member of the US National Academy of Sciences, Britain's Royal Society, and other academies in the USA and abroad. The American Philosophical Society awarded him the Benjamin Franklin Medal, with a citation that said he is "considered by many to be the preeminent theoretical physicist alive in the world today." His books for physicists include *Gravitation and Cosmology*, the three-volume work *The Quantum Theory of Fields*, *Cosmology* and published in April of 2021, *Foundations of Modern Physics*. Educated at Cornell, Copenhagen, and Princeton, he also holds honorary degrees from sixteen other universities. He taught at Columbia, Berkeley, M.I.T., and Harvard, where he was Higgins Professor of Physics, before coming to Texas in 1982.

Fig. 1: Chuo Pei Yuan and Cheng Ning Yang at MG2 in Trieste, Italy (1979).

The Sixteenth Marcel Grossmann Meeting (MG16) is a very special one in many respects: it will take place during a pandemic and in spite of the many difficulties, we have decided not to postpone it but to organize it as a virtual meeting. As described on the MG series webpage, these meetings started in 1975 with the first meeting at the International Centre for Theoretical Physics (ICTP) in Trieste (Italy) that I organized with Nobel Prize winner Abdus Salam. A second meeting followed in 1979, with a significantly larger participation including Nobel Laurate Cheng Ning Yang and a Chinese delegation led by Chuo Pei Yuan (see Fig. 1), including Fang Li-Zhi who had accompanied me during my entire first visit to China in 1979. The first truly international MG meeting followed in 1982 in Shanghai (China):this represented an especially important step forward both for the meeting and for China. A multi-millennia *"motto"* in China, which was then proclaimed on banners everywhere, read *"Friends from all over the world are welcomed"*.

We were soon at an impasse over the participation of scientists from Israel, since no diplomatic relations existed between China and Israel at that time and the Israeli scientists were not to be allowed to attend the meeting. A long negotiation began. The boundary conditions were clearly set by Steven Weinberg, a member of the present MG16 IOC: no MG meetings on Einstein's theory of general relativity could occur without the participation of Israeli scientists. The intervention of Yuval Ne'emann, also a member of the MG IOC then as well as the Minister of Science of Israel (see Fig.2), proposed a compromise that would admit at least one Israeli scientist. I went to Beijing alone, meeting every morning for a week with 12 Chinese representatives led by Chuo Pei Yuan going over all possible options. I stayed in an isolated villa not far from Tiananmen Square, accompanied by the 3 volumes of Matteo Ricci (RI MA TO) to keep me company. No solution was in sight the entire week. At the last moment, just before my departure, an agreement was finally reached allowing two Israeli scientists into China. The historic compromise would admit Gerard Tauber and Tsvi Piran into China using a special ICRA travel document I had proposed for them to be able to participate in the meeting, accepted by the Chinese Ambassador in Rome. This modified the thousand-year Chinese *"motto"* to read *"Scientists from all over the world are welcomed"*. The event was extremely beneficial for China and signaled the truly international nature of the MG meetings.

Fig. 2: From right to left: Chaim Weizmann, President of Israel; Yuval Ne'emann, Minister of Science of Israel; R. Ruffini.

I kept on meeting Tauber in the years which followed (see Fig. 3). Soon after, Yuval Ne'emann visited China. The development of bilateral relations, including military cooperation and economical tights, grow exponentially until the establishment of normal diplomatic relations between Israel and China in 1992.

Fig. 3: From right to left: Arrigo Finzi, Remo Ruffini, Gerard Tauber and Konrad Bleuler.

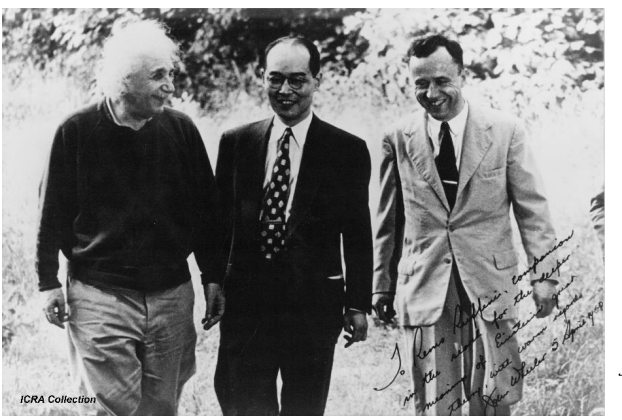


Fig. 4: Albert Einstein, Hideki Yukawa and John. A. Wheeler with a hand-written dedication to Remo Ruffini "To Remo Ruffini, companion in the search for the deeper meaning of Einstein great theory. With warm regards, John Wheeler 5 April 1968".

Given their key role played in the foundations of the MG meetings, I am very happy to propose on behalf of the MG16 IOC, two special Marcel Grossmann Individual Awards: one to Steven Weinberg for *"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory"* and another one to Tsvi Piran, *"for extending Relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory"*, in the words of John A. Wheeler's photo dedication to me (see Fig. 4).

Remo Ruffini

PREFACE

Since 1975, the Marcel Grossmann Meetings on Recent Developments in Theoretical and Experimental General Relativity, Gravitation, and Relativistic Field Theories have been organized in order to provide opportunities for discussing recent advances in gravitation, general relativity and relativistic field theories, emphasizing mathematical foundations, physical predictions and experimental tests. The objective of these meetings is to elicit exchange among scientists that may deepen our understanding of spacetime structures as well as to review the status of ongoing experiments aimed at testing Einstein's theory of gravitation either from the ground or from space. Previous meetings have been held in Trieste (MG1: 1975) and (MG2: 1979), Shanghai (MG3: 1982), Rome (MG4: 1985, MG9: 2000), Perth (MG5: 1988), Kyoto (MG6: 1991), Stanford (MG7: 1994), Jerusalem (MG8: 1997), Rio (MG10: 2003), Berlin (MG11: 2006), Paris (MG12: 2009), Stockholm (MG13: 2012), MG14 in 2015 and MG15 in 2018 both in Rome.

Due to the COVID-19 pandemic spreading in the last two years the decision was taken to organize the Sixteenth Marcel Grossmann meeting for the first time in history entirely online. Despite numerous challenges, related to the organization of large worldwide event, MG16 showed the strongest ever interest from the scientific community with a record-breaking number of almost 1200 registered participants and of more than 1000 speakers.

The traditional six-day schedule has been modified to account for different time zones of the speakers and each day the program of the meeting was divided in three blocks with the reference to the Central European Summer Time. The first block was starting at 06:30 in the morning, allowing comfortable time for speakers from Asia and Oceania. The second block was held in the daytime in Europe and Africa. The third block was starting in the afternoon and ending at 19:30 allowing accommodation of the speakers from the Americas. Each day the blocks of plenary sessions were interchanging with the blocks of about 30 parallel sessions each, making this one of the most intense MG meetings ever. All this was possible thanks to recent developments in communication technologies. The Indico open-source software was selected as a web platform for this meeting, while Zoom platform was adopted for the video-conferencing. The meeting was streamed on ICRANet YouTube channel.

The meeting started on Monday July 5 with the Award ceremony. The individual awards went to Demetrios Christodoulou, Tsvi Piran, Gerard 't Hooft and Steven Weinberg, while the Institutional Awards went to the S.A. Lavochkin Association, to the Max Planck Institute for Extraterrestrial Physics – MPE and to the Space Research Institute IKI of the Russian Academy of Sciences. Overall there were 54 plenary talks, 4 public lectures and 5 roundtables and about 90 parallel sessions. The plenary session "Events in Relativistics Astrophysics" on Monday have seen the contributions from Rashid Sunyaev, Michael Kramer, James Miller-Jones, Felix Mirabel. The public lectures were delivered by Razmik Mirzoyan, Asghar Qadir

and Mohammad Bagheri. Plenary talks on Tuesday session "Black holes and the Quantum" by Juan Maldacena, Ahmed Almheiri, Gerard 't Hooft, Mihalis Dafermos, Sergiu Klainerman, Abhay Ashtekar and Frank Wilczek were bracketed by two roundtables on "New results from SRG/eRosita" with the participation of Andrea Merloni, Prof. Rashid Sunyaev, Alexander Lutovinov, Chandreyee Maitra, Esra Bulbul and "Solar neutrinos and Borexino" with the participation of Gianpaolo Bellini and Wick Haxton. Plenary talks on Wednesday in the session "Lambda CDM tensions" by George Efstathiou, Scolnic Daniel, Marc Kamionkowski, Wendy Freedman, Priya Natarajan and Licia Verde were followed by the roundtable "Precision cosmology" with the participation of Licia Verde, Marc Kamionkowski, Piero Rosati, and the public lecture by Francis Halzen. Two blocks of Thursday plenary sessions "Black holes in GRBs" and "Precision tests" included the talks by Roy Kerr, Yuan Ha, Lorenzo Amati, Elena Pian, Carlos Raúl Argüelles, Di Li, Jianglai Liu, Claus Lämmerzahl, Gerhard Heinzel and Ignazio Ciufolini and were followed by the roundtable "GRB 170817A and GRB 190829A" with the participation of Eleonora Troja, Liang Li, Rahim Moradi, Jorge Armando Rueda Hernandez. Two plenary blocks on Friday "Massive stars" and "Physics behind stellar collapse" included the talks by Selma de Mink, Norbert Langer, Jiri Bicak and Tomáš Ledvinka, Ivan De Mitri, Rahim Moradi and Giancarlo Cella. Finally, two plenary blocks on Saturday "Current and future missions" have seen the talks by Shuang-Nan Zhang, Weimin Yuan, Makoto Tashiro, Ruoyu Liu, Jean-Luc Atteia, Jim Hinton and Nicholas White and were followed by the roundtable "What is in our Galactic center" with the participation of Reinhard Genzel, Carlos Raúl Argüelles, Andreas Krut, Jorge Armando Rueda Hernandez, Eduar Becerra Vergara. The program of the meeting can be found at the official website http://www.icra.it/mg/mg16 and at ICRANet Indico website https://indico.icranet.org/event/1/.

These proceedings include about 400 papers containing the results presented at the Sixteenth Marcel Grossmann meeting. The plenary papers from the meeting have been published in International Journal of Modern Physics D as they were submitted. The table of contents includes also the links to YouTube videos with talks given at the meeting and cover plenary talks, public lectures, roundtables and all parallel sessions. The general link to the videos from MG16 is: https://www.youtube.com/watch?v=QFe1lsSid-o&list=PLr5RLbSWSonsaOnZukBDs0qsNIWM8AvRF.

As the editors we would like to express our gratitude to all the chairpersons of the parallel sessions at MG16, who peer-reviewed the papers submitted for these proceedings, as well as to the ICRANet secretariat office and in particular to Cinzia di Niccolo, Elisabetta Natale and Yasmina Di Domizio, as well as to ICRANet system manager Gabriele Brandolini for their help in preparation of this publication.

Preface xxxvi

PART A
PLENARY SESSIONS

New results from testing relativistic gravity with radio pulsars
Michael Kramer 3

Dragging of inertial frames by matter and waves
Jiří Bičák and Tomáš Ledvinka 22

Probes of the progenitors, engines and physics behind stellar collapse
Chris L. Fryer 39

The observation of high-energy neutrinos from the cosmos: Lessons learned for multimessenger astronomy
Francis Halzen 59

The first results of PandaX-4T
Jianglai Liu on behalf of the PandaX Collaboration 85

XRISM: X-ray imaging and spectroscopy mission
Makoto S. Tashiro and the XRISM team 95

The SVOM mission
J.-L. Atteia, B. Cordier and J. Wei on behalf of the SVOM Collaboration 104

Quantum field theory with boundary conditions at the horizons
Gerard 't Hooft 133

The development of general relativity and the cosmological constant
Asghar Qadir 143

The irreducible mass of Christodoulou-Ruffini-Hawking mass formula
Yuan K. Ha 154

Reshaping our understanding on structure formation with the quantum nature of the dark matter
C. R. Argüelles, E. A. Becerra-Vergara, A. Krut et al. 164

First results of LHAASO
Ruo-Yu Liu for the LHAASO Collaboration 180

On the MG16 awards 2021
Remo Ruffini 196

The white dwarf binary merger model of GRB 170817A
J. A. Rueda, R. Ruffini, Liang Li et al. 217

PARALLEL SESSIONS

Accretion

• MHD Processes Near Compact Objects
Chairperson: Sergey Moiseenko
YouTube link: https://youtu.be/2WMTg06ZmV8

A semi-implicit multidimensional unstructured gas dynamical solver for astrophysical applications
Ilya A. Kondratyev and Sergey G. Moiseenko 242

Magnetized neutron stars propagating through a non-uniform ISM
O. D. Toropina, M. M. Romanova and R. V. E. Lovelace 255

Calculation of the kinetic coefficients of arbitrary degenerate electrons in magnetized dense matter
M. V. Glushikhina and G. S. Bisnovatyi-Kogan 264

Modeling of magnetic fields of accretion discs, using no-z- and RZ-approximations
M. V. Pashentseva and E. A. Mikhailov 272

• Accretion Discs and Jets
Chairpersons: Audrey Trova and Shokoufe Faraji
YouTube link: https://youtu.be/29Wj9RCVEKw

Limiting effects in tori clusters
D. Pugliese and Z. Stuchlik 280

Hydrodynamical transport of angular momentum in accretion disks in the presence of nonlinear perturbations due to noise
Subham Ghosh and Banibrata Mukhopadhyay 295

Properties of accretion disc models in the background quadrupole
Shokoufe Faraji 307

Magnetized tori around a uniformly accelerating black hole
Shokoufe Faraji and Audrey Trova 317

Multifrequency behaviour of high mass X-ray binaries (Time lag between optical and X-ray outbursts)
Franco Giovannelli 321

Active Galactic Nuclei

• The Black Hole in M87
Chairpersons: Brian Punsly and Jorge Rueda
YouTube link: https://youtu.be/l1lTgksyJag

Rotation of the crescent image of M87* and polarization of its ESE hotspot
Krzysztof Nalewajko 339

Magnetic reconnection in jet-accretion disk systems

Breaking Buchdahl: Ultracompact stars in semiclassical gravity
Julio Arrechea, Carlos Barceló, Raúl Carballo-Rubio and Luis J. Garay 2608

Einstein anomaly with tensors of odd order in six dimensional curved space
Kohei Yamamoto and Satoshi Yajima 2619

Quantum memory and BMS symmetries
Sanved Kolekar and Jorma Louko 2623

• Topological Methods, Global Existence Problems, and Spacetime Singularities
Chairperson: Spiros Cotsakis

YouTube link: https://youtu.be/H8Itnc_C10c

Gravitational singularities, scattering maps for bouncing, and structure-preserving algorithms
Philippe G. LeFloch 2630

Brane-world asymptotics in a nonlinear fluid bulk
I. Antoniadis, S. Cotsakis and Ifigeneia Klaoudatou 2645

Primordial synchronization of Mixmaster spatial points
Spiros Cotsakis 2657

• The Early Universe
Chairperson: Stefano Ansoldi

YouTube links: https://youtu.be/m80hHWgOlFs
https://youtu.be/6tyaZ8MMVtw

Quintessential inflation from Lorentzian slow roll
David Benisty 2663

Condensed light, quantum black holes and L-CDM cosmology: Experimentally suggested and tested unified approach to dark matter, dark energy, cosmogenesis and two-stage inflation
Victor Borsevici 2672

Helical magnetic fields lead to baryogenesis
Ashu Kushwaha and S. Shankaranarayanan 2692

Polymer Quantization of the Isotropic Universe: Comparison with the Bounce of Loop Quantum Cosmology
G. Barca, E. Giovannetti, F. Mandini and G. Montani 2700

General relativistic evolution equations for density perturbations in open, flat and closed FLRW universes and the problem of structure formation
Pieter G. Miedema 2708

Constraining beyond ΛCDM models with 21cm intensity mapping forecast observations combined with latest CMB data
M. Berti 2726

Entropy and irreversible processes in gravity and cosmology
Llorenç Espinosa-Portalés and Juan García-Bellido 2737

Fundamental Interactions and Stellar Evolution

• Why and How the Sun and the Stars Shine: The Borexino Experiment
Chairpersons: Giampaolo Bellini, Dmitry Naumov, Gioacchino Ranucci, Gemma Testera

YouTube links: https://youtu.be/hh5wDnM8miU
https://youtu.be/TG-HgBf7W4s
https://youtu.be/HLiis2LFeEs

Experimental detection of the CNO cycle
B. Caccianiga, N. Rossi, G. Testera et al. 2753

Borexino detector performances
A. Caminata, M. Agostini, K. Altenmüller et al. 2765

Study of antineutrinos from the Earth and the Cosmos with the Borexino detector
Sandra Zavatarelli, M. Agostini, K. Altenmuller et al. 2774

Unveiling the engine of the Sun: Measurements of the *pp*-chain solar neutrinos with Borexino
D. Guffanti, A. C. Re and O. Smirnov 2785

Electron neutrino survival probability in the energy range 200 keV–15 MeV
Marco Pallavicini on behalf of the Borexino Collaboration 2804

The relevance of pp-chain and CNO-cycle neutrino measurements for solar physics
F. L. Villante and A. M. Serenelli 2815

Role of the CNO cycles in stars
A. Ianni 2835

Geoneutrino observation
Tadao Mitsui for the KamLAND Collaboration 2840

Synthesis of the session: Why and how the Sun and the stars shine
Gianpaolo Bellini 2845

• **Rotation in Stellar Evolution**
Chairperson: Georges Meynet

YouTube link: https://youtu.be/9LNoiwa0nv8

The internal rotation of low-mass stars from solar and stellar seismology
G. Buldgen and P. Eggenberger 2848

The rotation of supermassive stars
L. Haemmerlé 2865

Fast Transients

• **What Can We Learn from a Growing Sample of Fast Radio Bursts?**
Chairpersons: Duncan Lorimer, Victoria Kaspi and Bing Zhang

YouTube links: https://youtu.be/yo4n1SgfUrQ
https://youtu.be/NwGooPauhjU

Cosmology with high-redshift FRBs
A. Fialkov 2880

• **Non Standard Cosmological Probes**
Chairpersons: Duncan Lorimer, Victoria Kaspi and Bing Zhang

YouTube links: https://youtu.be/EEFUgiFeMck
https://youtu.be/Ryb15AINfMs

Closing the cosmological loop with the redshift drift
C. J. A. P. Martins, C. S. Alves, J. Esteves, A. Lapel and B. G. Pereira 2890

Gamma-Ray Bursts as potential cosmological probes
L. Izzo 2906

Surface brightness fluctuations: The method and future applications
Michele Cantiello 2915

Preliminary results of analysis of Ia supernovae redshift distributions on data of the Asiago Supernova and Open Supernova Catalogues
I. V. Arkhangelskaja 2930

• **Photospheric Emission in GRBs**
Chairpersons: Gregory Vereshchagin and Damien Bégué

YouTube links: https://youtu.be/ZifnzoUXIFc
https://youtu.be/n7vWAVhFXiU

Understanding prompt emission: Where do we stand?
Asaf Pe'er 2946

On explaining prompt emission from GRB central engines with photospheric emission model
M. Bhattacharya and P. Kumar 2957

Monte Carlo simulations of photospheric emission in Gamma Ray Bursts
T. M. Parsotan and D. Lazzati 2972

The photosphere emission spectrum of hybrid relativistic outflow for Gamma-Ray Bursts
Yan-Zhi Meng, Jin-Jun Geng and Xue-Feng Wu 2982

On diffusive photospheres in Gamma-Ray Bursts
G. V. Vereshchagin 2989

Summary of the parallel session GB3
G. V. Vereshchagin and D. Bégué 3002

• High and Very High Energy Emission from Gamma-Ray Bursts
Chairpersons: Francesco Longo and Fabian Schüssler

YouTube links: https://youtu.be/ZUkLyyYowaM
https://youtu.be/zwN1mNVeUzA

Synchrotron and synchrotron self-Compton emission components in GRBs detected at very high energies
Jagdish C. Joshi, Vikas Chand and Soebur Razzaque 3009

The VERITAS gamma-ray burst follow-up program
D. Ribeiro for the VERITAS Collaboration 3017

MAGIC view of Gamma-Ray Bursts at very high energies
A. Berti on behalf of the MAGIC Collaboration 3030

Prospects for VHE monitoring of gamma-ray bursts with SWGO
G. La Mura, U. Barres de Almeida, R. Conceição et al. 3041

Theoretical implications on the very high energy emission from GRB 190114C
D. Miceli, A. Berti, Z. Bosnjak et al. on behalf of the MAGIC Collaboration 3052

AGILE and GRBs: 13 years of observations
A. Ursi on behalf of the AGILE Team 3062

Searching for Gamma-Ray Bursts with the High-Altitude Water Cherenkov (HAWC) observatory
K. L. Engel for the HAWC Collaboration 3074

• **Electromagnetic Counterparts of Compact Binary Mergers**
Chairpersons: Jonathan Granot and Paz Beniamini

YouTube link: https://youtu.be/AS7bwaT48us

CALET search for gamma-ray counterparts of gravitational wave events
Masaki Mori for the CALET Collaboration 3084

• **Unusual and New Types of Gamma-Ray Bursts**
Chairperson: Binbin Zhang

YouTube link: https://youtu.be/VrF0iU8Q6us

Off-axis jet scenario for early afterglow emission of low-luminosity Gamma-Ray Burst GRB 190829A
Yuri Sato, Kaori Obayashi, Ryo Yamazaki, Kohta Murase and Yutaka Ohira 3095

• **Gamma-Ray Burst Correlations: Observational Challenges and Theoretical Interpretation**
Chairpersons: Maria Giovanna Dainotti and Liang Li

YouTube links: https://youtu.be/gcEy2h6y1jg
https://youtu.be/m2pCT6RAmI0
https://youtu.be/GTCvcVhBjN4

GRB prompt phase spectra under backscattering dominated model
Mukesh Kumar Vyas, Asaf Pe'er and David Eichler 3101

Applying models of pulsar wind nebulae to explain X-ray plateaux following short Gamma-Ray Bursts
L. C. Strang and A. Melatos 3107

Searching for strange quark planets
Xu Wang, Yong-Feng Huang and Bing Li 3118

Probe the universe by using Gamma-Ray Bursts with X-ray plateaus
Fan Xu and Yong-Feng Huang 3124

A new perspective on cosmology through Supernovae Ia and Gamma Ray Bursts
B. De Simone, V. Nielson, E. Rinaldi and M. G. Dainotti 3130

Theory of plateau phase in Gamma-Ray Bursts
Asaf Pe'er 3141

Exploring the canonical behaviour of long Gamma-Ray Bursts using an intrinsic multi-wavelength afterglow correlation
S. R. Oates, J. L. Racusin, M. De Pasquale et al. 3150

• **GRB 170817A and Binary Models**
Chairpersons: Marica Branchesi and Giulia Stratta
YouTube link: https://youtu.be/FRBvkaLX5WU

Kilonova emission observed so far: A comparison with AT2017gfo
A. Rossi 3162

• **Binary-Driven Hypernovae of Type 1, 2 and 3**
Chairpersons: Carlo Luciano Bianco, Christian Cherubini and Simonetta Filippi
YouTube link: https://youtu.be/8IFLfget3C0

Neutrinos and gamma-ray production from proton-proton interactions in binary-driven hypernovae framework
S. Campion, J. D. Melon Fuksman and J. A. Rueda Hernandez 3172

General relativistic turbulence in spherically symmetric core-collapse supernovae simulations
L. Boccioli, G. J. Mathews and E. P. O'Connor 3184

Gravitational Waves

• **Sources of Gravitational Waves**
Chairperson: Andrew Melatos
YouTube links: https://youtu.be/Lr8b9nKsFm4
https://youtu.be/xuqJOXPDyVY
https://youtu.be/qzOrgojHsMg
https://youtu.be/KCJoWMd71pE

Mountain formation by repeated, inhomogeneous crustal failure in a neutron star
A. D. Kerin and A. Melatos 3194

Gravitational waves from neutrino mass generating phase transitions
Nobuchika Okada and Osamu Seto 3206

Efficiency of registration of chirp bursts and signals of collapsing stars by the Euro-Asian network of GW interferometers
V. N. Rudenko, S. L. Andrusenko, D. P. Krichevskiy and G. D. Manucharyan 3219

Joint analysis method on gravitational waves and low-energy neutrinos to detect core-collapse supernovae
O. Halim, C. Casentini, M. Drago et al. 3228

• **Mid-frequency Gravitational Waves (0.1–10 Hz): Sources and Detection Methods**
Chairperson: Wei-Tou Ni
YouTube link: https://youtu.be/sJ6A7a73Vxw

A cryogenic and superconducting inertial sensor for the Lunar Gravitational–Wave Antenna, the Einstein Telescope and Selene-physics
F. Badaracco, J. V. van Heijningen, E. C. Ferreira and A. Perali 3245

Space gravitational wave antenna DECIGO and B-DECIGO
S. Kawamura and the DECIGO working group 3254

Summary of the parallel session GW2
Dongfeng Gao, Wei-Tou Ni, Jin Wang et al. 3261

• **Numerical Relativity and Gravitational Wave Observations**
Chairperson: Nigel Bishop

YouTube links: https://youtu.be/eZPytAU4Zmk
https://youtu.be/th-3KqkxDnU

Salient features of the optimised PyCBC IMBH search
Koustav Chandra, Archana Pai, V. Villa-Ortega et al. 3277

Matter shells modifying gravitational wave signals
Monos Naidoo, Nigel T. Bishop and Petrus J. van der Walt 3286

Odd-dimensional gravitational waves from a binary system on a three-brane
D. V. Gal'tsov and M. Khlopunov 3301

Developments in numerical relativity and gravitational wave observations
Nigel T. Bishop 3309

High Energy

• **Very High Energy Gamma Rays**
Chairpersons: Razmik Mirzoyan and Alessandro De Angelis

YouTube link: https://youtu.be/jHM1RH20ZyM

Insights into the Galactic Center environment from VHE gamma-ray observations with ground-based facilities
C. Fruck 3316

The TAIGA experiment
M. Tluczykont, I. I. Astapov, A. K. Awad et al. 3324

Science perspectives of the Southern Wide-field Gamma-ray Observatory (SWGO)
K. L. Engel for the SWGO Collaboration 3343

• **Future Missions for High-Energy Astrophysics**
Chairpersons: Filippo Frontera and Shaolin Xiong

YouTube link: https://youtu.be/JgDsZX6RUkU

Laue lenses: Focusing optics for hard X/soft Gamma-ray astronomy
L. Ferro, M. Moita, P. Rosati et al. 3355

ASTENA: A mission concept for a deep study of the transient gamma-ray sky and for nuclear astrophysics
E. Virgilli, F. Frontera, P. Rosati et al. on behalf of the ASTENA Collaboration 3368

Polarimetric prospects of a new hard X-soft gamma-ray space mission for next decades
M. Moita, L. Ferro, F. Frontera et al. 3385

• **The SRG Mission: First Results from eROSITA and ART-XC**
Chairperson: Andrea Merloni
YouTube link: https://youtu.be/l0t1B716UcM

Prospect for WHIM detection in the cosmic web by *SRG/eROSITA*
H. Tanimura and N. Aghanim 3400

• **eXTP – Enhanced X-Ray Timing and Polarimetry Mission**
Chairpersons: Marco Feroci and Fangjun Lu
YouTube link: https://youtu.be/3d08eKmsImI

The role of eXTP in the multi-messenger astronomy era
G. Stratta and Gor Oganesyan 3403

• **Observations of HE and UHE Cosmic Rays**
Chairpersons: Ivan De Mitri and Fabio Gargano
YouTube link: https://youtu.be/l9DZyBMWO5c

CALET on the ISS: The first 5 years
Pier Simone Marrocchesi for the CALET Collaboration 3427

The fluxes of charged cosmic rays as measured by the DAMPE satellite
Paolo Bernardini on behalf of the DAMPE Collaboration 3442

Recent results from the Pierre Auger Observatory
E. Roulet for the Pierre Auger Collaboration 3449

The HERD space mission
F.C.T. Barbato on behalf of the HERD Collaboration 3455

PART D

History of Relativity

• **The "Fall and Rise" of Betelgeuse**
Chairperson: Costantino Sigismondi
YouTube link: https://youtu.be/VmbrE2gYmOM

The observation of the stars in daytime and near the horizon
Costantino Sigismondi and Paolo Ochner 3471

Fall and Rise of Betelgeuse: The summary of HR1 session
Costantino Sigismondi and Paolo Ochner 3475

Photometry of Betelgeuse at daylight
Otmar Nickel 3479

Evidence for dynamical changes in Betelgeuse using multi-wavelength data
Sneha Kachhara, Sandip V. George, Ranjeev Misra and G. Ambika 3485

The curious case of Betelgeuse
Jacco Th. van Loon 3494

Variable stars observed from city sites: The 2500 AAVSO-SGQ database
Costantino Sigismondi and Paolo Ochner 3501

Betelgeuse: An introductory course to observational astronomy
Costantino Sigismondi and Tiziana Pompa 3507

The meridian line of the Vatican obelisk to study the stellar aberration
Costantino Sigismondi and Lorenzo Ricciardi 3513

Betelgeuse, Sirius and the stars in the roman *Settecento*
Costantino Sigismondi 3519

• **History of Relativity, Gravitation and Cosmology**
Chairperson: Luis Crispino

YouTube link: https://youtu.be/RNbPUSp95PQ

On Einstein's last bid to keep a stationary cosmology
Salvador Galindo-Uribarri and Jorge L. Cervantes-Cota 3536

Jayme Tiomno: Relativity, gravity, cosmology, and the Marcel Grossmann Meetings
William D. Brewer 3547

A look inside Feynman's route to gravitation
M. Di Mauro, S. Esposito and A. Naddeo 3563

Towards detecting gravitational waves: A contribution by Richard Feynman
M. Di Mauro, S. Esposito and A. Naddeo 3576

Stellar gravitational collapse, singularity formation and theory breakdown
Kiril Maltsev 3596

The Hamilton-Jacobi analysis by Peter Bergmann and Arthur Komar of classical general relativity
D. Salisbury 3626

• Time and Philosophy in Physics
Chairperson: Shokoufe Faraji

YouTube link: https://youtu.be/986v-V5JJEk

The passage of time and top-down causation
Barbara Drossel 3631

Explaining time's passage
Jonathan J. Dickau 3646

A glimpse to Feynman's contributions to the debate on the foundations of quantum mechanics
M. Di Mauro, S. Esposito and A. Naddeo 3657

Summary of the parallel session HR3
Shokoufe Faraji 3671

Neutron Stars

• Dense Matter in Compact Stars
Chairpersons: Alessandro Drago and Jorge Rueda

YouTube links: https://youtu.be/U5Yr0oDVhqY
https://youtu.be/MvMDFh-1_bc

Massive compact stars in the two-families scenario
P. Char, A. Drago and G. Pagliara 3677

Quasi-universality of the magnetic deformation of neutron stars in general relativity and beyond
J. Soldateschi, N. Bucciantini and L. Del Zanna 3684

Screening and elastic properties of the NS crust in the OCP approximation
D. Barba González, C. Albertus Torres and M. A. Pérez-García 3703

Tidal deformability as a probe of dark matter in neutron stars
D. Rafiei Karkevandi, S. Shakeri, V. Sagun and O. Ivanytskyi 3713

Binary neutron star mergers with quark matter equations of state
Atul Kedia, Hee Il Kim, Grant Mathews and In-Saeng Suh 3732

Probing dense matter physics with transiently-accreting neutron stars: The case of source MXB 1659-29
Melissa Mendes, Andrew Cumming, Charles Gale and Farrukh J. Fattoyev 3736

• **Compact Stars as Laboratories for Testing Strong Gravity**
Chairpersons: Aurora Perez Martinez and César Augusto Zen Vasconcellos

YouTube link: https://youtu.be/C1KGecdNEfs

Vacuum properties and astrophysical implications
A. Pérez Martínez, M. Pérez-Garcia, E. Rodríguez Querts and A. Romero Jorge 3756

Testing extended theories of gravity with GRBs
L. Mastrototaro 3762

• **Pulsar Power in Physics and Astrophysics and Pulsars and Pulsar Systems at High Energies**
Chairpersons: Andrea Possenti and Pak-Hin Tam

YouTube links: https://youtu.be/gAG29DZwUbM
https://youtu.be/ytdUBFrViHI

News and views regarding PSR J1757–1854, a highly-relativistic binary pulsar
A. D. Cameron, M. Bailes, V. Balakrishnan et al. 3774

On the origin of the unique isolated X-Ray pulsar 1E 161348-5055 with 6.7 hr. spin period
V. Yu. Kim 3785

Advantages of including globular cluster millisecond pulsars in Pulsar Timing Arrays
M. Maiorano, F. De Paolis, A. A. Nucita and A. Franco 3791

Searching for pulsars in globular clusters with the MeerKAT Radio Telescope
F. Abbate on behalf of the MeerTIME/TRAPUM Collaboration 3799

Precision Tests

• **Gravitational Lensing and Shadows**
Chairpersons: Perlick Volker and Oleg Tsupko

YouTube links: https://youtu.be/6DXXWpMJ3IQ
https://youtu.be/F-K1gXn71_Y
https://youtu.be/B-V8r2HMztw

Gravitational lensing by rotating Simpson–Visser black holes
Sushant G. Ghosh and Shafqat Ul Islam 3812

Killing tensors in foliated spacetimes and photon surfaces
Igor Bogush, Kirill Kobialko and Dmitri Gal'tsov 3827

Decoding black hole metrics from the interferometric pattern of relativistic images
V. Bozza 3839

Symplectic evolution of an observed light bundle
N. Uzun 3844

Shadow of black holes with a plasma environment in 4D Einstein-Gauss-Bonnet gravity
Javier Badía and Ernesto F. Eiroa 3856

Aspects of neutrino mass hierarchy in gravitational lensing
Himanshu Swami 3865

Photon regions in stationary axisymmetric spacetimes and umbilic conditions
K. V. Kobialko and D. V. Gal'tsov 3874

Gravitational lensing by charged accelerating black holes
Torben C. Frost 3885

• Experimental Gravitation
Chairpersons: Angela di Virgilio and Claus Lammerzahl

YouTube link: https://youtu.be/mXcxztQ0nyk
https://youtu.be/tE3gIUBviTc

A manmade experiment aimed to clarify the gravity law in the Solar system
Alexander P. Yefremov and Alexandra A. Vorobyeva 3905

Gravitomagnetic field generation using high permittivity materials in superconducting magnetic energy storage devices
G. V. Stephenson 3910

Large ring laser gyroscopes: Geometry stabilization and laser control
U. Giacomelli, N. Beverini, G. Carelli et al. 3920

Dark gravitomagnetism with LISA and gravitational waves space detectors
A. Tartaglia, M. Bassan, G. Pucacco, V. Ferroni and D. Vetrugno 3929

Light rays in the Solar system experiments: Phases and displacements
Pravin Kumar Dahal and Daniel R. Terno 3942

The Ginger project – preliminary results
C. Altucci, F. Bajardi, A. Basti et al. 3956

• **Variation of the Fundamental Constants, Tests of the Fundamental Symmetries and Probes of the Dark Sector**
Chairpersons: Angela Victor Flambaum and Yevgeny Stadnik

YouTube links: https://youtu.be/NAZA-0tWHak
https://youtu.be/juhDGBJ12Lg
https://youtu.be/zxGgDP2sn60

Varying fundamental constants and dark energy in the ESPRESSO era
C. J. A. P. Martins 3963

• **Dragging is Never Draggy: MAss and CHarge Flows in GR**
Chairperson: Oldrich Semerak

YouTube link: https://youtu.be/ho31IgLNxu8

Testing the general relativistic nature of the Milky Way rotation curve with Gaia DR2
Mariateresa Crosta 3970

Spinning cylinders in general relativity: A canonical form for the Lewis metrics of the Weyl class
L. Filipe O. Costa, José Natário and N. O. Santos 3982

Magnetized black holes: The role of rotation, boost, and accretion in twisting the field lines and accelerating particles
Ondřej Kopáček and Vladimír Karas 3999

Spinning particle: Is Newton-Wigner the only way?
V. Witzany 4010

Gravitomagnetic resonance and gravitational waves
Matteo Luca Ruggiero and Antonello Ortolan 4019

Quantum Gravity

• **Loop Quantum Gravity**
Chairpersons: Marcin Kisielowski and Jerzy Lewandowski

YouTube links: https://youtu.be/VaLPseYWh9E
https://youtu.be/WFIgMqrQ07U

Studying the EPRL spinfoam self-energy
Pietropaolo Frisoni 4026

A spin foam framework for the black-to-white hole transition
Farshid Soltani 4045

Holographic properties of the bulk-to-boundary transmission of information in regions of quantum space
Eugenia Colafranceschi 4062

• **Quantum Gravity Phenomenology**
Chairpersons: Giovanni Amelino-Camelia and Jerzy Kowalski-Glikman

YouTube links: https://youtu.be/vYnVb2zNl0o

The structure of the multiverse from the entanglement entropy
Samuel Barroso Bellido 4082

Effective field theory from relativistic Generalized Uncertainty Principle
Vasil N. Todorinov, Saurya Das and Pasquale Bosso 4088

Stelle gravity as the limit of quantum gravity with maximal momentum
V. Nenmeli, S. Shankaranarayanan, V. Todorinov and S. Das 4107

Baryon asymmetry and minimum length
Saurya Das, Mitja Fridman, Gaetano Lambiase and Elias C. Vagenas . . . 4114

On quantum gravity and quantum gravity phenomenology
Douglas Edmonds, Djordje Minic and Tatsu Takeuchi 4126

WKB approach to the gravity-matter dynamics: A cosmological implementation
G. Maniccia and G. Montani 4146

Natural evidence for fuzzy sphere noncommutative geometry: Super-Chandrasekhar white dwarfs
Surajit Kalita, T. R. Govindarajan and Banibrata Mukhopadhyay 4159

A model of polymer gravitational waves: Theory and some possible observational consequences
Angel Garcia-Chung, James B. Mertens, Saeed Rastgoo, Yaser Tavakoli and Paulo Vargas Moniz 4166

• Loop Quantum Gravity: Cosmology and Black Holes
Chairpersons: Jorge Pullin and Parampreet Singh

YouTube links: https://youtu.be/CAuAK31Ukho
https://youtu.be/JlYnEzRiRR0

Primordial power spectrum from a matter-ekpyrotic scenario in loop quantum cosmology
Bao-Fei Li, Sahil Saini and Parampreet Singh 4178

The primordial power spectra in modified loop quantum cosmology
Bao-Fei Li, Javier Olmedo, Parampreet Singh and Anzhong Wang 4188

Primordial perturbations in kinetically dominated regimes of classical and quantum cosmology
B. Elizaga Navascués, R. Jiménez-Llamas and G. A. Mena Marugán 4193

Revisiting the Hamiltonian formalism of the Ashtekar–Olmedo–Singh black hole model
Alejandro García-Quismondo and Guillermo A. Mena Marugán 4211

A comparison of different choices of clocks in a reduced phase space quantization in loop quantum cosmology with an inflationary potential using effective techniques
Kristina Giesel, Bao-Fei Li and Parampreet Singh 4228

Initial conditions in LQC/mLQCs
Bao-Fei Li, Parampreet Singh and Anzhong Wang 4234

Holonomy corrections in effective midisuperspace models
A. Alonso-Bardaji and D. Brizuela 4239

Infrared signatures of quantum bounce in collapsing geometry
Harkirat Singh Sahota and Kinjalk Lochan 4247

Effective black hole interior and the Raychadhuri equation
Keagan Blanchette, Saurya Das, Samantha Hergott and Saeed Rastgoo . . . 4256

Effect of loop quantization prescriptions on the physics of non-singular gravitational collapse
Kristina Giesel, Bao-Fei Li and Parampreet Singh 4267

Summary of the parallel session QG3
Jorge Pullin and Parampreet Singh 4272

Strong Field

• Strong Electromagnetic and Gravitational Field Physics: From Laboratories to Early Universe

Chairpersons: Sang Pyo Kim and She-Sheng Xue

YouTube links: https://youtu.be/kexqTayqFiU
https://youtu.be/laymGp6x9Hg

Reliable equations of state of viscous strong and electroweak matter
A. Tawfik 4277

Neutral fermion pair production by Sauter-like magnetic step
T. C. Adorno, Zi-Wang He, S. P. Gavrilov and D. M. Gitman 4290

On the magnetic field screening in strong crossed electromagnetic field
S. Campion, J. A. Rueda Hernandez, S.-S. Xue and R. Ruffini 4306

Particle creation by strong fields and quantum anomalies
José Navarro-Salas 4317

Constraints on the non-minimal coupling of electromagnetic fields from astrophysical observations
Susmita Jana and S. Shankaranarayanan 4326

New partial resummation of the QED effective action
Silvia Pla and José Navarro-Salas 4337

Can a detector detect soft photons
Sanved Kolekar and Jorma Louko 4347

Breaking of the adiabatic invariance in the production of particles by strong fields
P. Beltrán-Palau, A. Ferreiro, J. Navarro-Salas and S. Pla 4352

Dynamics of relativistic electrons in non-uniform magnetic fields and its applications in quantum computing and astrophysics
Srishty Aggarwal and Banibrata Mukhopadhyay 4362

Validity of the semiclassical approximation in 1+1 electrodynamics: Numerical solutions to the linear response equation
Ian M. Newsome 4374

On Kerr black hole perfect MHD processes in Doran coordinates
C. Cherubini, S. Filippi, A. Loppini et al. 4387

Tadpole contribution to magnetic photon-graviton conversion
N. Ahmadiniaz, F. Bastianelli, F. Karbstein and C. Schubert 4393

• **The Effects of (Non)Linear Electrodynamics on the Properties of Astrophysical/Gravitational Compact Objects**
Chairperson: Seyed Hossein Hendi

YouTube link: https://youtu.be/SAIAXtQhavE

Correspondence of gamma radiation coming from GRBs and magnetars based on the effects of nonlinear vacuum electrodynamics
Tursynbek Yernazarov, Medeu Abishev and Yerlan Aimuratov 4401

Absorption of massless scalar waves by electrically charged regular black holes
Marco A. A. de Paula, Luiz C. S. Leite and Luís C. B. Crispino 4410

White Dwarfs

• **White Dwarf Explosions**
Chairpersons: Robert Fisher and María Pilar Ruiz Lapuente

YouTube links: https://youtu.be/ndaW6u2xuOo
https://youtu.be/IwjYaQaqJeI

Modeling Type Ia supernovae with explosions in white dwarfs near and below the Chandrasekhar mass
Friedrich K. Röpke, Florian Lach, Sabrina Gronow et al. 4420

Type Ia supernovae and their explosive nucleosynthesis: Constraints on progenitors
Shing-Chi Leung and Ken'ichi Nomoto 4427

Charged polarized white dwarfs with finite temperature as a possible source of type Ia supernovae
Sílvia P. Nunes, José D. V. Arbañil and Manuel Malheiro 4447

• **White Dwarfs, Magnetic Compact Stars and Nuclear Astrophysics**
Chairpersons: Manuel Malheiro and Jaziel Goulart Coelho

YouTube link: https://youtu.be/onicFElJQnA

CTCV J2056-3014 and other fast-spinning white dwarfs
C. V. Rodrigues, R. Lopes de Oliveira, A. Bruch et al. 4453

Gravitational waves from fast-spinning white dwarfs
M. F. Sousa, J. C. N. de Araujo and J. G. Coelho 4461

Highly magnetized white dwarfs: Implications and current status
B. Mukhopadhyay, M. Bhattacharya, A. J. Hackett et al. 4475

Electron captures and stability of white dwarfs
N. Chamel, L. Perot, A. F. Fantina et al. 4488

Massive hot white dwarfs: Consequences of finite temperature in the structure and on the onset of instabilities
Sílvia P. Nunes, José D. V. Arbañil and Manuel Malheiro 4508

Teaching relativity: A paradigm change

F. Herrmann* and M. Pohlig
Institute for Theoretical Solid State Physics, Karlsruhe Institute of Technology (KIT), Karlsruhe, Baden-Württemberg, Germany
**E-mail: f.herrmann@kit.edu*
www.kit.edu

The teaching of relativity usually starts with kinematics: The invariance of the speed of light, clock synchronization, time dilatation and length contraction, the relativity of simultaneity, Lorentz transformation and the Minkowski diagram. The change of the reference frame is a central topic. Only afterwards problems of relativistic dynamics are discussed. Such an approach closely follows the historical development of the Special Theory of Relativity.

We believe that this access to relativity is unnecessarily complicated, and unsuitable for beginners. We present the basics of a teaching approach in which the initial postulate of relativity is the identity of energy and relativistic mass. Reference frame changes are largely avoided.

Keywords: Special relativity, additional postulate, reference frame change, relativistic dynamics.

1. Introduction

Relativity, and we mean for the moment only special relativity, is more than 100 years old, but still has not found its place in school. Just compare: Faraday-Maxwell electromagnetism, which is certainly not simpler than special relativity, would still not be included in the curricula 120 years after its creation, i.e. in 1980. There are several reasons for this deficiency. Here we want to discuss only one of them: Relativity is still taught today as it has originated historically. One starts with a very special relativistic effect, and works through with great effort to the more important and useful general statements. It is as if one enters a splendid palace not by the beautiful main portal, but by some shabby servants' entrance.

We describe the basics of a course on special relativity. The concept has been tested and is used at numerous secondary schools: parts of it already in the lower secondary school, the complete program in the upper secondary school. The course is part of the *Karlsruhe Physics Course*.[1] It can be downloaded from the Internet in various languages. A bilingual English-Chinese version was published recently.[2]

We do not describe the details of this course. We are merely presenting some ideas that underlie its development. Some of the topics we address are also discussed in articles of the column *Historical burdens on physics*.[3]

We justify our paradigm change in Section 2. We choose a different "entrance" to relativity. We substantiate our choice in section 2.1. In sections 2.2 and 2.3 we begin with a critical discussion of two popular topics: the reference frame change,

and the role of the observer. Section 2.4 is about naming. How is the word mass used and how do we want to use it. Section 2.5 deals with the way to write Einstein's famous equation $E = mc^2$. We are thus prepared for our main topic, which will be treated in section 3: relativistic dynamics.

2. Paradigm change

2.1. *Additional postulate of the special theory of relativity*

The laws of the special theory of relativity, or special relativity for short, are obtained from those of classical mechanics by adding one extra postulate. Traditionally and for historical reasons, the choice was made for the invariance of the speed of light upon a change of the reference frame.

Once one has become aware that this choice as a starting point is only one of several possibilities, one discovers that completely new perspectives arise for the development of a teaching concept. We have decided to introduce the mass-energy equivalence as an additional postulate instead of the invariance of the speed of light.

With this choice, we arrive more quickly at that part of special relativity that we consider being the most important one, namely relativistic dynamics.

The traditional choice of the invariance of the speed of light has a rather incidental cause: when special relativity came into being, light was the only known system that behaved relativistically. Einstein's work – both his famous publication of 1905 *Zur Elektrodynamik bewegter Körper*[4] and his textbook *Grundzüge der Relativitätstheorie*[5] – begins with a detailed, and one can say somewhat tiring part on relativistic kinematics.

One might imagine what the course of history would have been if the first relativistic observation had been that a cup of hot coffee is heavier than a cup of cold coffee (or that the corresponding observation had been made with particles in an accelerator). The presentation of the theory of relativity in our textbooks would certainly be very different from what it is actually.

Of course, the mass-energy equivalence is not supported by our everyday experience (neither is the invariance of the speed of light). But one can make it easily plausible and discuss its consequences even in beginners' classes. It leads to surprising and at first unbelievable statements; but it does not lead to the cognitive conflicts one has to deal with in the traditional approach to relativistic kinematics, which questions our basic convictions about space and time.

2.2. *Reference frames and reference frame changes*

In the traditional approach to special relativity, the following topics are dealt with before relativistic dynamics is addressed:

The invariance of the speed of light
Clock synchronization

The relativity of simultaneity
Time dilatation and length contraction
Velocity addition
Lorentz transformation
Minkowski diagram

The problem with such an approach is that one begins with the most confusing part of the theory: the relationship between space and time.

Certainly, students can learn a lot of physics by analyzing the same process in different reference frames. But we should not forget that we are dealing with beginners, and it is better to stick to the old rule: Choose a suitable reference frame right at the beginning, i.e. a reference frame in which the description of your problem becomes as simple as possible, and don't change it anymore.

And above all, don't change the reference frame in the middle of dealing with your problem (as is usually done when discussing the twin paradox). By the way, in classical mechanics and electromagnetism, too, one can create the greatest confusion if one chooses the reference frame improperly or if one changes it in the middle of the discussion.

This is why our decision was not to make reference frame changes the main topic of our lessons and to avoid them as far as possible. Above all, the impression should not be created that special relativity is essentially a theory of reference frame changes – an impression that some presentations certainly arouse. Even the name relativity gives that impression.

2.3. *The observer*

Closely related to the question of the choice of the reference frame is the problem of the so-called observer. The observer seems to be particularly important in two areas of physics: in quantum physics (where the observer always appears as the one making a "measurement") and in the theory of relativity.

An observation is always made from a certain perspective. It thereby emphasizes something that does not play a particular role in the phenomenon to be described.

We believe the observation should not be in the foreground as long as the understanding of a process is the objective. This is especially true when teaching at school, i.e. beginners.

It is true that we get all the information about the world by observing and measuring. But the idea we form of the world is quite different from what we observe. So, if we wanted to explain the shape of the earth to someone, we would certainly not start with the shadow of the obelisk in Alexandria, but simply say: The earth is a sphere.

In our opinion when teaching physics we should primarily give a picture of what nature is like – not how it is perceived by an observer.

2.4. *The use of the term mass*

Mass is a physical quantity that until not so long ago did not cause any problems. It was known for which properties it is a measure.

With Einstein's special theory of relativity, this only changed insofar as the mass of a body became dependent on its velocity, temperature and other variables. It was no longer a quantity that had a characteristic value for a body or a particle.

Thus, a body, a particle, a field, or any other structure, has a mass that depends, among other things, on its velocity. The value that the mass assumes when the centre of mass of the particle or body is at rest is called its rest mass (symbol m_0). Even more appropriate would actually be the less common term *proper mass*, because when the centre of mass is at rest, this does not mean that the parts or particles of the system are at rest.

It is that simple, or, unfortunately, one must say: it could be that simple.

For there is an area of physics in which another use of the term mass has established itself: Particle physics. A particle has a well-defined rest mass. The rest mass is characteristic of the particle species. Among the various other parameters, such as electric charge, spin, lepton number, etc., it is considered the main characteristic. It seems to constitute the identity of the particle. For this property, a compact, plausible name was needed, and particle physicists simply called it mass. Thus, in particle physics, the term mass refers to only part of the quantity that describes the inertia of a particle.

However, this custom also spread beyond particle physics, and this results in several misunderstandings and ambiguities. What is to be understood by the mass of a macroscopic body that is at rest? Is it the mass that would be measured with a (very accurate) scale, or is it the sum of the (rest) masses of the particles that constitute the body? This is a question that particle physicists probably don't ask, but we teachers do.

We have therefore decided to use the term mass (symbol m) exclusively for the quantity that measures gravity and inertia, no matter what kind of object is considered and in what state it is. Thus, a hot cup of coffee has a larger mass than the same coffee when it is cold. A photon has a mass and a magnetic field has a mass (a liter of magnetic field near a neutron star has a mass of some hundred grams).

By the way, if one follows this use of the term mass, it makes no sense to say that mass is a "form of energy" or that mass can be converted into energy.

2.5. *The identity of mass and energy*

First, let us look at the term *mass-energy equivalence*. It is a pity that a simple fact is expressed so unclearly. The word equivalence is certainly not wrong, but why not say directly: Mass and energy are the same physical quantity.

If one were to ask someone who has never seen the equation $E = mc^2$ to express this fact in a formula, he would probably write something like this:

$$E = k \cdot m \ . \tag{1}$$

The factor k tells us how the units joule and kilogram are converted into each other. As the definitions of the units kilogram and joule are independent of the choice of the reference frame, k is a universal constant.

Its value is obtained by a measurement. One finds

$$k = 9 \cdot 10^{16} \mathrm{J/kg} \ . \tag{2}$$

But what is wrong with writing

$$E = mc^2 \ ? \tag{3}$$

Every student learns in mathematics that a linear relationship between the variables x and y is written as

$$y = a \cdot x \ . \tag{4}$$

On the right side first the factor of proportionality a, and second the independent variable. The unbiased student might interpret the famous equation (3) this way: The energy is proportional to the square of the speed of light – and not: energy and mass are the same physical quantity. One might object: This can easily be explained to the students. Of course it can. But doesn't the statement become clearer if one writes $E = k \cdot m$? Would the iconic character of equation (3) survive if it were formulated in this way?

3. The laws of dynamics

In the *Karlsruhe Physics Course*[1], the extensive quantities energy, momentum, electric charge and entropy are introduced as basic quantities. Especially momentum and entropy have a very direct and vivid interpretation. Momentum is a measure of the "amount of motion", that is, what one would colloquially call "impetus" or "drive". Entropy measures almost perfectly what would colloquially be called the amount of heat (not to be confused with the rather difficult concept of heat that has established itself in physics).

Therefore, in the context of relativity, it is natural to ask in the first place for the dependence of different quantities on momentum. Momentum is our independent variable. We give momentum to a body or particle and ask how it reacts to it: How does its mass (= energy) behave? What happens to its velocity? In other words: We ask for the functions $E(p)$ and $v(p)$.

3.1. *The energy momentum relationship*

To derive $E(p)$, we take over as much as possible from non-relativistic physics. In addition, we only require the identity of mass and energy, i.e. we assume the

validity of equation (1). We start with the change dE of the energy, that results from a change of the momentum dp.

$$\mathrm{d}E = v\mathrm{d}p \ . \tag{5}$$

With $p = m \cdot v$ we obtain

$$\mathrm{d}E = \frac{p}{m}\mathrm{d}p \ . \tag{6}$$

Replacing m with E/k, and reordering returns

$$E\mathrm{d}E = kp\mathrm{d}p \ . \tag{7}$$

We thus obtain

$$\mathrm{d}E^2 = k\mathrm{d}p^2 \tag{8}$$

and

$$E^2 = kp^2 + C \ , \tag{9}$$

where C is the constant of integration.

The value of C can easily be determined, because for $p = 0$ the energy E assumes the value of the rest energy E_0. Thus, C must be equal to ${E_0}^2$. We therefore get

$$E^2 = {E_0}^2 + kp^2 \tag{10}$$

and for the sought-after relationship between energy and momentum we get:

$$E(p) = \sqrt{{E_0}^2 + kp^2} \ . \tag{11}$$

The red line in Figure 1 shows the graphic representation of relation (11). Two limiting cases are of particular interest.

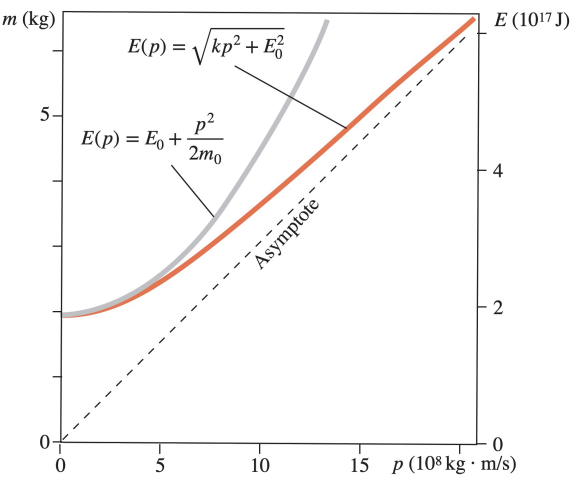

Fig. 1. Relationship between mass/energy and momentum (red line). For large values of the momentum the curve approaches the asymptote (dashed line), for small values the classical quadratic relation (grey line).

For small momentum values, equation (11) changes to

$$E(p) = E_0 + \frac{kp^2}{2E_0} = E_0 + \frac{p^2}{2m_0} \ . \tag{12}$$

We obtain the classical kinetic energy, increased by the rest energy (grey line in Figure 1).

If the momentum is very large, so that ${E_0}^2$ can be neglected in comparison with kp^2, equation (11) turns into

$$E(p) = \sqrt{k}p \ , \tag{13}$$

see the dashed line in Figure 1. For bodies whose rest mass is 0 kg, equation (13) applies for all values of the momentum, not only for large values (Figure 2). Thus, in the highly relativistic limiting case, energy and momentum are proportional to each other. This shows that there is a similarity between these quantities, which becomes even clearer when we solve equation (11) according to ${E_0}^2$

$${E_0}^2 = E^2 - kp^2 \ . \tag{14}$$

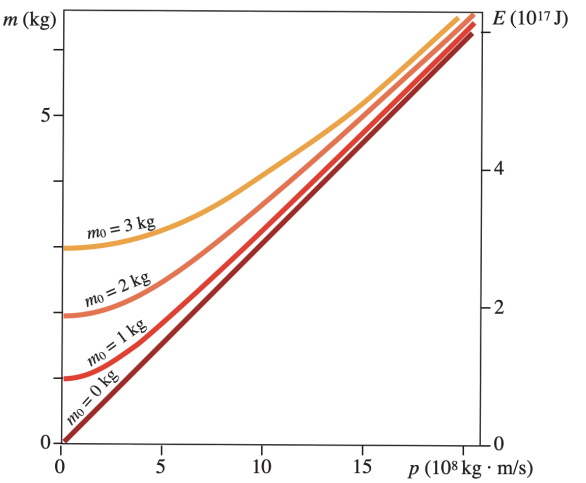

Fig. 2. Energy momentum relationship for four different rest masses. For photons (rest mass zero) the relation is linear.

We thus have the rule: If the momentum of a body changes, its energy changes in such a way that the difference $E^2 - kp^2$ retains its value. This value is the square of the rest energy E_0.

3.2. *The velocity momentum relationship*

Now our second question: How does the velocity of a body depend on its momentum? We solve $p = mv$ for v, then apply equations (1) and (11) and obtain

$$v(p) = \frac{p}{m} = \frac{kp}{E} = \frac{kp}{\sqrt{{E_0}^2 + kp^2}} \,. \tag{15}$$

If we replace the rest energy with the rest mass we get

$$v(p) = \frac{kp}{\sqrt{k^2{m_0}^2 + kp^2}} \,. \tag{16}$$

Figure 3 shows the dependence of the velocity on the momentum for different rest-masses. From equation (16) follows that the velocity of a body approaches a terminal value as the momentum increases. It is

$$\lim_{p\to\infty} v(p) = \lim_{p\to\infty} \frac{kp}{\sqrt{k^2{m_0}^2 + kp^2}} = \sqrt{k} \,. \tag{17}$$

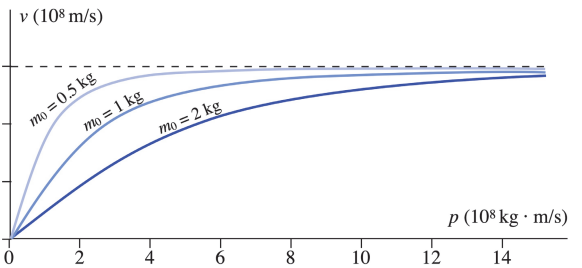

Fig. 3. Dependence of the velocity on the momentum for different rest masses.

Up to now, k only played the role of a conversion factor, but now it gets a physical meaning. Its value is the square of the terminal speed. Since k is a universal constant, its square root, i.e. the terminal speed, is also a universal constant. The terminal speed is the same for all bodies and particles and is independent of the reference frame.

This can be seen in Figure 3. The diagram also shows: the smaller the rest mass of a body is, the "faster" it approaches the terminal speed.

Let us come back to equation (16). We see: If one supplies momentum to a body, its velocity initially increases linearly with the momentum, while its mass almost does not change. This is the Newtonian limiting case. When its momentum has become very large, its velocity no longer changes, but its mass increases.

But what is the value of k and thus the value of the terminal speed? So far, nothing has been said about it. The answer to this question can only be obtained by a measurement. There are several ways to do that: Either one increases the momentum of a particle until its velocity no longer changes (in a particle accelerator)

and then measures its velocity, or one measures the velocity of photons, i.e. particles of rest mass zero. Photons always move with the terminal speed.

Because of the great importance of the terminal speed, one gives it its own symbol

$$c := \sqrt{k} \ . \tag{18}$$

The measurement results in

$$c = 3 \cdot 10^8 \mathrm{m/s} \tag{19}$$

and therefore

$$k = 9 \cdot 10^{16} \mathrm{J/kg} \ . \tag{20}$$

The constant c is also called speed of light. But our derivation shows that light does not play a particular role in special relativity. That is why we prefer to call c terminal speed.

3.3. *Mass and inertia*

From classical physics we are used to consider mass as a measure of inertia. Let us first clarify what is meaningfully understood by inertia.

To determine the inertia of an object, we supply a certain amount of momentum to the object and we look at the resulting change in velocity. The more momentum $\mathrm{d}p$ is needed to achieve a desired change in velocity $\mathrm{d}v$, the greater the inertia.

Therefore we can define the inertia as

$$T := \frac{\mathrm{d}p}{\mathrm{d}v} \ . \tag{21}$$

We first consider a classical motion, i.e. a motion with $v \ll c$. We know the $p - v$ relationship to be

$$p = m \cdot v \ . \tag{22}$$

This results in

$$T = m \ , \tag{23}$$

which is no surprise.

If however the movement is relativistic, i.e. if no longer $v \ll c$, things become more complicated. From equation (15) we obtain

$$p(v) = \frac{m_0 v}{\sqrt{1 - \frac{v^2}{c^2}}} \tag{24}$$

and

$$T(v) = \frac{\mathrm{d}p}{\mathrm{d}v} = \frac{m_0}{\left(1 - \frac{v^2}{c^2}\right)^{\frac{3}{2}}} \ . \tag{25}$$

The inertia now depends on the velocity. It can no longer be described by a single number. By the way, it is also not identical with the so-called relativistic mass.

We know a similar behavior from other contexts. The current-voltage relationship of an ohmic resistor can be characterized by a single number, its resistance. In general, however, the resistive behavior of an electrical component cannot be characterized by a single number. What we need is the $U - I$ characteristic. The situation is like that of inertia. In general, one cannot say that the mass is a measure for the inertia of a body. Rather, the inertial behavior of a body is characterized by a characteristic curve, equation (25). Sometimes the quantity defined by equation (25) is called the longitudinal mass. We think this is rather clumsy. The simple facts are thereby somewhat obscured.

4. Conclusion

The development of a teaching concept for the school, in our case for the secondary school, is a balancing act.

On one hand, teaching at school differs fundamentally from popular science presentations. The latter can limit themselves to showcasing the spectacular, the impressive and the surprising of the scientific results – one can almost say: to exhibit them like objects in a museum.

School teaching has to meet other requirements. The statements must be logically coherent. They have to fit into the previous teaching and form a foundation for the future teaching, for example, at the university.

On the other hand, we must make sure that we do not treat high-school students like university students, that we do not overburden them. Let us not forget: One can calculate and prove without generating understanding.

It should also be borne in mind that most high school students a priori have no particular interest in physics.

We have tried to develop a course under these constraints. We would like to emphasize once again that the above remarks do not represent the content of our course. We have presented only what we believe is different in our approach from that of other textbooks.

Teaching relativity: Computer-aided modeling

F. Herrmann and M. Pohlig*
Institute for Theoretical Solid State Physics, Karlsruhe Institute of Technology (KIT), Karlsruhe, Baden-Württemberg, Germany
**E-mail: pohlig@kit.edu*
www.kit.edu

Mathematical derivations alone do not necessarily lead to physical understanding. Tools that can replace the mathematical treatment of a physical process and at the same time increase the physical understanding are computer-aided modeling programs, also called system dynamics software. Examples of such software are Stella, Berkeley Madonna, Wensim, Dynasys, Powersim or COACH 7. They solve differential equations and systems of differential equations with numerical methods. One works with a graphical user interface. We want to show how such a software can be used to get from a non-relativistic model to a relativistic model with only minimal modifications. Equating mass and energy alone, ensures that the model provides essential statements of relativistic dynamics: the existence of a terminal velocity for all physical motions, the relativistic dependence of the velocity of a body on its momentum, the relativistic relation between momentum and energy of a body.

Keywords: Teaching relativity, computer-aided modeling, system dynamic software, Coach 7.

1. Introduction

There are two reasons why learning relativity is difficult. First, there is a widespread belief that relativity is essentially a physics of reference frame changes. Second, mathematics, which seems to be indispensable for a first approach to relativity according to common usage, is a major, even often insurmountable, hurdle for many students. Therefore, the structure of our course follows two didactic recommendations: 1. avoid reference frame changes 2. reduce the use of mathematics to the most necessary. We fulfill the first recommendation by teaching dynamics before kinematics. Instead of postulating that the speed of light is invariant under reference frame changes, we declare from the very beginning that energy and mass are the same physical quantity. We call it energy when its value is measured in joules and mass when measured in kilograms. The second recommendation can be fulfilled if we use a suitable modeling software, a so-called system dynamics software (SDS). In a SDS, physical quantities and their relations are described by graphical symbols and are intuitively understandable. Since its usage is self-explanatory to a large extent, we do not need to go into details of the handling here.

As a representative of such a software we use COACH 7.[1]

2. Teaching relativity using a system dynamics software

2.1. *Momentum flow into a body*

We create a model for a body which is accelerated from rest. Its momentum, which is zero at the beginning, increases as a constant momentum current flows into it (as a force is exerted on it). In a first step we treat this model non-relativistically. In the second step, the model is transformed into a relativistic model by a small modification.

In a SDS model, momentum p and other substance-like (extensive) quantities such as electric charge Q, energy E, or entropy S are represented by boxes. All these quantities change their values by an inflow or an outflow. (Entropy can also change its value by being produced). In the model, these currents are represented by thick arrows, Figure 1. Since in our lessons momentum is not introduced as a derived quantity, it gets its own unit of measurement, the Huygens, abbreviated Hy. The unit of its current is Huygens per second (Hy/s). The unit Hy is SI-compatible. We thus have 1Hy/s = 1 N.

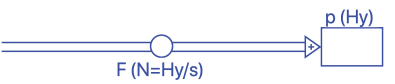

Fig. 1. A temporally constant momentum current F leads to a linear increase of the momentum p.

Since the body is accelerated from rest, its momentum at the beginning of its motion is 0 Hy. We assume the momentum current to be constant in time, we set e.g. $F = 1$ N. When the model is started, the simulation begins running and the actual momentum is calculated for previously defined time steps.

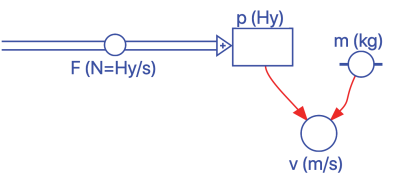

Fig. 2. The velocity is calculated from momentum and mass.

In order for our model to be able to tell us something about the velocity of the body, we must add the mass m of the body to the model, in Figure 2 represented by a circle. We choose $m = 1$ kg for a first simulation and $m = 2$ kg for the second one. The velocity is calculated using $v = p/m$. This relationship is stored in circular symbol for the velocity v. Thin, red arrows are pointing from the symbols for p and m to the symbol of v. This ensures that the actual values of p and m are available

for the calculation of v at any instant of time during the simulation. In concrete terms, this means that while the simulation is running, the momentum is divided by the mass at fixed time steps, and thus the actual velocity v is calculated.

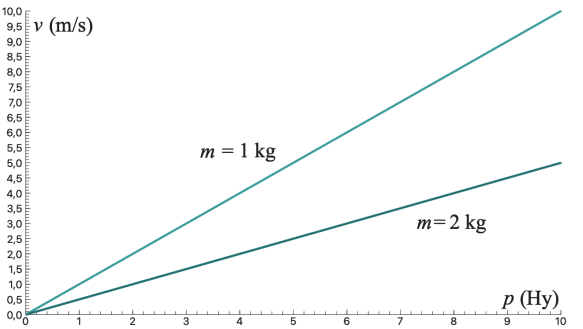

Fig. 3. $v - p$ diagrams or bodies of masses 1kg and 2 kg.

The dependencies of the various variables occurring in the model can be displayed graphically in output windows. Figure 3 shows the v-p diagrams for two bodies of masses 1 kg and 2 kg.

2.2. *Together with momentum energy is flowing into the body*

We now add the kinetic energy of the body to our model, Figure 4.

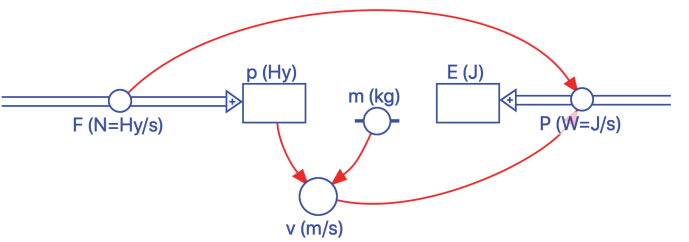

Fig. 4. The energy current P into the body is calculated from the velocity v of the body and the momentum current F (force).

Also the energy E is represented by a box. Since the body is accelerated from rest, not only the momentum but also the kinetic energy must have the initial value $E_{\text{int}} = 0$. Like the momentum current, the energy current (power) into the body is represented by a thick arrow. It can be calculated as $P = vF$. The software provides the energy-momentum diagrams for $m = 1$ kg and $m = 2$ kg, Figure 5.

These graphs could be described by the formula

$$E_{\text{kin}} = \frac{p^2}{2m} \,. \tag{1}$$

However, this equation has not been used by the SDS.

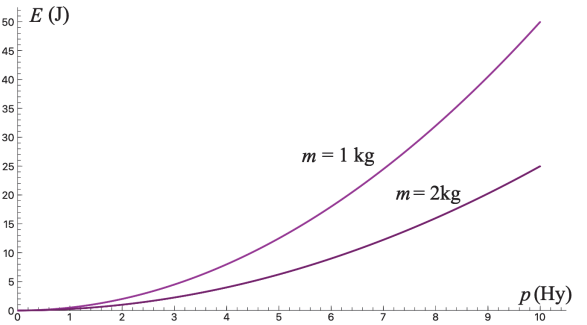

Fig. 5. $E - p$ diagrams generated with the SDS for $m = 1$ kg and $m = 2$ kg.

2.3. *From the classical to the relativistic model*

The two models described up to now serve as basic models for others, such as for "free fall in the gravitational field of the earth", for "falling with friction" and others.

If momentum is replaced by other substance-like quantities such as electric charge or entropy, analogous models are obtained from electricity and thermodynamics, respectively. In this way, students learn to use the modeling software as a tool in other subfields of physics. So when they create relativistic models, they are already familiar with the tool. We now want to create a relativistic model by modifying our non-relativistic model appropriately, Figure 4. For this purpose, only a small modification has to be made. The mass, which was originally a constant,

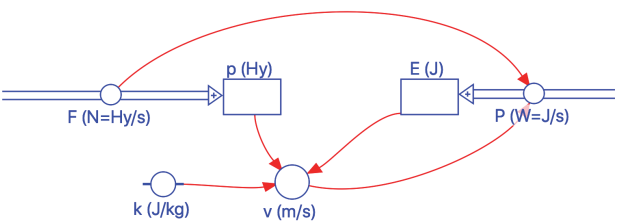

Fig. 6. Relativistic model: The constant mass is replaced by the total energy of the body.

is now identified with the energy[2] according to

$$E = k \cdot m \tag{2}$$

Here, the energy is no longer the kinetic energy but the total energy of the body. Figure 6 shows the modified model. The initial value of the energy is no longer 0 J, but it is equal to the value of the energy that the body has at rest. We choose $E_{\text{int}} = 10$ J and for another simulation $E_{\text{int}} = 5$ J. To transform the unit kilograms into joules, we have to multiply the mass by k. We first set its value arbitrarily to $k = 16$ J/kg. The actual true value of k will be discussed later. The velocity of the body is now calculated according to

$$v = \frac{p}{m} = \frac{kp}{E} \ . \tag{3}$$

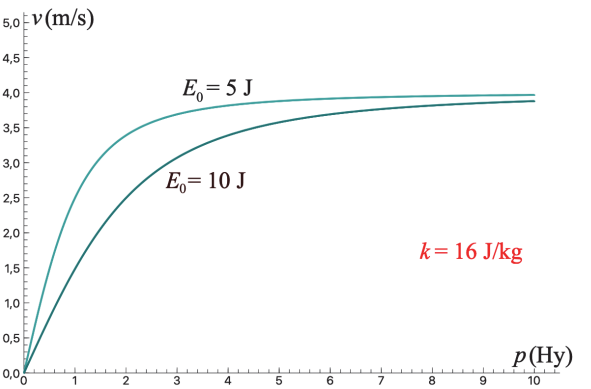

Fig. 7. $v - p$ diagrams obtained with the relativistic model.

As Figure 7 shows, the v-p diagrams are different from those in Figure 3. It can be seen that the velocities of both bodies approach a common terminal velocity of 4 m/s. One "plays" with further, freely chosen values for the rest energy and always finds the same terminal velocity. Furthermore, the v-p diagrams show that light bodies reach the terminal velocity quicker than heavy ones. Finally, one recognizes that for sufficiently small momentum values the velocity of a body increases linearly with momentum. This confirms what is already known from non-relativistic mechanics.

The diagrams are graphs of the relation

$$v(p) = \frac{p}{m} = \frac{kp}{E} = \frac{kp}{\sqrt{{E_0}^2 + kp^2}} \ . \tag{4}$$

However, we don't need to know this equation, or to derive it, in order to be able to read the important properties of this relationship from the diagrams.

The diagrams show that for relativistic motions the following rules hold:

- small momentum values: $v \sim p$
- large momentum values: $v = \sqrt{k}$

By choosing other initial values for the energy and other values for k, one easily gets convinced of the generality of these rules. For the diagrams in Figure 8, the values 9 J/kg, 16 J/kg and 25 J/kg were selected for k. The terminal velocity results to be 3 m/s, 4 m/s and 5 m/s, respectively.

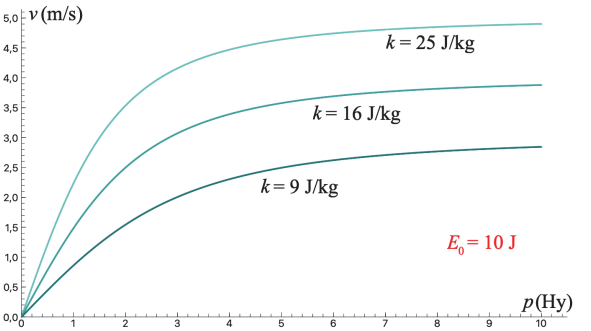

Fig. 8. $v - p$ diagrams for different k values.

We see that the value of the terminal velocity is just the square root of k. While k used to be merely a conversion factor between kilogram and joule, it now acquires a physical meaning. Moreover, from the fact that a conversion factor for units is universal, the terminal velocity also has a universal value. It must be a universal constant. For this reason, we give the square root of k, i.e. the terminal velocity, a symbol of its own, namely

$$c := \sqrt{k} \tag{5}$$

Up to now, we had chosen the value of k and thus also that of c arbitrarily. But which value has nature given to k resp. c? Experiments show that $k = 9 \cdot 10^{16}$ J/kg and therefore $\sqrt{k} = c = 3 \cdot 10^8$ m/s.

Another relationship that our model provides in the form of a diagram is that between energy and momentum, Figure 9. The diagrams shown are graphs of the equation:

$$E(p) = \sqrt{{E_0}^2 + kp^2} = \sqrt{{E_0}^2 + c^2 p^2} \tag{6}$$

For small momentum values we get the non-relativistic relation between kinetic energy and momentum, shifted by the rest energy of the body:

$$E(p) = \frac{p^2}{2m} + E_0 \tag{7}$$

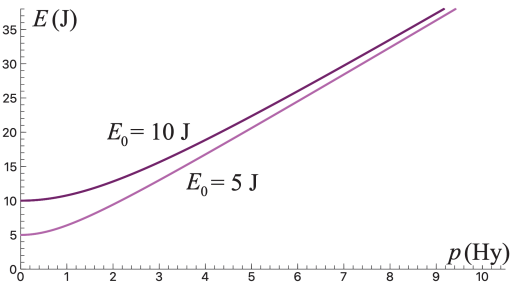

Fig. 9. $E - p$ relation in the relativistic model. The rest energy was set to 5 J and in the second run to 10 J.

Moreover, we see that the ratio of energy and momentum is the same for large values of the momentum.

$$E(p) = \sqrt{k} \cdot p = c \cdot p \tag{8}$$

3. Conclusion

A non-relativistic SDS model which describes the behavior of a body whose momentum increases linearly, i.e. into which a constant momentum current is flowing, becomes a relativistic model by a small modification. The change consists in equating the quantities mass and energy. The new model then provides diagrams that are well-known from relativistic physics. The software provides them without using the respective equations. From these diagrams, important results of relativity can be interpreted and understood. The use of computer-aided modeling in teaching has the advantage of getting rid of the mathematical ballast and that one can concentrate on the physical content. Our experience shows that even younger students can easily learn a software like COACH 7 and use it to work out challenging results in relativistic dynamics.

Solstices and Equinoxes in 1703 at the meridian line of St. Maria degli Angeli in Rome, and the stellar aberration of Sirius

Costantino Sigismondi

The 1703 was the first year of full operation of the meridian line in the Basilica of St. Maria degli Angeli in Rome. The instants of solstices and equinoxes, the *Anni Cardines*, obtained by comparing transit timings of Sun and Sirius, also in daytime, are affected either by the East deviation of the meridian line of about 5' Eastward (geometrical effect), either by the stellar aberration of Sirius (relativistic effect). Similarly the seasonal shifts of Sirius' declination observed by Bianchini are here firstly recognized as depending on the stellar aberration in ecliptic latitude. The eccentricity of the Earth's orbit and the orientation of its axis in the space can be measured, since Ptolemy, by knowing the exact timing of the solstices and the equinoxes. The dates of 1703 equinoxes and solstices have been published by Francesco Bianchini in local roman mean time, referred to the local (roman) mean noon, i.e. after the solar meridian mean transit time. By using the observations of the three lunar eclipses of 1703 we found the equation of time for that year, and the UTC corresponding timings of the beginning of the seasons. This operation lead to find the contribution of the Sirius aberration to the instant calculated by Bianchini with respect to the current celestial mechanical models of IMCCE.

Keywords: St. Maria degli Angeli, Meridian Line, Stellar Aberration, Sirius, 1703, Solstices, Equinoxes, Ecliptic Longitude, UTC, UT1, TDT, TT, Roman mean time.

1. Stellar aberration measures in 1701 before Bradley's discovery

The stellar aberration was discovered by James Bradley in 1727, and the same astronomer discovered the nutation of the Earth's axis in 1737. At the meridian line of St. Maria degli Angeli, the giant Clementine Gnomon, built by astronomer Francesco Bianchini (1662-1729) and funded by the Cardinal Gianfrancesco Albani (1649-1721), elected pope on 23 November 1700 with the name of Clement XI.

The effects of stellar aberration have been detected on the Polaris (2006), and on Sirius (2021, present work).

The aberration of the Polaris influenced the measure of the latitude of the pinhole, the gnomon of the meridian line, made by Bianchini on January 1-8, 1701.

The aberration on Sirius affected the instant of the equinoxes and the solstices, calculated with the difference between solar and stellar meridian transit, the latter observed also in full daylight. To obtain such evidence of the first special relativistic effect observable, a complete calibration of the meridian line has been carried since 2018. With the IGEA observational campaign, Informatized Geometric Ephemerides for Astrometry: all the reference points present of the 45 meters long meridian line have been calibrated, by comparing solar observations and ephemerides.

At the Marcel Grossmann Meeting XI (Berlin, 2006) the evidences of Polaris' aberration were discovered in the latitude, from the measures by Bianchini at the Gnomon, and now at the Marcel Grossmann XVI edition we can afford the evidences on Sirius' stellar aberration with the increased precision on the calibration of this giant instrument, the second *Heliometer*, or solar telescope, of its times, after the one of Cassini in St. Petronio, Bologna.

2. Managing dates and timing of 1703, in local mean time

The equation of time shifts the instants of the meridian transit day by day with respect to an absolute time reference such as UTC. The eclipses' ephemerides are based upon the terrestrial dynamical time TDT, while the terrestrial rotational time UT1 includes the slowing down effect of the Earth's rotation in act since 1700. To translate 1703 local time to modern UTC to the nearest second we exploited the observations of the three lunar eclipses occurred in 1703, all made by Bianchini. The equation of time of that year come out from the comparison between the observed instants of eclipse's beginning and end -in local mean time- and the corresponding instants in TDT computed by the NASA ephemerides.

3. The dates and timing for 1703 lunar eclipses from NASA ephemerides

The three lunar eclipses of 1703 have been observed by Francesco Bianchini and published in the same book (Bianchini, 1703) where the great meridian line, the *Clementine Gnomon* was presented. The instants of beginning and end of lunar eclipses are independent of the position of the observers on the Earth, and they can be calculated with a suitable celestial mechanical model of the lunar orbit (provided by NASA). They occurred very close to the solstices, making the procedure of their absolute timing (expressed in TDT and then in UTC) particularly accurate.

The maximum phase of the eclipse is indicated in TD, terrestrial dynamical time to the nearest minute in the figures, and to second accuracy in the website. The maximum of the eclipse is recovered in local time after doing the average between starting time and ending time of the eclipse, to the nearest second. In the details of the *Canon of five millennia of lunar eclipses*, also the starting time and the ending time of the eclipses are provided. The eclipses have been observed by Bianchini at the telescope, improving the accuracy of the measurements.

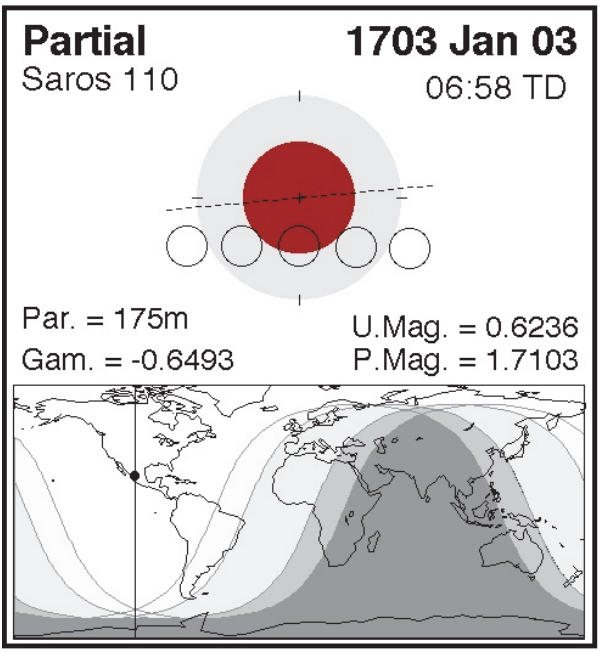

Fig. 1. The lunar eclipse of January 3^{rd} 1703

4. Solstices and equinoxes and the equation of time in the ephemerides

The dynamical model for the Earth's orbit includes the perturbations of all planets, and they are implemented in the most advanced ephemerides. IMCCE provides an online service back to 4000 B. C. for the dates of the astronomical beginning of the seasons. The comparison with the corresponding instant of 1703 as calculated by Bianchini required a conversion into UTC of the local timings. It is available online a service, *Planetcalc*, with the equations of time, from 500 B. C.

We need a self-consistent derivation of the UTC timing of the equinoxes and the solstices in 1703, being the Equation of Time itself depending on the Earth's orbit eccentricity, which is derived from the the observed beginning of the seasons, namely the equinoxes and solstices.

The obliquity component goes to zero four times per year at the equinoxes and the solstices, while the eccentricity component vanishes twice per year at the apsides (aphelion and perihelion). This is well shown in *Planetcalc* website.

5. Synchronization of the equation of time with lunar eclipses in 1703

The dates of the apsides (as shown in Sigismondi and Pietroni, 2019) and the obliquity of the year are used to compute the equation of time for that year,

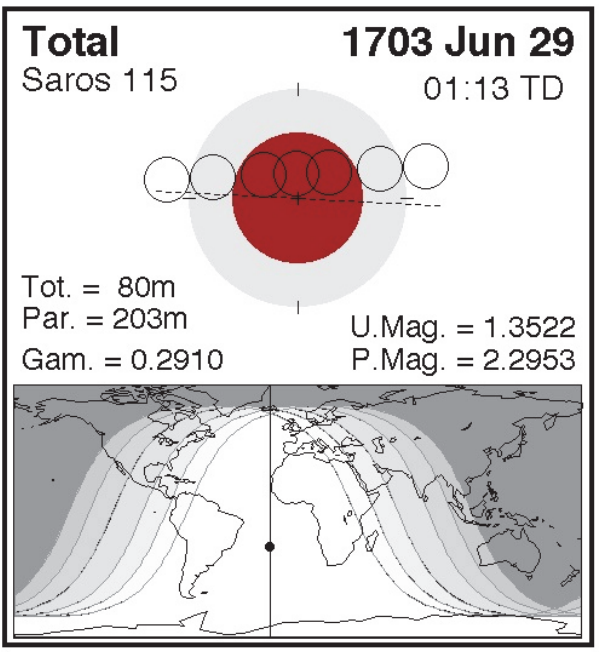

Fig. 2. The lunar eclipse of June 29^{th} 1703

but an independent synchronization with UTC is needed, to verify the IMCCE ephemerides, and the lunar eclipses were used exactly to assure that synchronization. On June 22^{nd} 1703 the equation of time of Planetcalc is -1.11 minutes, and in 28^{th} June, last solar transit before the lunar eclipse, it is -2.38 minutes. It means that this local noon should occur 2 m 22 s before a mean solar noon fixed (e.g. CET Central European Time). For Rome the mean noon is at 12:10 CET, then 12:12:22 the transit time for 28^{th} June, 1703. The eclipse was computed as maximum at 1:13 TD on 29^{th} June, so 2:13 CET. Bianchini's beginning of totality is at 13:18:15 after solar meridian transit of 28^{th} June, and the end (emersion) is 14:38:15. The middle of totality (maximum phase) is at 13:28:15, obtained by averaging. The solar transit in the same publication occurred at 12:07:36 so that the eclipse's maximum was at 02:05:51. The terrestrial dynamical time for the eclipse has been computed (Espenak and Meeus, 2009) on 02:12:47 (1:13 TD in figure 1). The TD, is ahead with respect to Bianchini's roman mean time of 6 min 56 s.

6. Including $\Delta UT1$ in the final timing

The procedure shown in detail for June 29^{th} has been applied to the other eclipses of 1703, that Bianchini observed also with Filippo Maraldi (January 3^{rd}) and alone (December 23^{rd}), recovering the Roman average time adopted by Bianchini for his observations, with respect to the Terrestrial Dynamical Time. The adopted value

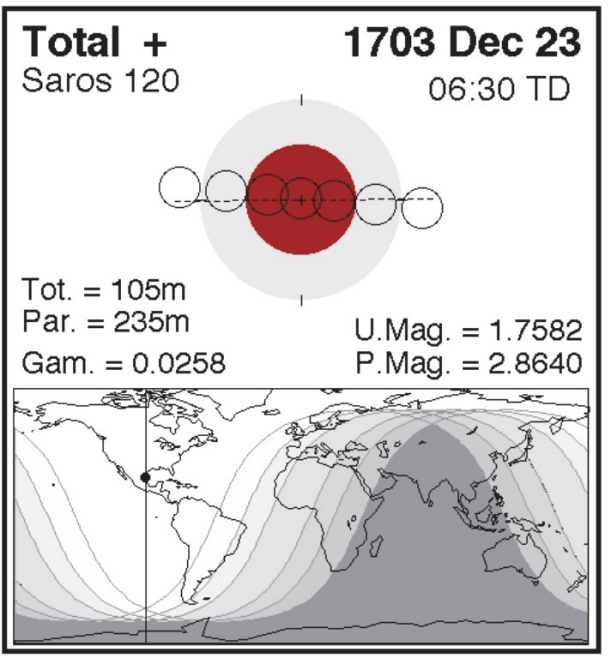

Fig. 3. The lunar eclipse of December 23^{rd} 1703

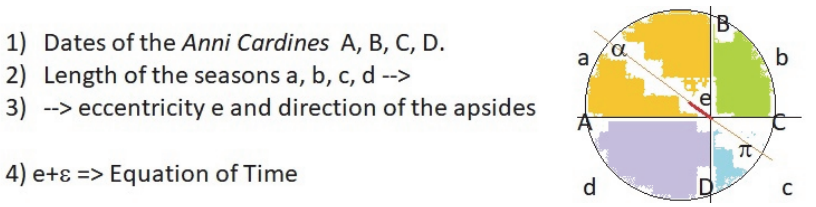

Fig. 4. The connection between the beginning of seasons' times and the eccentricity, and the equation of time. Aphelion α and perihelion π, the apsides, are also sketched.

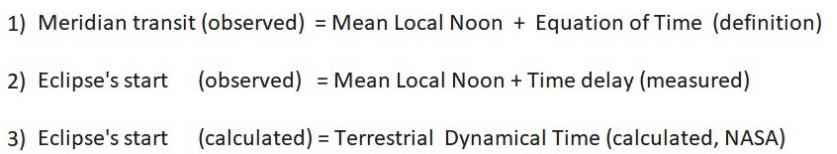

Fig. 5. The relations existing between Mean Noon, Equation of time, solar transit time and terrestrial dynamical time TD.

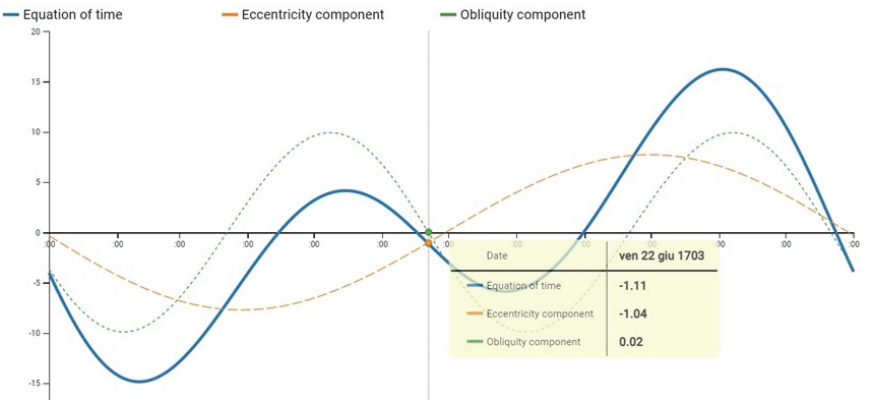

Fig. 6. The equation of time for 1703, as computed with Planetcalc.

for ΔUT1, of 7-8 seconds for the 1703, and due to the de-rotation effect of the Earth upon continental uplift after the ice age, is added to TD to obtain the coordinate universal time UTC for these observations, and for the dates and timing of solstices and equinoxes in 1703. These instants of seasons' beginning dates have been used for studying the aberration effect on the solstices and equinoxes in 1703 at the meridian line of St. Maria degli Angeli in Rome, demonstrating that Sirius' aberration and the deviation from Celestial North of the meridian line have caused the departure from IMCCE calculated times for 1703 seasons' starts (Sigismondi, 2021).

7. The dates and timing for 1703 *anni cardines*

Bianchini used the term *Anni Cardines* for the solstices and the equinoxes, because they are related to:

- Inclination of the Earth's axis on the ecliptic plane (the plane of the orbit), called *obliquity*;
- Position of the apsides in the Earth's orbit, which determines the *eccentricity*.

They were published in the book *De Nummo et Gnomone Clementino* of 1703, as well as on a marble epigraph in the presbytherium.

These instants are expressed in mean local time, after/before the mean meridian transit or midnight (anti-)transit. So to recover their instants as expressed in UTC it was necessary to recover three lunar eclipses observed in the same year and published by Bianchini in the same book (Bianchini, 1703): January 3, June 29 and December 23 (see below). After this operation of synchronization, we made the comparison with the IMCCE ephemerides for 1703.

Fig. 7. The epigraph of 1703 *Anni Cardines* in the presbytherium of St. Maria degli Angeli in Rome.

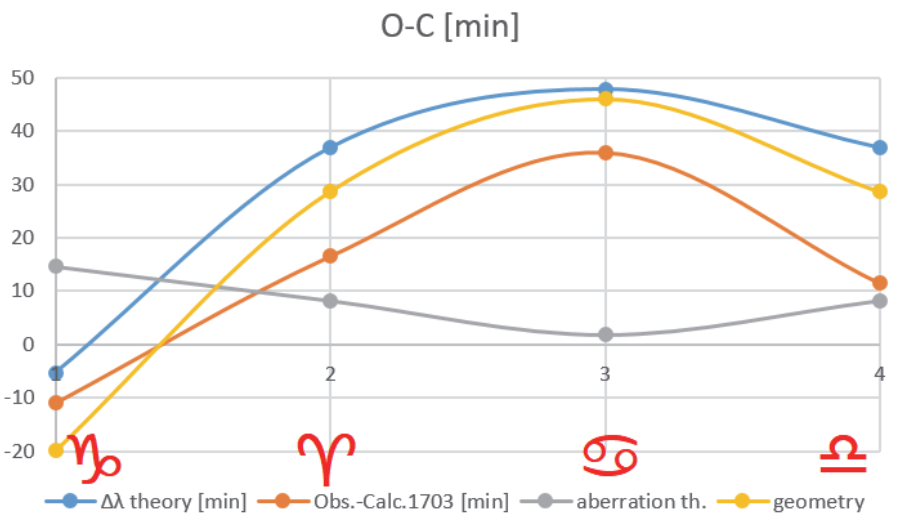

Fig. 8. The epigraph's timings translated into UTC and compared with IMCCE ephemerides.

8. Sirius' aberration and the East deviation of the line

Before the present analysis it was not clear that Bianchini used only Sirius for timing the solar meridian transits, also in daytime. The reason can be practical: Sirius is the brightest star in the sky and it can be seen in full daylight with a telescope through the open window 60 cm × 40 cm located over the pinhole. I made personally observations of meridian transits of Antares, Ras Alhague and Venus in daytime, outdoor at the meridian line of the Vatican obelisk, and the brightness of the star is crucial. Nevertheless on the meridian line of St. Maria degli Angeli there are reported 22 stars, with their ecliptic coordinates of 1701. This lead us to intend that all the 22 stars were used during the measurements (Bedinsky and Nastasi,

2007), while only Sirius was certainly used, after the examination of the documents of Bianchini.

The *Anni Cardines* are with ecliptic longitude 0°, 90°, 180°, 270°.

Sirius in 1701 had ecliptic longitude 97°57′53" (fig. 3), and it was supposed to change only for the precession, until James Bradley discovered the aberration in 1727.

9. Seasonal aberration in ecliptic latitude

Francesco Bianchini (1703) considered also the meridian shift of Sirius, as of seasonal and of meteorological cause. Here I have demonstrated that it was due to the stellar aberration in ecliptic latitude (being Sirius not on the ecliptic plane but nearly at −40°).

Fig. 9. The coordinates of Sirius in 1701 from the Stellar Atlas of Philippe de la Hire, as reported on the meridian line of St. Maria degli Angeli.

10. Discussion

The measurements reported by Bianchini on the epigraph are plotted in orange, and they are in very good agreement with the blue line which includes the effects of the line's deviation (geometry in yellow) and of the stellar aberration in grey. The geometrical effect is much larger, nevertheless the aberration's contribution matches exactly as needed, especially in the cases of opposition (Sun in Capricorn) and conjunction (Sun in Cancer) with the star. The accuracy of the method applied

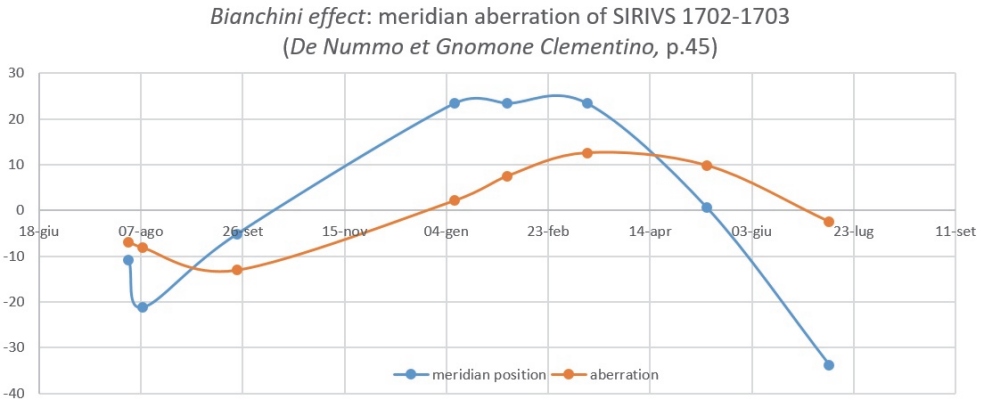

Fig. 10. The meridian position of Sirius along the year. Bianchini thought it was a meteorological effect, while it is due to aberration in ecliptic latitude.

at the Clementine meridian line is enough to recover the *Anni Cardines* within 10 minutes, as Bianchini declared in his book. The departure from this value, up to 30 minutes, is due to a systematic error (the deviation of the whole line toward East of 5.2', or 70 mm at its Northern extreme, 45 meters from the pinhole's vertical) combined with the special relativistic effect of the stellar aberration of Sirius, used in all measurements.

11. Conclusions

An important contribution of this paper is the verification that Sirius was the star always used in the meridian measurements, to compute the ecliptic coordinates of the Sun with respect to a fixed star. Finally the effect of meridian shift of Sirius along the year, was clearly recognized by Bianchini as seasonal, and it is, not because of seasonal humidity variations, but of special relativistic origin: due to the stellar aberration in ecliptic latitude, which is a rather big effect being Sirius of ecliptic latitude $b = -40°$.

The operation of synchronizing the mean solar time of Rome in 1703 with the Terrestrial Dynamical Time and then with the Universal Time Coordinated, has made possible recovering the Equation of Time of 1703 and the comparison between modern ephemerides and these data, to distinguish clearly the stellar aberration's contribution of Sirius, from the one due to the Eastward deviation of the line.

Positional astrometry at arcsecond accuracy using historical instruments, with light equipment

Costantino Sigismondi
ICRA, Sapienza University of Rome,
Rome, Italy
E-mail: sigismondi@icra.it
http://www.icra.it/solar

Lorenzo Ricciardi
University of Rome 3,
Rome, Italy

It is possible to make solar astrometry at arcsecond level using a meter, a watch and a smartphone at the Clementine Gnomon (1702, a giant pinhole-camera obscura). Similarly at the Vatican obelisk's meridian line (1817) the transit timing's accuracy is better than one second with the same instruments, and a small monocular. The differential positions with respect to the zodiacal marble disks allow to reach the arcsecond accuracy even outdoor.

Keywords: Video-timing, Equation of time, Spherical Astronomy, St. Maria degli Angeli, Vatican Obelisk, Meridian Line, Solstices, Equinoxes, Zodiacal signs, UTC, Ephemerides, Altazimuthal coordinates.

1. The giant pinhole camera obscura of the Clementine Gnomon (1702)

Measures of solar astrometry at arcsecond level have been done with a pencil, a meter, a watch and a smartphone at the Clementine Gnomon (1702). The Clementine meridian line is 45 meter long. The new calibration tables of the reference points on the meridian line in the Basilica of St. Maria degli Angeli, have been recently published (2021). Each measure of the solar image position is referred to its nearby marker with known position with respect to the pinhole, within ± 0.5 mm. The solar images limbs can be located on the floor within ± 1 mm. 2 arcseconds of angular position accuracy is obtained for winter observations with focal length of nearly 50 meters, while 5 arcsec is reached in summer with 21 m length involved. The pencil is used for signing the limbs' positions on the meridian line, the meter is sufficient to measure the distances of these limbs from the nearest reference point (there are 42 of them along the line), the watch synchronized with UTC is video recorded along with the solar transit to get the single frame accuracy on contact's times. A timing accuracy down to 0.3 s is reached with the average air turbulence conditions. This result is observed by N parallel transits averaged.

Examples on application of Cassini's and Laplace's corrections for air refraction on the observed data to obtain the real celestial coordinates of the date are presented (Sigismondi, 2019). This research was aimed to understand the Bianchini's effect, claimed in the book De Nummo et Gnomone Clementino (Bianchini, 1703). According to his observations Sirius changed its meridian position during the seasons because of some meteorological effect. We proved that the relativistic stellar aberration was the cause, thanks to this whole series of accurate observations of the Sun during all kind of weather conditions. This historical instrument gives the possibility to see the arcsecond, as half of a millimetre during winter, as no other instrument in the World, at the same time to many people. A set of more than 100 transits video is also presented for remote observations during all year's seasons.

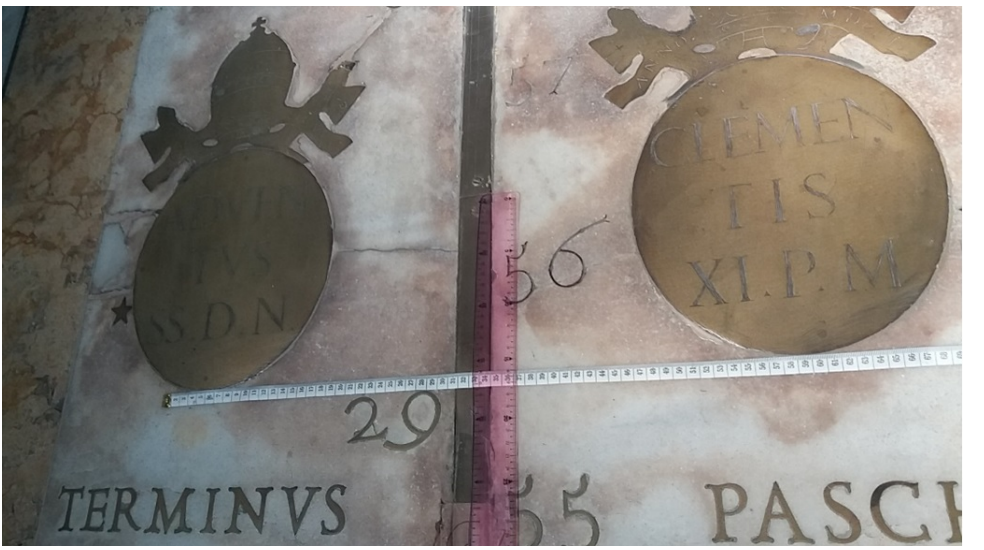

Fig. 1. The ellipses of the Sun on 20 August 1702 on the meridian line of St. Maria degli Angeli. They are an example of measurement of the solar image on the floor with respect to the references on the meridian line [e.g. the number 55's marker].

2. The outdoor Vatican obelisk's meridian line (1817)

At the Vatican obelisk's meridian line solar positions as well as stellar and planetary transits have been measured. The obelisk of St. Peter's square has a meridian line since 1817. This line is two times longer than the Clementine line, and it allows potentially accurate measurements, despite the low contrast obtainable outdoor.

A scheme of the correspondence between the features on the top of the obelisk and the marble zodiacal disks on the square is published in figure 2.

The limit of the penumbra of the obelisk's shadow has been recovered with an accuracy of 2 mm during the Summer solstices of 2020 and 2021, repeatedly, by

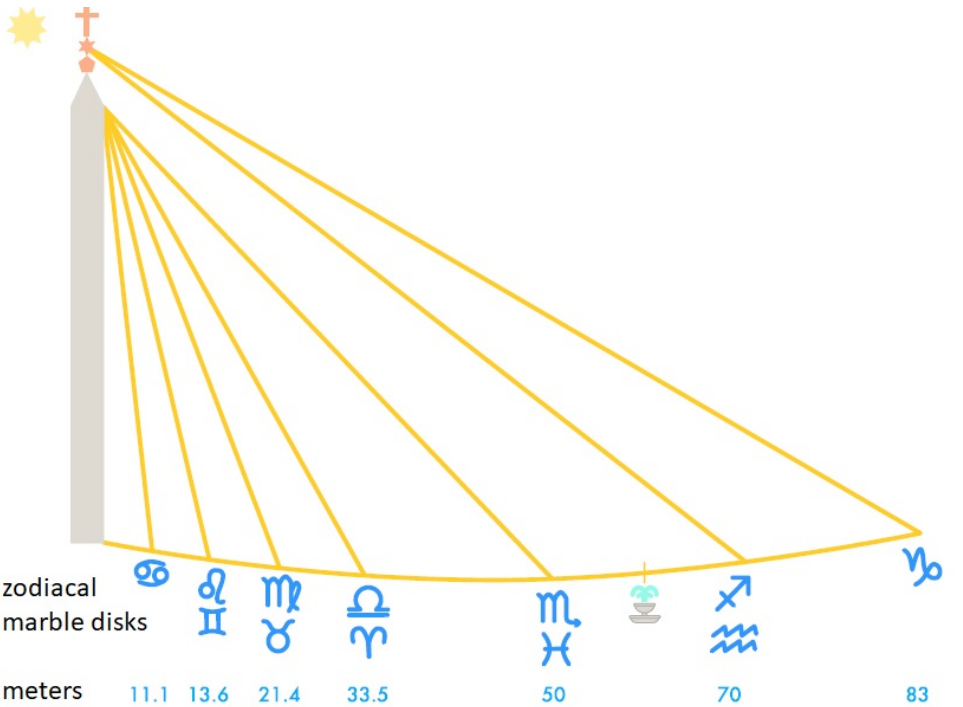

Fig. 2. The zodiacal signs on the meridian line of St. Peter's square as connected with the top of the obelisk. The distances from the axis of the obelisk are reported in meters from all the zodiacal marble disks.

moving the smartphone used for the video making, up and down near the limit and observing its cast shadow. The shadow's limits measured during 20 minutes of observations (fig. 3) on the Cancer and Leo's disks showed the rotation of the obelisk with respect to the East-West direction of 24 mm around its axis. This is the first indication on the astronomical accuracy of the re-collocation of the obelisk in September 1586 (Sigismondi, 2016). Observing the shadow's penumbra the massive presence of Sahara's sand in the upper roman atmosphere has been detectable. The contrast of the shadow almost vanished at noon time during the most sandy days. These observations were confirmed by the aerobiological measurements made in Tor Vergata University in the same period, and by the following presence of dry sand all over the city (Travaglini, 2021).

Moreover the projection of the image of the Sun when being occulted by the obelisk, obtained by a monocular 7×18, on the marble zodiacal disks (or on movable cardboard projection screen) has been video recorded during the meridian transits, attaining a timing accuracy of 1 second. The 18 mm-lens telescope projects on the marble a sharp image of the Sun, of about 30-45 mm of length, screened by the direct sunlight (fig. 4).

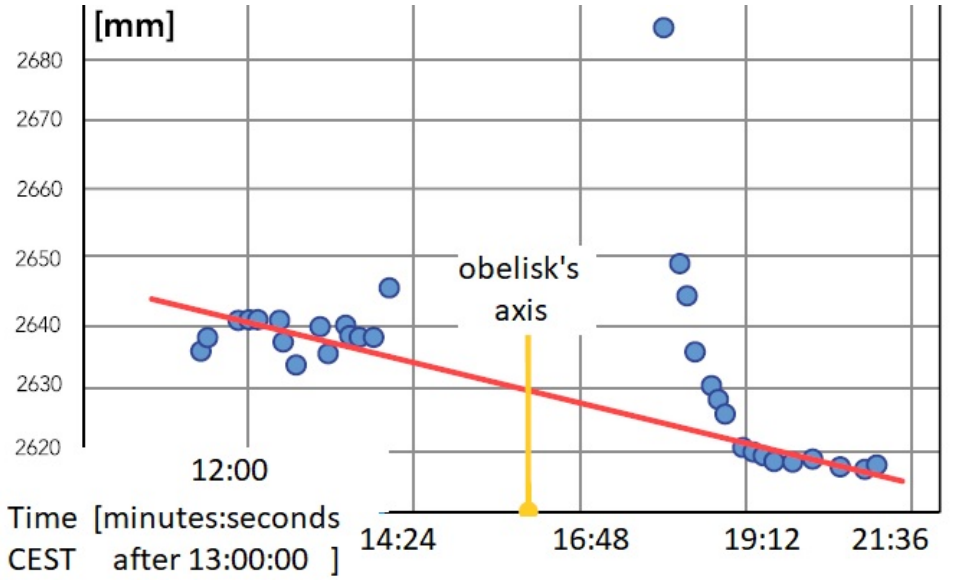

Fig. 3. The rotation of the obelisk with respect to East-West direction determines the variation of the shadow's length detected around the meridian time (24 July 2021) on the Leo disk, measured from the Cancer's black star.

2.1. *Parallax error*

The crucial problem of the all direct observations (with or without telescope) is the on-axis location of the lens or of the eye. It is a parallax error.

A mm shift from the meridian axis, with 4 mm/s velocity of the shadow corresponds to 0.25 s of timing shift. From the summer to the winter solstice the ground velocity of the shadow ranges from 2 to 6 mm/s, making the corresponding accuracy on the timing ranging from 0.5 to 0.2 s per mm.

To obtain a timing absolute accuracy ranging from 1 s to 3 s the parallax problem has to be solved. The solar shadow have not this problem, but their contrast makes the accuracy ±3 s. Using a telescope to project the eclipses on the marble disks we improved the accuracy to ±0.5s. The naked eye measurements of the stellar and planetary alignments while standing on the meridian line show an accuracy of ±1, reduced to ±0.5 s by using a ground mirror posed exactly in the middle of the meridian line and aiming at it. and the planetary/stellar transits observed with the mini-telescope standing on the meridian line. Stellar transits with the naked eye at the monocular are easier to be seen and audio-recorded because of the strong illumination of the square by night.

The achievable accuracy on many measurements from the same point, as for Antares' transits on the Capricorn disk, has been ±10 arcsec on the central azimuth of the meridian transit behind the obelisk. The first video record of a full daytime transit (October 28, 2021 of Venus) confirms that result within a σ, as well as the transit of Fomalhaut observed on November 4, 2021 from the same disk.

Fig. 4. The approach of the Sun to Scorpio black star in 2021 on the marble disk in S. Peter's square: the three dimensional star on top of the obelisk is projected next to the black star. That black star is 4 cm wide.

3. Solstices, zodiacal signs and equinoxes

In the solstices the solar altitude above the horizon reach a maximum (June) or a minimum (December) well represented by a parabola. In St. Maria degli Angeli the influence of the aphelion (4-6 July) and of the perihelion (2-4 January) on the measured altitude of the Sun is well visible as the minimum/maximum's shift of the fitting parabola on dates symmetrical to the solstice and more and more widely spaced. For St. Peter's meridian line the approach to Scorpio zodiacal sign shows

already well the change in solar meridian altitude day by day, projected on the marble disk (fig. 5).

Fig. 5. The approach of the Sun to Scorpio from 16 to 23 October 2021, looking at the obelisk of St. Peter's from the Scorpio's black star on the marble disk. The solar profile is reported with light yellow circles.

For a more precise measurement of the winter solstice a solid metal holder has been prepared for the mini-telescope. The principle is the same of the tripod with fixed angle, with a larger stability to guarantee high precision measurements, with the image shifting of $4 - 5\%$ of its length of 40-50 mm during the solstice's days.

4. Equinoxes and linear interpolation

The parabolae for the solstices and the linear interpolation for all zodiacal signs' ingresses are required to fit the observed data. This is a very good training for data analysis practice.

The observations of the equinoxes require the accurate knowledge of the Gnomon's height and geographical coordinates, and two observations: one before and another after the equinox, are necessary to have the possibility of interpolation.

Fig. 6. The fixed-angle monocular-holder built as Winter solstice meter.

These measurements confirmed the accuracy of ±10 minutes claimed by Bianchini, provided the systematic deviation of the line from the Celestial North. Similar result is obtained at St. Peter's square meridian line.

5. Level function of the mini-telescope at fixed angle

The mini-telescope with a fixed inclination can be used to test the horizontality of the seven disks. The Virgo's one shows a larger inclination because there the meridian line is reaching its minimum level in the square, before the equinox and toward the Scorpio's disk. The St. Peter's square is concave, allowing to convey the rainwater to the sewage system.

6. Special measurements

The meridian line of St. Maria degli Angeli allows to measure the position of the Sun with a great precision. The solstices can be measured also off-meridian as differential measures, always from the same reference point on the floor of the Basilica (e.g. the Summer solstice "royal" marker along the 173° azimut). The precision of 1 mm yields an angular accuracy in the range of a few arcseconds. The zodiacal marble disk of St. Peter's square meridian line have been used as fixed references, to make differential measurements of meridian transits. These differential measures

Fig. 7. The measurements of the Fall equinox on September 23, 2019 in the Basilica of St. Maria degli Angeli.

are used to recover their relative alignment with North and the obelisk's axis, and the alignment between the Sun entering the sign, the black star of the disk (see fig. 4) and the ending top features of the obelisk. The accuracy here is within 2 mm, as the one attained with the penumbral limit measured directly (fig. 3).

The measures of planetary and stellar transits have been:

- Antares from July 21 to August 21 (before sunset), Capricorn
- Ras Alhague, August 21-September 6, Virgo
- Fomalhaut, November 4 2021, Capricorn
- Saturn, Sagittarius, October 2021
- Venus in full daytime, 19-28 October 2021, Capricorn
- Jupiter, October 2021, Scorpio
- δ Capricorni, October 2021, in Scorpio
- μ and ϵ Aquarii, respectively of magnitude 4.91 and 3.96 under an unusual clear sky for Rome on October 11, 2021.

Fig. 8. The measurements of the Fall equinox on September 23, 2021 in St. Peter's square, on the meridian line. The solar image is the ellipse on the intersection of the two meters-tapes.

The lunar transits have been also recorded, and the lunar limb position precisely located. The planetary transits timing with a precision of a second allow to detect directly the nature of their motion (direct or retrograde) by comparing with the previous transit and the sidereal day length. The stellar and planetary transit paralleled the solar ones to measure the local western deviations of the meridian line on all the zodiacal disks. In particular Antares, Venus and Fomalhaut were used for the last point in the Capricorn solstice. The stellar transits allow to measure the sidereal day and the stellar aberration with a 0.01 s precision obtained over several days, either with naked eye video recorded measures (Sigismondi, 2021, these Proceedings).

6.1. *Distances on the meridian line in St. Peter's square*

The accuracy on the measures made on the floor of the square would require the use of metal meters at least 50 m long, or total stations, but due to security requirements in the square this is not possible. So we adopted a technique used in Athletics Track & Field to measure the long jump run-up length with the feet. The length of 10 adjacent feet with shoes is accurately measured to find its own unit with a mm accuracy. Distances up to 300 feet are accurate within 1%, as we could verify from the center of the colonnade of St. Peter's square, by measuring the distances of some columns from their centre.

Fig. 9. The mini-telescope and its tripode, used also as level-meter. The image of the Sun is evidenced inside the cloudlet.

7. The marble zodiacal disks and the Gregorian cycle of four centuries

There is a 4-years periodicity in the ingress' dates into the zodiacal signs, due to the Julian leap year. The 29th of February resets almost completely the 5 h 49 m 11 s of average excess of the tropical year versus the civil one of 365 days. But only over 4 centuries the Gregorian reformation of the calendar is complete. Then the sequence of the dates represented in figure 10 with the addition of 22 December, Solstice in Capricorn (fig. 6, logo), is the result of a rounding to the day of these instants. The complete sequence corresponding to the dates represented on the marble disks happened in 1815. Here the procedure applied to the IMCCE calculated dates:

- Spring in Aries 21 March 1815 11h31m UT become 21 March
- Summer in Cancer 22 June 1815 8h59m UT become 22 June
- Autumn in Libra 23 September 1815 à 22h43m UT become 23 September
- Winter in Capricorn 22 December 1815 à 15h44m UT become 22 December

This sequence will be the same for all 12 zodiacal signs ingresses in the year 2215.

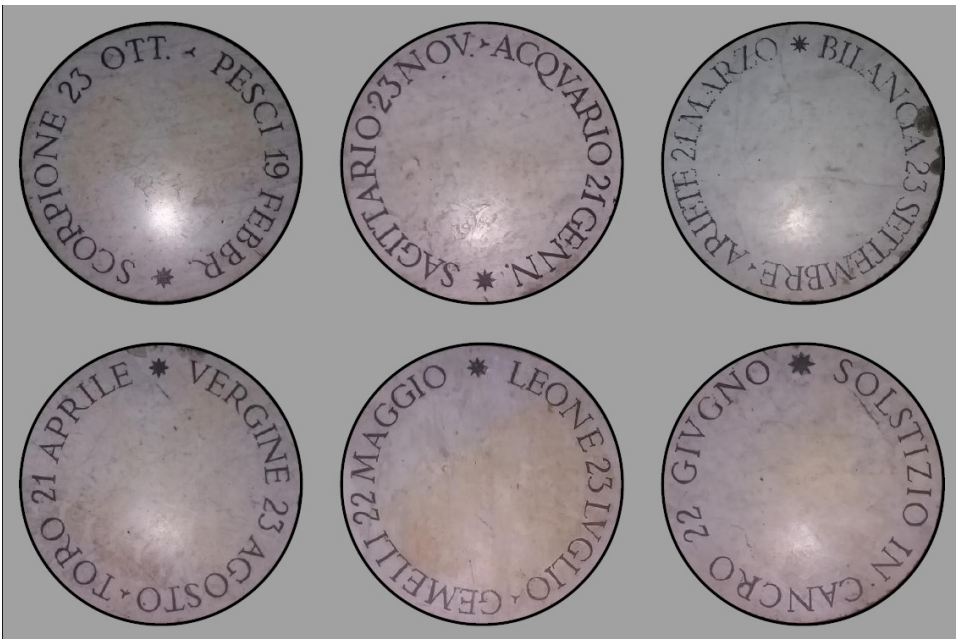

Fig. 10. Six of seven zodiacal disks: the Solstice in Capricorn 22 December is in the circular logo of figure 6. The dates of the zodiacal ingresses are the ones of 1815, and they will repeat in 2215.

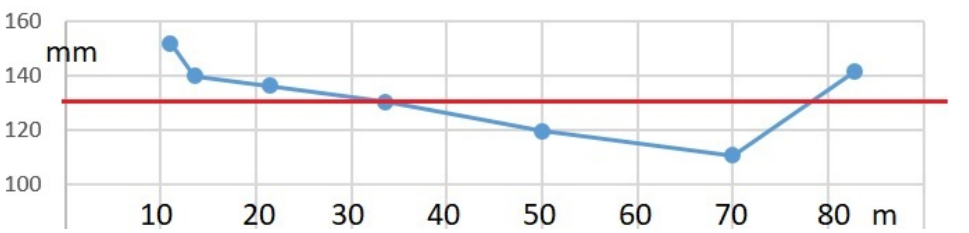

Fig. 11. On the seven zodiacal disks the meridian line is always West of the axis of the obelisk. The cross above the obelisk is also West of its axis, and it was reliably the sighting scope for the alignment of the austral zodiacal disks.

8. Deviation of the meridian line of St. Peter from Celestial North

The deviation of the meridian line has been measured from the obelisk's axis, and it is Westward.

The cross does not cast its shadow on the black stars of Leo and Cancer's disks; while it does from the Virgo-Taurus disk on.

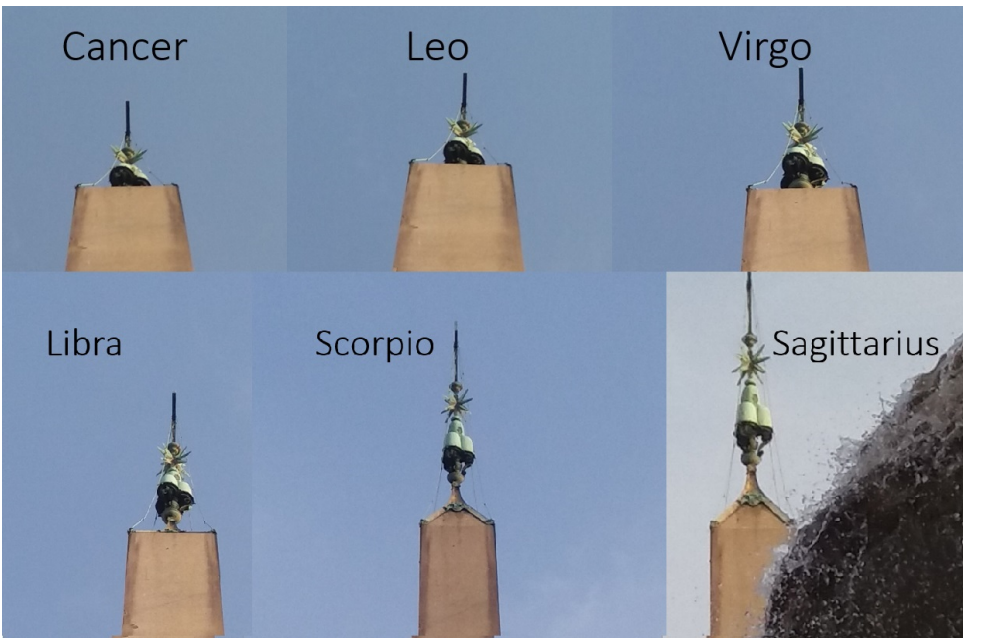

Fig. 12. The top of the obelisk as seen from all zodiacal disks.

9. Conclusions and perspectives

The positions of the celestial bodies is at the basis of Celestial Mechanics, and every gravitational theory: either Newtonian or Einstenian. To distinguish the latter are necessaries data with arcsecond level of accuracy. The measurements made at the historical meridian lines of St. Maria degli Angeli and St. Peter's square, with light equipment included:

- small meter tape
- radio synchronized watch
- a smartphone used for video and/or audio records
- "calibrated" feet
- a monocular 7×18 on small tripode

All these measurements on field allowed to know:

- the absolute calibration of the line's orientation
- the motion of the Sun, Moon and planets with respect to reference stars
- the stellar aberration with respect to the atomic time UTC
- Sun and planets' motion controlled with ephemerides (Stellarium 0.20.2)
- the variation of the Earth's rotation time $\Delta UT1$

Young students 14-15 years old understand better the season's rhythm as ruled by the solar rays' inclination at noon, as well as the astronomical observation considered as a real physics experiment, requiring calibration and errorbar evaluations, and long time basis (like the whole month needed for measuring the Sidereal Day up to 0.01 s). Also the data analysis experience with linear and parabolic fits has been mentioned. Finally, last but not least, the relevance of astronomy in the cultural heritage, owing the importance of the historical places were they can experience it: St. Maria degli Angeli, Diocletian's baths transformed into church by Michelangelo, and St. Peter's square realized along the centuries by the contributions of several popes, cardinals artists and scientists, namely Sixtus V, Domenico Fontana, Egnazio Danti, Pietro Maccarani and Filippo Luigi Gigli for the meridian line and Gianlorenzo Bernini for the colonnade's astronomical orientation from solstices' sunrises and sunsets.

Daily, seasonal, and equinoctial solar paths on a school soccer field

Costantino Sigismondi
ICRA, Sapienza University of Rome,
Rome, Italy
E-mail: sigismondi@icra.it
http://www.icra.it/solar

The shadow of a wall cast by the Sun on a soccer field has been used to measure the change of the altitude and azimuth of the Sun along the day and through the seasons. The change of curvature parameter of the daily hyperbola shadow's path, has been recovered in the days around the spring equinox 2021. The study of the daily paths has been possible with chalk and meter during school days, on this field, and the data have been reported on a spreadsheet. The students were impressed by this whole-year experiment, while normally at school the experimental sessions are one-hour long.

Keywords: Solstices, Equinoxes, Shadows, Altitude, Azimuth.

1. Sun's paths on a soccer field

The shadow of a 10 meters wall (its vertex) cast on the soccer field of the Technical Institute Galileo Ferraris in Rome, 41.878 415° N, 12.454 662° E, coordinates WGS84 of the gnomon (fig. 2), has been used to perform daily measures with an accuracy up to a few millimeters. The gnomon's shadow, measured from the bottom and from the side of the field with a tape meter, in the best sets of measurements, presented rms below 1 mm. The hyperbolae drawn by the Sun through these shadows changed their aperture coefficient from Winter to Spring, passing to zero at the equinox. The students learned literally "on field" what means accuracy to the millimeter level, during several months. They learned how to do linear interpolations and extrapolations to predict the positions of the shadows in the next 10 minutes... or in the days without data (weekends and holidays).

The curvature radius of the hyperbolae is also measurable with three points along 20 minutes, repeated 3 times in a hour lesson.

All these achievements are possible during a single hour of lesson. The students remember well past situations, because they made practical actions.

The experience presented here with 14 and 15 years old students, started in February through May 2021.

The spring equinox was calculated by interpolation of aperture's parameters these months, with good agreement with the actual date.

The activity in open air and the use of the chalk on the field to mark the shadows' limits, the use of the meter and the care for the zero positions, have been appreciated alternatives to the normal indoor teaching.

2. Procedure

The positions of the shadow's cusp (e.g. fig. 3) are taken with respect the corner of the field as x and y. The curve connecting the daily positions (about ten each time) is plotted to see immediately its form. The meridian point (a, b) is measured and made center of a new coordinates system, with the appropriate translation. The meridian axis has an equation computed in the first days of observations, by marking the position of the shadow at the very instant of the meridian transit. Its angle α with respect to the axis x and y of the soccer field is used to apply the following rotation.

$$\begin{cases} x' = (x-a)\cos(\alpha) - (y-b)\sin(\alpha) + a \\ y' = (x-a)\sin(\alpha) + (y-b)\cos(\alpha) + b \end{cases}$$

Fig. 1. The equation of the roto-translation around the meridian point (a,b), to obtain a curve symmetric to the y' axis, with its vertex on the new origin (0,0).

A parabola fits with fair approximation the curve so obtained, by using a common spreadsheet (e.g Excel, LibreOffice, OpenOffice). The hyperbolic fit requires more passages, not automatically implemented in the spreadsheets.

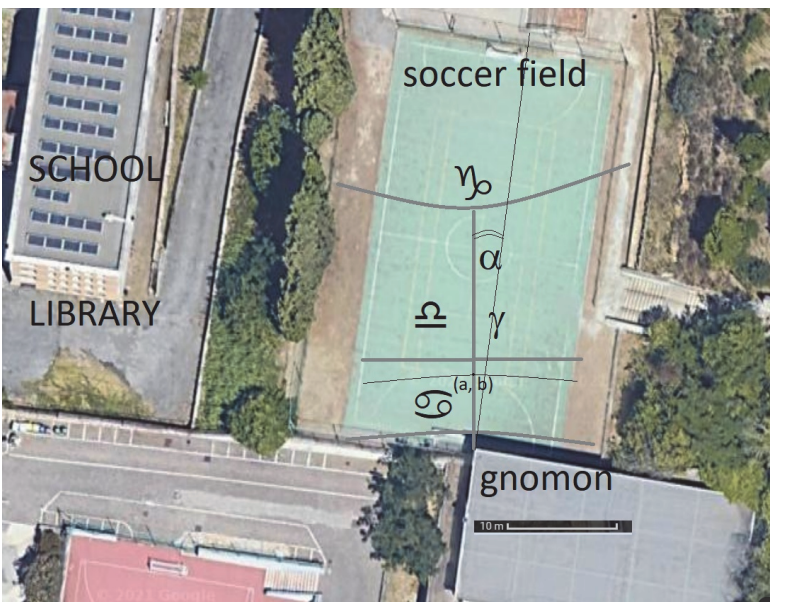

Fig. 2. The school's soccer field as seen from satellite, with the meridian line scheme superimposed.

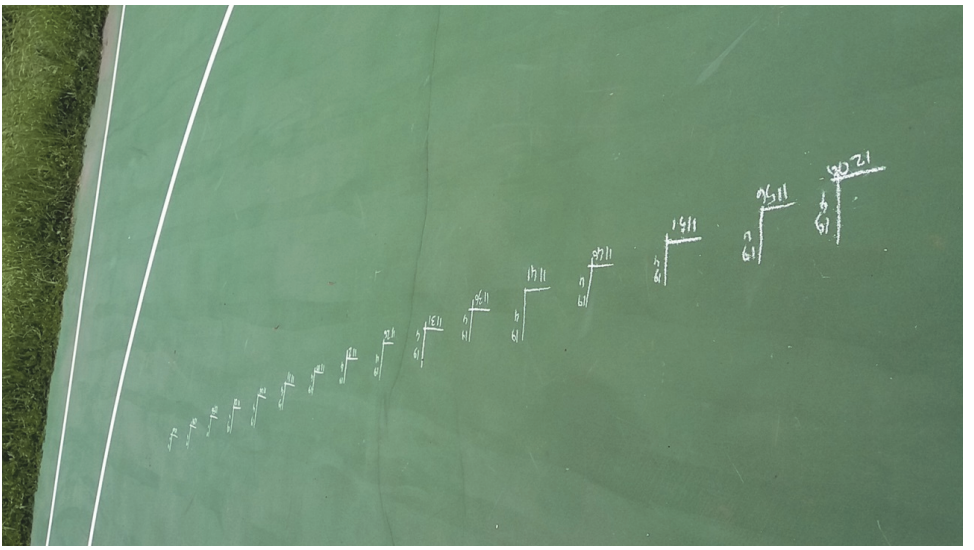

Fig. 3. The hourly path of the shadow's limit from 10:46 to 12:06 of 9 April 2021: the progress of the gnomon's shadow is visible.

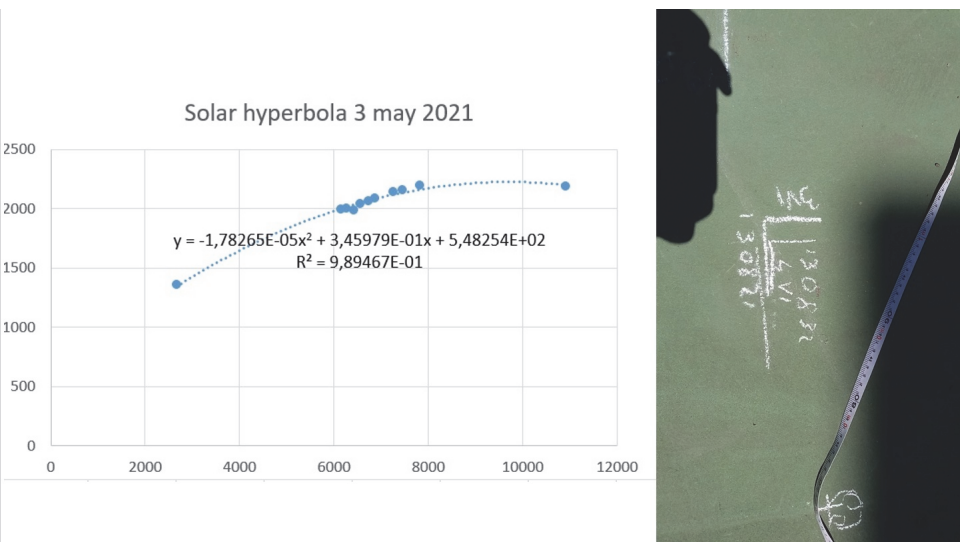

Fig. 4. The shadow on June 3rd 2021 and the plot of daily positions of May 3rd 2021, before the roto-translation.

3. Conclusions

The method presented is to fit the hyperbola of the shadow's positions of the wall's cusp on the soccer field, with the equation of a parabola. The accuracy achieved

is within 20 arcseconds, or 2 mm for each position of the shadow on the field. The path of two consecutive days, even near the summer solstice (where the positions are very close one to another), are well distinguishable each day from the other one. This procedure has been adapted to Excel spreadsheet, and the hyperbolic fits have been realized with the parabolae. The results obtained in the soccer field allowed to check the curvature's change during the equinox, and they have been published in detail (2021).

This is a suitable introduction to the trigonometrical methods of Celestial Mechanics, affordable by many schools and all students. These practical activities, made with increasing accuracy, may pave the way to understand the problems in experimental general relativity.

Teaching relativity at the AstroCamp

C. J. A. P. Martins

Centro de Astrofísica da Universidade do Porto, and
Instituto de Astrofísica e Ciências do Espaço, Universidade do Porto,
Rua das Estrelas, 4150-762 Porto, Portugal
E-mail: Carlos.Martins@astro.up.pt

The AstroCamp is an academic excellence program in the field of astronomy and physics for students in the last 3 years of pre-university education, which often includes a course (or a significant part thereof) on Relativity. After an introduction to the principles, goals and structure of the camp, I describe the approach followed by camp lecturers (myself and others) for teaching Special and General Relativity, and some lessons learned and feedback from the students. I also provide some thoughts on the differences between the physics and mathematics secondary school curricula in Portugal and in other countries, and on how these curricula could be modernized.

Keywords: AstroCamp; Secondary education; Summer schools; Relativity.

1. The AstroCamp vision

The AstroCamp[a] is an academic excellence program in the field of astronomy and physics, organized by CAUP and the Paredes de Coura municipality (with the support of several national and international partners) for students in the last 3 years of pre-university education, i.e. roughly 15-18 year old students.

Our key goals are

(a) Promote scientific knowledge, with high-quality training in a secluded and tranquil setting
(b) Stimulate student curiosity and skills of critical thinking, team work and group responsibility
(c) Stimulate interactions between students with different backgrounds and life experiences but common interests

The camp was created in 2012, and now accepts applications from 42 eligible countries. Participation is strictly by invitation, after an application period (in April) and a selection phase (in May) which includes an interview in English. The camp itself takes place in August, in the Corno de Bico Protected Landscape area of the Paredes de Coura municipality (in the northwest of Portugal) and lasts 15 days. One of our points of principle is that for students in Portuguese schools the camp has no costs. Some students from other countries will also have support, others

[a] `https://www.astro.up.pt/astrocamp/`

may need to pay part of the costs or find their own support locally. In any case, significant efforts are made to keep costs low, and the maximum cost for foreign students is 400 Euro.

The main academic activity consists of two courses (each with 15h of lectures and a 2h written exam), given by currently active researchers with a PhD in a relevant area. Depending on the year, more than two courses are offered, but each student will only take two of them. In most of the 10 editions so far, one course or a significant part thereof was devoted to Relativity (both Special and General). This is to a large extent driven by the camp students themselves: one of the principles of the camp is that students are involved in the choice of the courses offered in the camp, and Relatively is clearly the prime example of a topic that the students feel is not satisfactorily covered in their school classes (if it is at all), and for which their school teachers are often unable to provide further information.

Other camp activities include observational and/or computational projects, stargazing sessions and documentaries, community service projects and evening talks which in early editions were open to the local public, but are now webcast live. There are also several other recreational activities such as hiking (including an overnight hike coinciding with the peak of the Perseids meteor shower). Interested students can also engage in several post-camp projects at CAUP and elsewhere. Our guiding vision is to provide the students with unique opportunities beyond the standard school systems, also after the camp. The extent to which students make use of all of these is of course up to them.

The camp is residential, with all students, teachers and camp monitors (university students, which most often are AstroCamp alumni) staying in the camp for the full 15 days. (Exceptionally, teachers may stay for reduced periods.) Due to COVID-19, the 2020 edition exceptionally had a hybrid format, with students living in Portugal in residence at the camp, and students living in other countries joining virtually in all activities where this was feasible. In the 2021 edition only one student had to participate remotely, and we naturally hope that the 2022 edition will be fully residential again.

2. Some statistics and outcomes

In the first four editions the camp only accepted applications from Portuguese students studying in Portuguese schools. Starting in 2016 the list of eligible countries has expanded, and currently the camp can accept applications from students matriculated in one of the last 3 years of pre-university education in any of 42 eligible countries[b], provided they are national citizens from one of these countries.

[b]These are: Andorra, Argentina, Austria, Belgium, Brazil, Bulgaria, Canada, Chile, Croatia, Cyprus, Czechia, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Latvia, Liechtenstein, Lithuania, Luxembourg, Malta, Monaco, Netherlands, Norway, Poland, Portugal, Romania, San Marino, Serbia, Slovakia, Slovenia, Spain, Sweden, Switzerland, United Kingdom, United States of America and Uruguay.

In the 10 editions so far the camp had a total of 133 accepted students with 15 different nationalities. Some basic statistical information on the participants can be found in Table 1. It is worthy of note that the camp does not have quotas of any kind; the outcomes are therefore the result of the merit and academic potential of the candidates.

Table 1. Basic statistical information on the 2012-2021 AstroCamp students.

Accepted Students	2012-2015 Editions	2016-2021 Editions
Portuguese	100%	53%
Foreign	N/A	47%
Grade 10	24%	31%
Grade 11	52%	47%
Grade 12	24%	22%
Boys	47%	40%
Girls	53%	60%

Note: Grades 10, 11 and 12 are the names of the last three years of secondary education in the Portuguese school system. The student ages corresponding to these grades are country-specific, but broadly speaking Grade 10 students are 15 or 16 years old, while Grade 12 students are 17 or 18 years old.

One of the most rewarding deliverables of the AstroCamp is our Solar System Trail. This is the second scale model of the Solar System, in the Iberian Peninsula (and one of only sixteen in Europe, as far as we know), that is accurate both in terms of the sizes and of the distances of the objects. It was built during the first four AstroCamps, and a full hiking trail which follows the objects in the system—the Sun, the planets up to Neptune (including the Earth's Moon), and Ceres—was officially opened on 13 August 2016. The trail has recently been included among the teaching resources for Grade 7 students, so for a new generation of Portuguese students this may well be providing their first contact with astronomy. The trail also has an accompanying website[c] which at the time of writing only has a Portuguese version but is due to be expanded and replicated in at least 10 different languages in early 2022.

Most editions of the camp also included a computational project, lasting about 20 hours, aiming to provide the students with an introduction to scientific programming and statistics and data analysis in astrophysics. In several cases, the students continued working on these projects after the camp, and contributed to peer-reviewed publications in top academic journals.[1–3] At least one more such publication is expected soon.

[c] `https://www.astro.up.pt/trilhosistemasolar/`

3. Teaching special and general relativity

As previously mentioned, One AstroCamp principle is that students are involved in the choices of the courses taught in the camp, as well as in the ones they actually take. This is a multi-stage process, which we run in parallel with the student applications. A call for courses is issued at the beginning of each calendar year, and the submitted proposals undergo a scientific and pedagogical check, leading to a courses shortlist. The students shortlisted for the interviews are then asked to rank the shortlisted courses according to their preferences; this is done in a double-blind way—students don't know who would teach each course, and organizers don't know individual student preferences until after the student places are assigned. The courses to be offered are then decided and assignment to students, and a final tweaking of course contents can be done if there are overlaps between them. As an example, in the 2021 edition the shortlist included 6 courses, of which 3 were taught in the camp (with each student taking 2 of them).

So far, courses on Relativity/Cosmology (or containing at least ca. 5 hours of content on this) have always been selected by the students when offered. Various lecturers have been involved (in addition to the author), from Canada, Germany, Italy, The Netherlands, Portugal, Spain and the UK, some of them teaching twice.

Topics are covered both at the conceptual and (at least for some of them) also at the more detailed mathematical level. In our experience, most students also enjoy learning about the relevant historical context and background.

Galilean relativity topics covered include

(a) Galilean mechanics and acceleration
(b) Inertial frames and Galilean Transformations
(c) Historical developments from Galileo to Newton (Gassendi, Huygens, Descartes, etc)
(d) Newton's Laws and Equivalence Principle (inertial and gravitational masses)
(e) The XIX Century background to Relativity: Mechanics versus Electromagnetism

Special relativity topics covered include

(a) Derivation and interpretation of the Lorentz-Fitzgerald transformations
(b) Minkowski geometry and spacetime diagrams
(c) Special Relativity and the Principle of Relativity
(d) Invariance of the speed of light and its consequences
(e) Time dilation and Lorentz contraction: Cosmic rays and Twin paradox
(f) Physical meaning of inertial frames

Finally, topics pertaining to applications of relativity covered include

(a) Relativity and the GPS
(b) The Schwarzschild solution and black hole properties

(c) Derivation of the Friedmann and Raychaudhuri equations, and simple solutions thereof
(d) Cosmology, including Hubble's law and simple FLRW universes
(e) Gravitational waves, including their detection

Examples of conceptual questions on these topics that have been previously used in AstroCamp course exams are listed in the Appendix. Student feedback clearly shows that the Newtonian physics curriculum is unattractive, and often containing significant misconceptions. Camp students usually follow conceptual aspects very well (even when finding some of them counter-intuitive); any difficulties usually pertain to their mathematical background, which is partially correlated with their age.

4. Lessons learned, and the COVID-19 impact

The experience of ten camp editions (of which six included foreign students) reveals significant differences between the secondary school curricula in different countries, and sometimes in different regions of the same country. There are also country-specific differences between public and private (or international) schools. In Portugal, it is clear that private schools (and even a few public schools) routinely apply grade inflation. This further reinforces the prior expectation that grades alone do not provide a fair selection process. This is why, from the first edition, the application procedure includes a student motivation letter, a teacher recommendation letter and, importantly, an interview to shortlisted candidates.

Since the camp accepts students from the last three years of secondary education, one challenge for the camp teachers is that the mathematical background will be quite diverse. Specifically, derivatives introduced at different ages in different countries, and integrals are not a given even for Grade 12 students, who have finished secondary education and are about to start university. However, in our experience this is not a problem for bright students: through direct interaction with teachers or camp monitors, they can quickly gain a working knowledge, e.g. of differentiation rules, which allows then the follow the course contents that rely on them.

One rather surprising lesson is that schools can actually be a bottleneck in disseminating information on the AstroCamp to students. Specifically, from our experience less than 20% of Portuguese schools that receive direct camp information from us (including, in some editions, A4 or A3 sized posters and leaflets) actually transmit it to their students, and the fraction of students that find out about the camp through a school teacher is small—while the number is not trivial to estimate, it is clearly below 50%.

A recent challenge was provided by COVID-19. This led to a hybrid format edition in 2020, with foreign students interacting with camp teachers, monitors (including some online tutors) and students in residence at the camp through online collaboration tools such as Zoom, Discord and Colaboratory online collaboration.

This was was nevertheless very successful despite the fact that foreign students participating in this edition had a very limited experience of the camp, and clearly demonstrates that remote collaboration tools enable new teaching and mentoring opportunities, which we intend to pursue.

A more surprising realization emerged in the 2021 edition, in that the COVID-19 impact on students' cognitive and social skills and emotional maturity was clearly visible. Inter alia, although the level of the courses and exams has been kept constant in recent editions (roughly at the level of a course from first year undergraduate physics degree at a top Portuguese university), the average grades of the students were lower and, in particular, for the first time in ten editions two students failed their exams. It is likely that this impact will be noticeable for several years to came. This is all the more scary since these are bright students—the impact on average ones may be much more serious.

As the AstroCamp starts its second decade, this is a good time to revise and update its format, structure and rules, also taking into account the most recent challenges. There is clearly some room for growth—more in extension and scope than in numbers—making the camp an international reference for events of this kind.

5. Epilogue: Improving Portuguese secondary scientific education

The experience of 10 years of organizing the AstroCamp (together with teaching one course in each edition, and leading other scientific activities therein) also leads to the conclusion that the Portuguese secondary education system, in scientific areas, is clearly lagging behind those of other developed countries, and needs urgent revision and modernization.

In an effort to contribute to an urgent and much needed debate, I may suggest four very specific measures

(a) It is clear that Portuguese students are, on average, far less familiar with scientific programming that their foreign peers. (The Portuguese school system current offers a 'Computational Applications' subject, but this is a total waste of time[d].) One must urgently introduce a compulsory scientific programming subject in Grades 10 to 12 grades, using languages such as Python, Octave or Julia, and connected to other subjects, especially Physics, Chemistry, Biology and Mathematics.
(b) In the Portuguese school system, Physics and Chemistry are taught as a single subject in Grades 10 and 11, and are only separate subject in Grade 12.

[d] As well as an insult to the intelligence of most students, were it not for the fact that it allows an easy high grade to be obtained, which will count towards the students' university application.

Moreover, very few students take Grade 12 Physics, either because the school does not offer it or because the students consider it a hard subject (form the perspective of getting a good grade) and prefer softer subjects such as English, Psychology or the infamous Computational Applications. This is a crass mistake. Physics and Chemistry should be separate subjects from Grade 10 (and, arguably, even earlier).

(c) The Portuguese school system has national exams which, depending on the subject, are either at the end of Grade 11 or Grade 12. The former, which currently include the Physics exam, is a clear mistake. The Physics national exam (and indeed all national exams) should be cumulative and at the end of Grade 12. Moreover, Grade 12 Physics should be made compulsory for students intending to apply for university physics and engineering degrees

(d) Last but not least, these is a vast disconnect between the secondary school environment and that of university (not to mention that of research, business, etc). A way to bridge the gap would be to reward students with top results in national exams with summer internships at research labs or tech companies (with the student matching done by the hosts). As a way to foster equal opportunities, these internships should not be merely awarded to the students with the numerically highest grades but, for example, to the student with the highest grade in each district (or, more ambitiously, each municipality in Portugal—in the former case this kind of program would reach about 20 students, while in the latter it would reach about 300.

All of these are, at least in principle, easy to implement and would have dramatic and comparatively rapid (as well as quantifiable) impacts. The main bottlenecks, other than political will are our blatant 'teaching to the test approach' (manifest in the blind acceptance of school rankings, but partially stemming from the university numerus clausus system), and the pathological reluctance of teacher unions to any kind of change. The latter can be, at least in part, ascribed to the fact that most secondary school science teachers are in their 50s or 60s. This is especially relevant in the context of the first of the above points, since these teachers and have little computing literacy, and none in coding and scientific programming. Nevertheless, delaying the modernization of the system, with these and other measures, simply increases the personal and financial costs for future generations.

Acknowledgments

This work was financed by FEDER—Fundo Europeu de Desenvolvimento Regional funds through the COMPETE 2020—Operational Programme for Competitiveness and Internationalisation (POCI), and by Portuguese funds through FCT - Fundação para a Ciência e a Tecnologia in the framework of the project POCI-01-0145-FEDER-028987 and PTDC/FIS-AST/28987/2017.

Appendix A. Conceptual question examples

The following is a partial list of relevant conceptual questions that have been used in at least one AstroCamp exam. Except for the last one (with is a proposed essay topic) they are all multiple choice questions.

Two inertial observers measure the speed of the same beam of light and obtain the same finite value. This would surprise Newton because

(a) According to him the speed of anything should depend on the frame of reference.
(b) He expected the speed of light to be infinite in inertial frames.
(c) In inertial reference frames he believed light to be stationary.
(d) He believed light should have an infinite speed in all frames.

The Michelson-Morley experiments were an attempt to

(a) Measure the speed of light.
(b) Test the Lorentz-Fitzgerald transformations.
(c) Measure the Earth's speed relative to the Sun.
(d) Detect the Earth's movement relative to the aether.

Relative to an object at rest, a moving object is

(a) Shorter and younger.
(b) Longer and older.
(c) Shorter and older.
(d) Longer and younger.

Special relativity (SR) and general relativity (GR) corrections must be taken into account for the GPS system to work. If these satellites were moved to LEO,

(a) Both corrections would decrease.
(b) The SR correction would decrease and the GR one would increase.
(c) The SR correction would increase and the GR one would decrease.
(d) Both corrections would increase.

If an astronaut in a windowless rocket feels pressed against the back of her seat, she won't be able to tell

(a) Whether the rocket is accelerating or moving at constant speed.
(b) Whether she is accelerating or resting on the surface of some planet.
(c) Whether the rocket it moving at constant speed in space or at rest in space.
(d) Whether she is at rest in space or freely falling towards some planet.

A green animal lives on an extremely dense planet. When observed from space,

(a) It will look green.
(b) It will look white.

(c) It will look blue.
(d) It will look red.

Which of these is not a direct test of the Einstein Equivalence Principle?

(a) Measurements of gravitational redshift.
(b) Tests of the stability of fundamental couplings.
(c) Measurements of the precession of Mercury's perihelion.
(d) Tests of the universality of free fall.

Essay topic: Describe the relation between physical reality and the mathematical models with which we describe it. In particular, comment on how this relation may differ in the contexts of the pure and applied physical sciences (e.g., theoretical physics and engineering).

sigismondi@icra.it

Among the celestial bodies of the solar system, the ones passing closer to the solar mass are the sungrazing comets. The sungrazers can approach the Sun with a perihelion more than 60 times closer than Mercury, experiencing a local effect of perihelion relativistic precession 60 times larger. Mercury requires 15 years, or sixty orbits, to totalize the same effect. The sungrazers have generally no more than a single orbit, because they vanish at the perihelion passage. The observability of such phenomena with SOHO coronagraphs is discussed.

Keywords: Sungrazing comets, perihelion relativistic precession

1. Generalities on sungrazing comet

The sungrazing comets are a class of comets whose known number significantly increased in the last 26 years, since the SOHO coronagraphes entered in function, at the rhythm of about hundred per year. The gravitational studies on such comets, starting from Newton are presented in the references.[1–21]

Their orbital parameters suggest their grouping as related to a few parent bodies, and we recall the statistical work on comets made by Enrico Fermi in 1922 as thesis for the Normal School of Pisa.

The sungrazing comets are the celestial bodies which approach more closely the mass of the Sun: then their orbital parameters are influenced by both General Relativity and non-gravitational effects, like mass loss and outgassing. The General Relativity effects and the non-gravitational effects are compared to understand the observational accuracy required on Mercury's perihelion. The studies carried by Le Verrier and Newcomb in the second part of XIX century, were possible because the orbit of Mercury is rather eccentric e=0.2056. When some objects may graze the solar surface, a very high eccentricity e=0.99 is considered to produce some visible effect. The accuracy on the determination of the orbital parameters of sungrazing comets is also investigated, to enforce with observations all these theoretical

concepts. The identification of new sungrazing comets is possible online, at the SOHO website, and it has been realized by the high school students of Galileo Ferraris Institute, Rome, as curricular activity, with great enthusiasm, especially with the real time discoveries of January 18, 2021 (fig. 3).

2. Measurability of the relativistic precession

$$\delta\theta = 6\pi \cdot GM_{\odot}a/c^2b^2$$

Planet	Planet (mean)	a AU	e	Perturbation [arcsec/cy]	$e \cdot \delta\theta$ [arcsec/cy]
Mercury	Mercury	0.38709893	0.20563069	43.03	8.847
Venus	Venus	0.72333199	0.00677323	8.63	0.059
Earth	Earth	1.00000011	0.01671022	3.84	0.064
Mars	Mars	1.52366231	0.09341233	1.35	0.126
Jupiter	Jupiter	5.20336301	0.04839266	0.06	0.003

Fig. 1. The relative observability from Mercury to Jupiter, as indicated by Dennis Sciama (1972).

The eccentricity larger than 0.99, that the sungrazer can present, and a perihelion's advancement of $60 \times 43''$ produces an effective visibility of 43', larger than the apparent diameter of the Sun.

The problem is that the comet is rarely visible after the perihelion, because it vanishes, and when it is visible the effect is small due to a less close encounter with the photosphere.

3. Conclusions and perspectives

The sungrazers are comets belonging to groups with similar geometrical parameters, originated by a close encounter of a big comet with the solar photosphere. They experienced the largest General Relativistic effect of perihelion precession possible in our solar system, even if for only one passage. The amplitude of such effect can be such as 0.75°, but its measurability with the SOHO coronagraph is very difficult due to the relative inclination angles with Earth's orbit; moreover the sungrazers vanish after the passage to the perihelion due to the closeness with the photosphere. The possibility to "discover" averagely a new sungrazer each week makes interesting the discussion of such effect in secondary school's physics class, where the students become protagonist of the discoveries through inspecting the SOHO movie theatre, in real time. The introduction to observational General Relativity can be effective through this approach, for the young students.

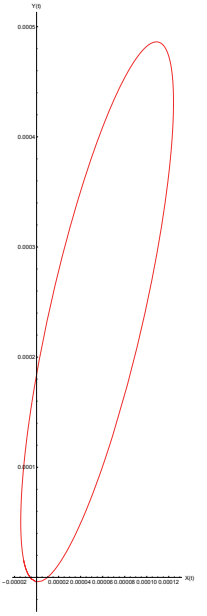

Fig. 2. One complete orbit of a sungrazer comet calculated with a computer code developed by Bozza and Pietroni (2021), distance given in parsecs; orbital parameters: semimajor axes $a \simeq 52AU \simeq 7.64 \times 10^{12}$ meters, eccentricity $e = 0.98$, inclination $i = 160°$, period $P = 360$ ys. The relativistic Lagrangian has been used to evaluate the perihelion advancement, and compared with the non-relativistic one. The interaction with the solar atmosphere is not taken into account, to close the orbit.

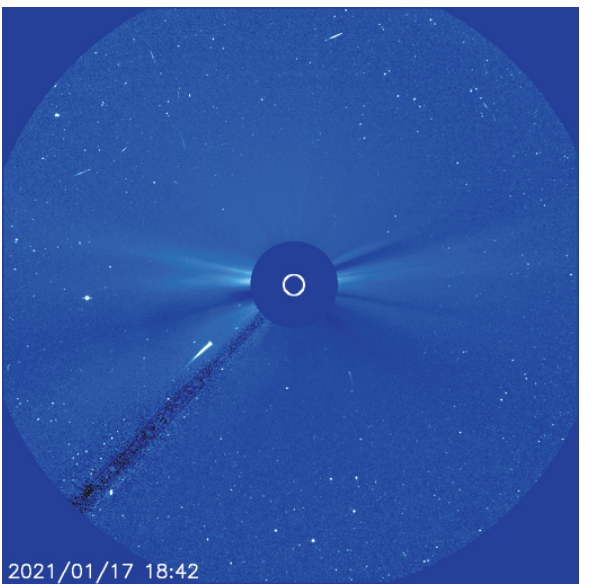

Fig. 3. Two sungrazer comets at the same time on January 17, 2021, observed by SOHO C3 coronagraphs, and "discovered" at school in real time.

The three Summer solstice's markers of 1721 unveiled in the Basilica of Santa Maria degli Angeli in Rome

Costantino Sigismondi
ICRA, Sapienza University of Rome, Rome, Italy
E-mail: sigismondi@icra.it
http://www.icra.it/solar

The solar image is projected through a pinhole inside a camera obscura in the great meridian line in the Basilica of Santa Maria degli Angeli in Rome: the daily path of 1721 summer solstice has been recovered as passing through three markers on the floor of the Basilica, near the summer part of the meridian line. The function of these three markers was considered ornamental until now, because no written documents have been found on them. Moreover two of the three markers today are no longer illuminated by the Sun, after 1750.

The same technique has been applied to the three solar markers in St. Maria degli Angeli, finding that they belong to the same 1721 solstice of three centuries ago, within a few millimeters of accuracy.

Keywords: St. Maria degli Angeli, Meridian Line, 1721, Solstices, Equinoxes, Maria Clementyna Sobieska, James III Stuart.

1. The 1721 Summer solstice perpetuated in St. Maria degli Angeli

The Meridian Line of Santa Maria degli Angeli in Rome has been realized in 1700-1702 upon the will of Pope Clement XI, since when he was Cardinal, after the project of Francesco Bianchini (1662-1729) to measure with unprecedented accuracy the tropical year and the variation of the obliquity of the ecliptic. At this Great Gnomon the seasonal effects on the atmospheric refraction and the effects of stellar aberrations were measured, but while the first were recognized the latter become systematic effects included in the errors of measurements.

At the Marcel Grossmann Meeting of Berlin (2006) this discovery was firstly presented; after other historical data were analyzed (2014), while in International Astronomical Union General Assembly of 2018 in Vienna the recognition of two brass markers as solstice markers was announced.

The two markers belong to the summer solstice because they are on the same daily hyperbola of the solar center entering Cancer in 1721. One of the two brass markers, named after this paper the King's marker, is no longer illuminated by the Sun since 1750 Vanvitelli's renovations of the Basilica, which modified the pinhole's visibility from all the floor.

A third marble marker, considered as ornamental until now, it is on the same hyperbola and it is on the floor of the Basilica, about 7 meters far from the other.

The different material of this third marker delayed our discovery of the strict correlation of the three markers. This marble was dedicated to the King James III Stuart in 1721; the well known inscription says: FELIX TEMPORVM REPARATIO meaning "Return to good times", very probably after his marriage in 1719 1st of September (Francesca Ceci, 2021), with Maria Klementyna Sobieska and the birth of their son on 31 December 1720.

These markers are offset with respect to the great meridian line, because on the Cancer's marble no more modifications were possible. This chronological sequence explains also why in his book of 1703, Bianchini did not mention these markers.

Fig. 1. Two markers: King James' (Jacobus in Latin) III in marble and Klementyna Sobieska's in brass, the one still illuminated by the Sun.

2. Observations and inspections

The three solstice's ellipses, two in brass (half ellipses, as the only one still illuminated by the Sun in the right-side of figure 1) and one in marble (whole ellipse, left-side figure 1) with the dedicational epigraph containing the date (adding together the capital letters as Latin numbers) are no longer hit by the Sun's image, excepted the last one, before the meridian line.

In 2018 the two brass decorations have been recognized as half ellipses of the Summer solstice's Sun. This year 2021, exactly three centuries after their realization, the all three markers have been recognized as belonging to the same "memorial addition" to the great meridian line.

With this addition, made very reliably by Francesco Bianchini, the royal couple Maria Clementyna Sobieska (1701-1735) and James III Stuart (1688-1766), king without land, married since 1719 and living in Rome under the protection of the pope, has been celebrated by realizing three summer solstice markers.

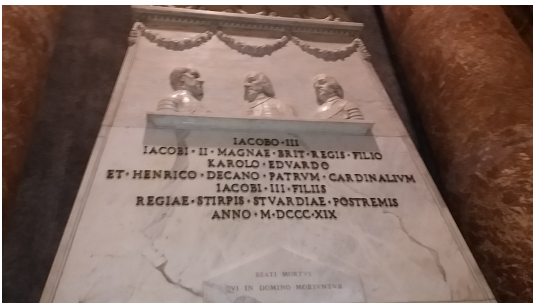

Fig. 2. The cenotaph of King James III in St. Peter's Basilica, were he is buried.

Fig. 3. Maria Klementyna Sobieska: the same image used in her cenotaph, in St. Peter's Basilica, in front of James III (painter Martin van Meytens, according to Wikipedia 2021.

3. Fitting the three positions with one hyperbola

The giant pinhole meridian line has been somewhat reproduced in a school environment, with the possibility to mark the soil with chalk and to bring many measurements with the meter, that are impossible in the Basilica. The hyperbolic paths of the Sun's shadow on the floor showed clearly the change of curvature from North to South at the spring equinox. The same method developed to fit the equation of the hyperbola to the shadow's positions of the cusp of a wall on the soccer field (Sigismondi, 2021, these Proceedings) has been applied on these three positions, marked by the historical ellipses.

These three ellipses have been considered as ancient observations, marked on the floor of the Basilica at their exact position.

The hyperbolic fits has been realized either with a parabola, either with an hyperbola: a millimeter accuracy in the positions of the Sun on the 1721 Summer solstice's path has been found in Santa Maria degli Angeli. The equation of the hyperbola of the 1721 summer solstice has been recovered with respect to the current solstice (2021) at 33.38 centesimal parts on the meridian line (on the body of Cancer in fig. 4). The meridian line is the y- axis, the origin is the 33.38 point on it, and the x-axis is perpendicular to the meridian line.

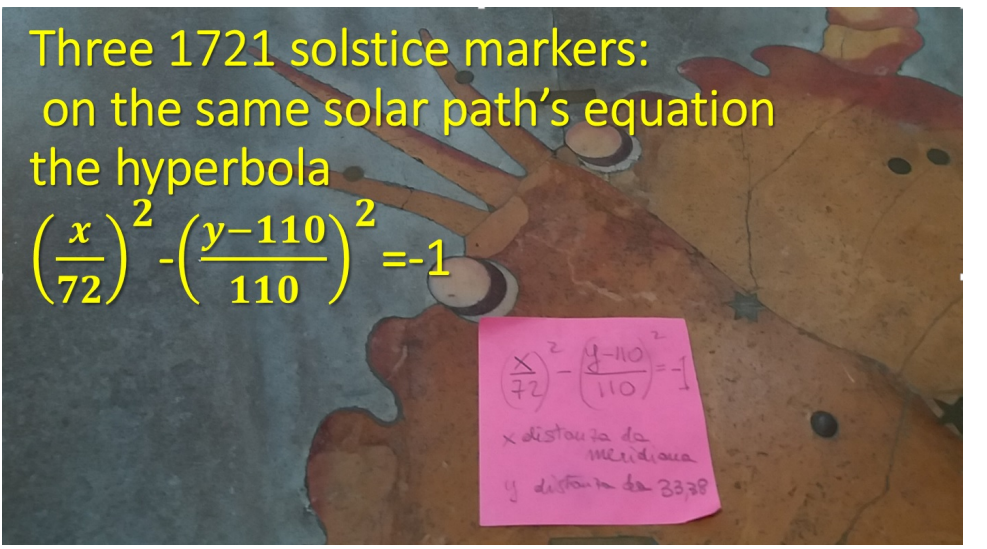

Fig. 4. The equation of the 1721 summer solstice's path as derived from the three markers. The parameters in the equation are expressed in meters.

4. Obliquity variation in three centuries

In 2021 the difference of Earth orbit's obliquity has been evident after 3 centuries, as a shift of 15 mm (fig. 5). The brass' profile is the 1721 one, while the luminous disk is the 2021 solar position. The new pinhole installed for the 2018 IGEA[a] campaign[9] has the same position along the meridian axis of 1702.

Fig. 5. Obliquity meter: differential measure of June 20, 2020 compared with 1721 at the Summer solstice. The image of the Sun is formed over the Queen's marker, the second in the sequence.

[a]IGEA standing for Informatized Geometric Ephemerides for Astrometry, started on October 27, 2018 and was named in honor of Igea Contessa (1918 Oct 27-2009 Dec 11)

Fig. 6. The marble marker with the inscription. A pencil shows its dimension.

5. Conclusions: High science in *Roman Settecento*

It is natural that the policy of the popes during the life of James III Stuart was oriented toward the restauration of the catholic dinasty at the throne, and Francesco Bianchini as close friend of Clement XI collaborated to this policy. The title of the new work of J. L. Heilbron (to appear in 2022) dedicated to Bianchini seems not to depart significantly from his approach in *The Sun in the Church* of 1999, with *tranchant* sentences on the papal policy of 1700. This paper along with the other one concerning the aberration of Sirius and the Equation of time in 1703 complete a 20 years' cycle of measurements and studies on the meridian line of St. Maria degli Angeli, inspired by Heilbron's book (1999), but in the direction of showing the prestige and the accuracy of roman astronomy, on the cutting edge of celestial mechanics of the eigtheenth century, instead of an easy *bavardage* on the court's intrigues as the forthcoming new title suggests.

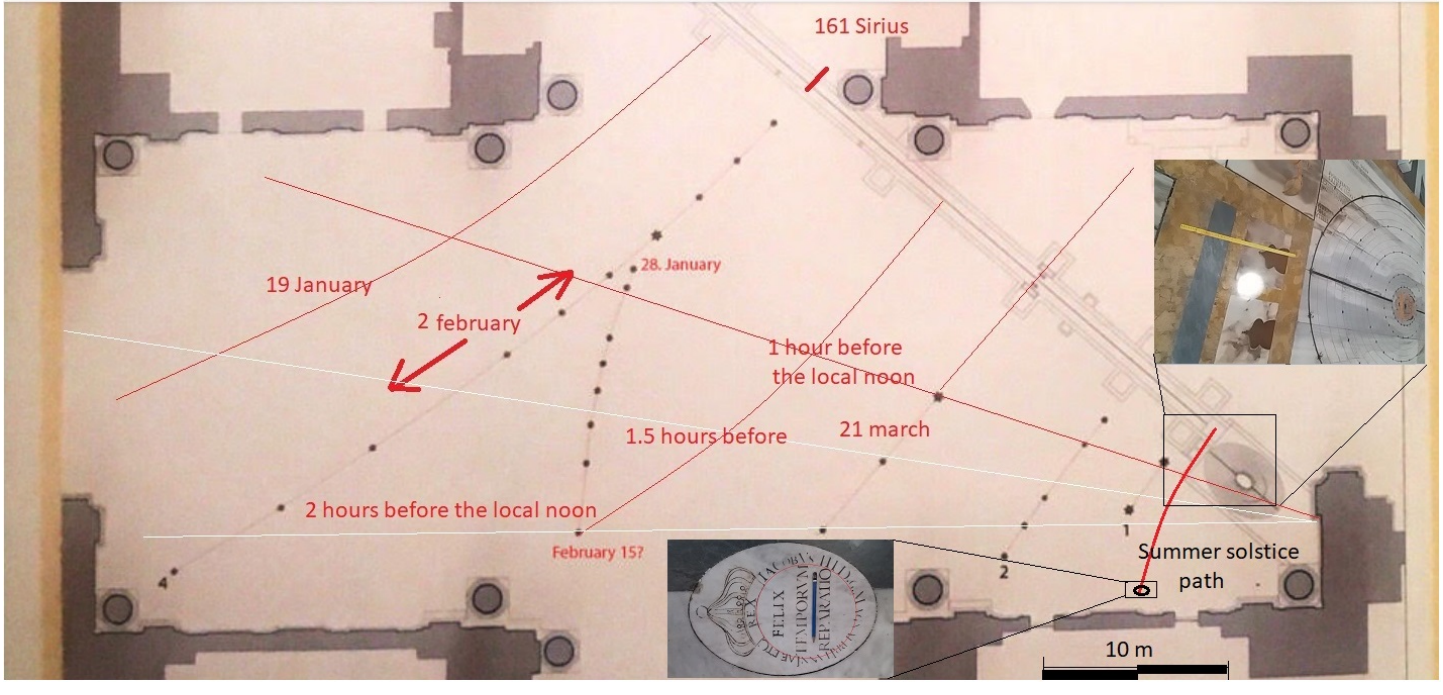

Fig. 7. Location on the map of the Basilica of the three markers.

Fig. 8. The Sun between the two brass markers, and the boreal line with the ellipses of the Jubilee years.The great meridian line starts on the left of this photo, taken on 4th July 2021 at 13:01. The Sun moves left in this photo, from the King's to the Queen's marker.

Fig. 9. The Sun's image appeared just after the King's marker on July 3rd 2021 at 12:58. It is the King's one because it was hit first by the Sun. Nowadays the Sun does not illuminates parts of the floor of the Basilica from the pinhole, after the intervents of Luigi Vanvitelli in 1750, which obscurated with a decorative arch the pinhole. Roger J. Boscovich cut the arch in correspondence of the meridian line, and the above image of the Sun is appearing from this cut.

d.treagust@curtin.edu.au

The Einstein-First project is designed to resolve a conflict between modern science and the science taught at school, which is a significant cause of students' negative attitudes to STEM. Our program resolves these contradictions by teaching our best understanding of the universe, dubbed Einsteinian Physics, from an early age. We use models and group activities in a carefully crafted 8-year learning progression, to give students a basic understanding of the language and concepts describing our physical universe, from quarks to the big bang. Einstein-First works with teachers to develop courses, lesson plans and training workshops. These components all contribute to curriculum trials where student learning and attitude outcomes can be assessed. Every trial of curriculum modules or short intervention programs has yielded exciting, positive outcomes including surprising gender equalising effects and benefits for less academic and disadvantaged students. There are multiple classroom trials in place in local partner schools. In this paper we present an overview of the Einstein-First program and give examples of the ability of students from age 8 to 12 to comprehend modern scientific concepts.

Keywords: Einsteinian Physics; Science Education

1. Introduction

The experimental educational project called Einstein-First is a collaboration of scientists and educators who are concerned about the current school science curriculum which: a) includes misconceptions b) is irrelevant c) does not meet needs of people in the modern world. The existing science curriculum completely ignores the modern, awesome discoveries of relativistic astrophysics and makes teaching of modern concepts impossible.[1] For example, the first direct observation of gravitational waves in 2015 and the rapid development of gravitational wave astronomy, have provided a new spectrum for understanding the Universe as well as providing evidence to support the theory of relativity predicted by Einstein a century ago.[2] The discovery of gravitational waves has inspired new developments in areas such as optomechanics, the quantum mechanics of gravitational wave detectors, as well as observational investigations of black holes, neutron stars and heavy element nucleosynthesis.[3] Also, in the last century, science has given us knowledge of the tiniest things in

the universe and vast distances to the edge of the visible universe, and with it, the modern technologies on which our lives depend. Recently, in 2021, the Nobel prize in physics was awarded for modelling of complex systems related to climate change and the discovery of the interplay of disorder and fluctuations in physical systems from atomic to planetary scales.[4] These are all examples of modern discoveries that are not included in the current Australian science curriculum.

Primary and secondary school science curricula still rely on outdated scientific paradigms of traditional Newtonian physics based on classical concepts, research methods, postulates, and standards. Thus, the revelations of modern science and even the vocabulary of modern physics is denied to early and middle school students. The consequences of this situation may be that students are not able to digest the core concepts related to new discoveries during higher level of schooling with the subsequent loss of students' interest in the science presented as being irrelevant to real life events across the world.[5] Einsteinian physics, encompassing both general relativity and quantum mechanics provides a better understanding of modern reality and is relevant to students' everyday life. Unfortunately, general relativity and quantum mechanics have typically been reserved for specialist high school physics subjects and mainly taught at the tertiary level. For the overwhelming majority of students, modern physics may be inaccessible. Year 10 is the last year of compulsory science in Australian schools and can be the last opportunity for the education system to foster scientific literacy on our school population.

One reason for keeping children away from Einsteinian physics is because these concepts are considered to be difficult to comprehend at an early age. In 2004 Kathleen E. Metz stated "Science frameworks have frequently limited the content targeted for the early grades to such simple and concrete ideas that they offer little explanatory power. Even pre-schoolers seek explanation".[6] Einstein-First has demonstrated, through numerous studies and peer reviewed published results that Einsteinian physics can be successfully integrated into a curriculum at all levels of schooling from Year 3 to Year 10[7–11] when taught at the appropriate level. These results concur with the statement of the distinguished Harvard and Oxford educator Jerome Bruner that: "Any subject can be taught effectively in some intellectually honest form to any child at any stage of development".[12] In a spirit of Bruner, this project is designed to test the introduction of general relativity and quantum mechanics to children in a manner that will be powerful, fun and mind-expanding.

Another reason for the opposition to the teaching of Einsteinian physics in primary and lower secondary school is the false belief that advanced mathematics is a prerequisite for understanding modern physics. While advanced mathematics is not required, new mathematical skills are important. To allow children to understand the scales of the universe from atoms to galaxies, we need to also rethink mathematics education. Understanding the main concepts of Einsteinian Physics requires the development of students' mathematical concepts in three important ways: a) understanding the vast range of scales of the universe, which necessitates the development

of logarithmic thinking[13] b) the development of probabilistic thinking,[14] and c) the development of vector understanding.[15] These skills also have importance for understanding the financial world, global issues such as environmental problems, gambling and risks, and skills such as drone navigation.

Overall, education needs to remain relevant in order to impart knowledge of the modern world to the new generation. Furthermore, physics practitioners, who are at the forefront of modern investigations and discoveries, should be part of the educational partnership to ensure that contemporary scientific trends find their way into the school curriculum at every level. For that reason, "Sharing our best understanding of reality with kids" is the driving motivation of the Einstein -First project.

Our vision is that every student, by Year 10, the last compulsory year of science in Australia, will have knowledge of our best understanding of the nature of space, time and gravity, the quantum world of atoms and photons, and the universe from quarks to the big bang. We want to give students the language of science so that no one need suffer from science illiteracy. We want students to know the epic stories of the struggle to understand the universe, which we teach through plays, songs and games. We want two common phrases to become obsolete: "I can't understand science" and "You must be a genius to understand that stuff".

In 2019 the Australian Research Council funded a five-year project to develop an integrated Einsteinian Physics-focused curriculum across primary and secondary schools. An early outcome has been the book *Teaching Einsteinian Physics in Schools*, published in August of 2021.[16] To produce this book, we had to find out if young children could understand Einsteinian concepts. To do this we developed activities that would make Einsteinian concepts intuitively understandable. Then we conducted trials and gathered evidence, which showed that young children comprehended and enjoyed learning Einsteinian concepts.[17] The successes of the Einstein-First program has been demonstrated also through studies on; long-term impact,[18] gender benefits,[19] advantages for underachieving students[7,9] and positive teacher response.[20] Particularly with further trials we made three specific exciting discoveries:

(1) the less-academic students developed knowledge and understanding on a par with the more-academic students[7,9],
(2) students' attitudes to science improved strongly[17] and
(3) girls entered programs with less knowledge than boys but on completion had performance on a par with boys when learning more difficult concepts.[19]

The goal of Einstein-First is to modernize school science so that all students by Year 10, should have a basic understanding of the science behind modern technology, and the universe, from its tiniest components like atoms to vast structures like our Milky Way galaxy.

2. Einstein–First Overview

2.1. *Einsteinian physics*

In the early 1900's, discoveries by Albert Einstein and others revolutionised our understanding of physical reality. Evidence of the existence of photons led to quantum theory, and evidence that space is curved confirmed Einstein's general theory of relativity. Today, the theories we term Einsteinian Physics have been tested to exquisite precision, with the crowning glory being the recent detections of gravitational waves from colliding black holes and neutron stars, the 2017 Nobel Prize announcement and the three million dollar Breakthrough Prize shared by the gravitational waves discovery team, including four members of this project. The Einsteinian conceptions of space, time, gravity, light, energy and matter represent our deepest understanding of the Universe. Einsteinian Physics unleashed the technological revolution that underpins modern civilisation, forming the basis for computers, mobile phones, GPS and more. Gravitational wave detectors themselves harness concepts of space as a rippling, stretchable fabric, as well as the quantum properties of light and quantum uncertainty, which underpins their exquisite measurement technology.

The Einstein-First project aims to introduce Einsteinian Physics starting with Year 3. For this age, we focus on Einsteinian concepts of understanding the atomic nature of matter (Brownian motion), Einstein's proof that light comes as photons, photons have momentum and that heat in solids fluctuates as phonons (1917).

2.2. *Educational contradictions*

Einstein and his collaborators revolutionized our understanding of space, time, light, matter and gravity. Einsteinian Physics, developed about 100 years ago, has extraordinary explanatory power, and has enabled the development of technologies that revolutionised our lives such as mobile phones, cameras, solar panels, and medical imaging. Despite the power and importance of Einsteinian physics, children from Primary to Year 10 are taught 19^{th} century physics concepts in school, sometimes implicitly and sometimes explicitly. Hence the modern understanding of physical reality is withheld from the majority of students. The few students who do specialise in physics in Year 11 and Year 12 have to learn a new paradigm. This situation is grossly inefficient and leads to the general view that science is a domain for experts alone.

2.3. *Children's awareness*

Children pick up bits of modern science from media, the internet, and children's books but at school almost all of this relevant, modern and exciting science is withheld. From an early age most have heard of time warps, black holes and $E = mc^2$, but school learning contradicts all this. They currently teach that time is absolute, geometry is Euclidean, and mass does not change with energy. Children are aware that most of their school science is "old stuff" because there is more

modern science on *The Simpsons* than there is in the classroom. Hence students see school science as being boring and irrelevant.

Many teachers and schools do wonderful things with robots, coding and more, to enhance STEM education but usually within the outdated curriculum. We realized that we needed to address the fundamentals and start at primary school when students are best able to assimilate the new language of Einsteinian physics.

2.4. *How the contradictions in science education arose*

New theories that change our way of thinking are always hard to get used to. When the new physics was discovered, people claimed that the new theories were much too complex for ordinary people to understand. Physicists did little to dispel these views and curriculum designers accepted them. This combined with early views of education theorists (now dispelled by recent research[21,22]) that children cannot learn abstract concepts. In the 1930s atoms, photons, electrons and curved space were all newly discovered concepts that were inferred but not directly observed.

However, in the modern era all the things that were conceptual have changed their status: they are now observed, imaged and part of observational reality, and a few clicks away on the internet. Because physical science underpins everything from biology to plate tectonics, the lack of conceptual foundations means that the key motivational content of science — the ongoing stream of scientific discoveries – is not taught and hence students adopt a negative attitudes towards existing science curricula. Also, the few students who specialise must suffer an abrupt shift in paradigm from Newtonian to Einsteinian physics that makes their learning more difficult.

2.5. *International partnerships*

There is widespread concern that school curricula do not meet the needs of modern children. The development of the Einsteinian Physics curriculum started with a collaboration of Australian and multinational teams. Currently, there is a lot evidence from different groups around the world, including our partner researchers, that middle school and even primary school children can understand concepts of mass and gravity,[23] theory of relativity,[24] theory of atoms[25,26] and the connection between wavelength and momentum.[27] However there is no evidence in the literature that any school jurisdictions in the world are embracing the need for modernising the curriculum. This modernization includes both the physics concepts and the associated mathematical concepts needed to understand the Universe.

2.6. *A contradiction-free curriculum*

We are working to overcome the deep-seated conflict between children's learning in schools and the current science that underpins all modern technology. During the years of rapid childhood learning when minds are most fluid, children are learning obsolete 19^{th} century concepts that contradict modern science. Awesome discoveries

are withheld because both the concepts and language are inaccessible to young learners. Here are some examples:

(1) In Year 3 students learn about heat without reference to atoms because atoms are considered too conceptual, and not to be taught until children are 12-14 years old.
(2) Children are taught that mass is always conserved in chemical reactions despite the fact that recent conceptually simple experiments are able to measure the mass loss of an atom when it emits a photon, a consequence of Einstein's $E = mc^2$.
(3) Students learn implicitly that time is absolute even though our GPS navigators must correct for the time warp between Earth and the satellites' orbits.

The modernization of the school curriculum requires the integration of new knowledge with innovative approaches. To identify a new learning methods and activities, the Einstein-First project encompasses two key ideas: a) "never underestimate the child's abilities to absorb new information and cope with new ideas",[28] and b) the central concept of the theory of constructivism in education that is "complex ideas can be taught at a simplified level first, then re-visited at more complex levels later on".[12]

Our learning framework is divided into the three stages.

1. Primary School: Opening minds to Einsteinian concepts and creating expectations. We use qualitative and experiential activity-based learning to emphasise the language of Einsteinian Physics.
2. Middle School: Basic understanding of Einsteinian concepts, using semi-quantitative activity-based learning, including the use of graphs and simple calculations.
3. High School: Developing a quantitative understanding of Einsteinian concepts, as well as a quantitative understanding, that includes calculations.

Einstein-First is creating a seamless learning progression that begins in early primary school and is designed to ensure that every student develops an intuitive understanding of physical reality. Currently, Einstein-First is developing curricula for every school level from Year 3 to Year 10 as well as introducing the language of modern science in Year 2. The modules of curriculum are presented below:

Year 3	Atom frenzy and Hot stuff
Year 4	May the forces be with you
Year 5	Fantastic photons and Our place in the universe
Year 6	Electric world
Year 7	Warp spacetime: Gravity from the Earth to black holes
Year 8	From mc^2 to renewable energy
Year 9	Quantum world: quarks to photons
Year 10	Climate change to cosmology

2.7. *How have we made Einsteinian physics accessible? Models, toys, analogies and drama*

Einsteinian physics is imagined by most primary and secondary school teachers to be impossibly difficult. This is because those who learnt the 19^{th} century paradigm cannot envisage ideas like space having a shape, and matter having properties of both waves and particles. Children, however, accept Einstenian concepts with ease when taught with appropriate models and activities.

In order to make modern physics understandable we use multiple, interactive methods that are discussed in detail here.

2.7.1. *Activities and toys*

Most of the universe is beyond the reach of our normal senses it is either, too big, too small or invisible. We need to find creative analogies and models so that concepts and ideas can become tangible. We understand and remember things not just with abstract thought, but with our bodies, by doing things. Furthermore, for all children toys are critical means of learning.

Our diversity of toys and models are simple, robust, and inexpensive. They allow students to learn complex concepts intuitively, mainly through group activities. For example, students roll steel balls around a central mass on a stretched lycra sheet (often called a space-time simulator). The 2D lycra sheet is our toy space-time. The balls orbit the central mass due to the curvature of the membrane caused by the central mass. These orbits resemble the orbit of planets around stars. The greater the central mass, the greater the curvature of space-time and the stronger the force of gravitation exerted on the orbiting bodies.

2.7.2. *Crossing boundaries, playing Einstein*

The discovery of Einsteinian physics was the culmination of centuries of enquiry by scientists all over the world. There were intellectual battles between scientists, notably between holists and atomists in the 19th century. The holists who believed that matter was smooth and continuous forever, lost the battle when conclusive evidence was found for electrons (1897), photons (1905) and atoms (1911). Bringing these human stories to life helps students understand the progress and process of science and shows science as an epic human endeavour. In our reading plays, often performed in drama lessons, inquisitive students mix with scientists from across the ages, enacting the process of discoveries. Characters such as Einstein, sing songs and recite aphorisms that help cement the Einsteinian vocabulary with fun and humor.

2.7.3. *Mathematics for the modern world*

To allow children to understand the scales of the universe from atoms and galaxies, we need to rethink mathematics education. Modern science understanding depends

on fundamental mathematical areas that go beyond primary school arithmetic. Einstein-First has introduced early activity-based learning in three crucial areas: huge and tiny (powers of ten), maths of arrows (graphical vectors), and maths of chance. In our use of mathematics we are creating seamless learning progressions that begins in early primary school, designed to ensure that everyone develops an intuitive understanding of concepts crucial for understanding, for example, the size of the whole observable universe, the electromagnetic spectrum and the quantum world. This mathematics also has social importance for understanding money, weather, risks and gambling. Starting at the youngest ages, we teach these topics with fun activities designed to open children's minds to ideas that mathematics is more than numbers, maths is easy, and maths is fun.

3. Methods of Einstein-First

In this section we present examples of four activities of Einstein-First methods to deliver concepts of modern science and associated mathematics concepts of probability, big and small numbers, and vectors.

3.1. *Early learning of powers of 2 and powers of ten by cutting up tape measure*

Exponential notation is essential to our ability to comprehend the scale of the Universe from the tiniest component to the Hubble volume. To introduce exponential notations we use a paper cutting activity. Students cut a one meter paper tape measure into repeated halves. Then they cut another one meter paper tape measure into tenth to learnt that ten powers of two are approximately three powers of ten. Then this exercise is mentally extrapolated to find how many times this process needs to be continued to reach the size of the atom.

3.2. *The entire Universe in a single book*

To introduce big and small numbers and the scale of the Universe we have developed a novel long-term activity consisting of the creation of a 130 page book called *Powers of the Universe*. All numbers describing the known Universe can be placed in this book. Each page is a power of ten. Line position on each page is designated for various quantities, all expressed in SI units. For example there are line bands for distances, masses, energy etc. Students use all possible methods (e.g., using Google) to discover numbers at all scales. For example, they start the book at the page labelled -37, while they indicate, that 10^{-37} is the rest mass of the neutrino. Page +90 shows the total number of photons in the Universe and page +2 is the mass of a human.

Through this activity, students investigate the scale of our universe and expand their knowledge and their ability to envisage big and small numbers.

3.3. *Children pushing a car to discover vector addition*

In order to introduce the concept of vectors at early age we use activity in which students push their teacher's car. Students in the class altogether push a car on a flat car park under the supervision of a class teacher. Teachers use creative questioning to encourage all students to contribute answers about what happened and why it happened. In this way, students represent the pushing forces by vectors and learn rules of head to tail adding vectors. Then we introduce the concept of the resultant. To reinforce the learning, students use magnetic arrows on magnetic boards to investigate the sum of the vectors from where they find out that the resultant is not dependent on an order of adding arrows.

3.4. *A boy and his atom. Feeling hidden atoms pattern*

The world's smallest movie *A boy and his atom* is used to introduce atoms and molecules, and how we are able to see and move them. Students watch a short video from IMB[29] and discuss how the Atomic Force Microscopy works. Students work in pairs. One student makes the image using playdough and toy atoms in a form of marbles and covers it with a piece of cloth. Then the other student determines the hidden pattern by feeling in the same way that an atomic force microscope "feel" when it scans a surface. Finally, the student draws a picture of the pattern.

All of these activities mentioned above along with others were included in recent short programs for students from Year 3 to 8.

4. Four Recent Programs

The Einstein-First project has held short programs in schools over the previous six months to teach students about atoms and molecules, heat, forces, light and gravity. Group activities, hands-on learning and team competitions were all parts of the programs. Students' attitudes and knowledge were assessed using pre- and post-questionnaires that students completed on the first and last day of the programs. Assessments of the attitudes and knowledge were administrated for 15 minutes before and after the programs. Every lesson was delivered using the following method:

a) The first 15 minutes were used to review what they had learnt in the previous lesson and to introduce the idea they would be learning that day;
b) The main part of the lesson was dedicated to the associated activity and concepts; and
c) The final 15 minutes were set out for discussion or completion of the worksheets.

4.1. *Discovering black holes*

This four-week, eight-hour program was designed for motivated Year 7 and Year 8 students from various schools. This program had a total of 20 students, including a

6-year-old gifted student). The program was presented by current PhD students involved in the Einstein-First project. Each two hour session consisted of Einsteinian physics concepts as well as the mathematics that accompanied them. By doing activities on a space-time simulator (see section 2.7.1), students visualized the concept of gravity, black holes, and deflection of light. Students summarised their learning with the following phrase *"Space-time tells matter how to move; matter tells space-time how to curve."*

All of the above activities, as well as others in the program, require the development of mathematical skills to comprehend both big and small numbers. Understanding big and small numbers aids in comprehending the nature of supermassive black holes and how little displacements in the interferometer arms are essential to detect gravitational waves. For example the activity described in Section 3.1 was used for understanding powers of ten for these numbers.

4.2. *How big is an atom? How small is a light year?*

Twenty six Year 5 and 6 students participated in a four-session program on big and small numbers. The lessons were delivered by a mathematics teacher in the presence of the PhD student who developed the program. Each session lasted 1 hour, teaching mainly mathematics associated with Einsteinian physics. The main goal of the program was to teach students about the scale of the universe and how to use powers of ten to understand big and small numbers as described in Sections 3.1 and 3.2. Students also took part in a reading play called "Ten times Alice" in which the main character eats magic cookies or a magic liquid to grow ten times smaller or bigger than her companions. This play was created for students to practice proportional reasoning and multiplication by 10.

4.3. *Vectors and forces*

This short program was aimed at Year 4 students. The main goal of the program was to give an understanding of how vectors are used in physics and addition of vectors. There were 2.5 sessions that were presented to 27 students. The program was presented by the leader of the Einstein-First project with assistance of a current PhD student. Each session lasted 90 minutes and encompassed concepts of forces and geometry associated with them. We used the activity presented in Section 3.3 to practice vector addition and the concept of a resultant. After, children applied the ideas of vectors pulling wooden blocks with rubber bands in different direction to find the final movement (Fig. 1). The program also included activities with balance, for example, balancing a big wooden ruler horizontally on one finger to understand conception of the resultant.

4.4. *Atom frenzy*

Twenty-four Year 3 students participated in the 12-session atoms and molecules program delivered by the project's senior member and Phd student. Each session was

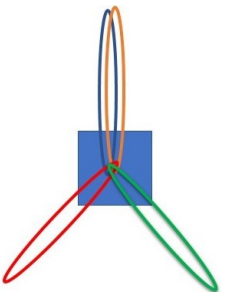

Fig. 1. Each coloured loop above represents a rubber band being pulled by an external force. Students are tasked with finding the resultant of four forces applied to wooden block with rubber bands as detailed in Section 4.3.

90 minutes and delivered through engaging, hands-on activities. We used various methods of understanding of atoms from children acting as atoms to boxes of balls that represent atoms, states of matter and heat. Students learnt three molecules H_2O, CO_2, O_2, N_2, using tennis and ping-pong balls with magnets inside representing toy atoms.

5. Results and Discussion

The section presents some outcomes of the programs described in Section 4.

5.1. *Results from the programs "Discovering Black Holes" and "How big is an atom? How small is a light year?"*

Students' understanding of the exponential function, writing numbers in scientific notations, and calculations significantly improved. Fig. 2 presents the results from the programs described in the sections 4.1 and 4.2. We evaluated students' choice to write big numbers such as *a) one hundred b) one million c) one trillion and d) one billion* before and after interventions. We discovered that just 26% of students chose powers of ten to write the numbers before the program. However, after the program, all students were able to write the numbers in powers of ten accurately. According to the research findings from program 4.2, 73% of participants chose to write numbers in powers of ten, compared to only 12 percent at the start.

Overall, we found that primary school students were capable of using powers of ten in reasoning about big numbers.

5.2. *Results from the programs "Forces and vectors"*

Results from the program 4.3 is shown in Fig. 3. A question was asked about force vectors and resultant to evaluate what they had learnt from the car-pushing activity (3.3). More than 80% of students accurately added vectors after the program.

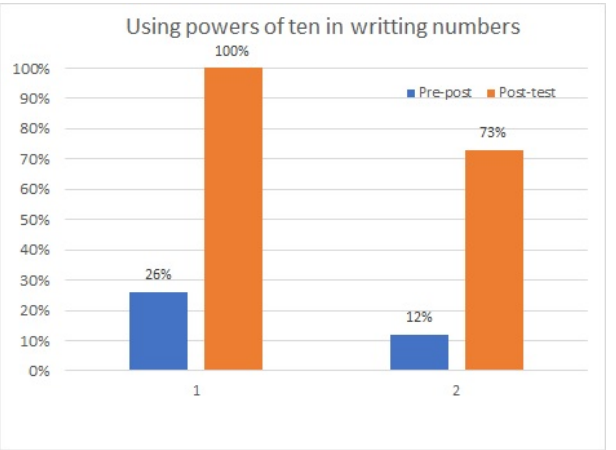

Fig. 2. The percentage of students using powers of ten in writing numbers before and after programs 1) 4.1 and 2) 4.2.
Q: Using powers of ten (or otherwise) write the numbers below: a)one hundred b) one million b) one billion c) one trillion.

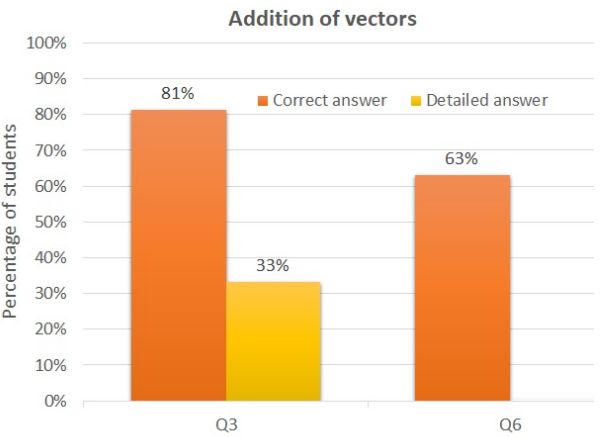

Fig. 3. The percentage of students, giving correct answers on the questions about arrows addition after program Vectors and Forces.
Q3: Eight children pushed the teacher's car, but seven children pushed in the opposite directions. Draw the resultant arrow? What was the total Force?
(Orange light indicates that one answer is correct. Yellow indicates that both answers are correct and detailed picture is provided.)
Q6: Four kids pull the wooden block in different direction using four rubber bands (the picture was provided) In what direction will the block move? Draw an arrow for the direction.

However, only 33% of students were able to determine the resultant of two opposing forces.

Q6 is an extension of Q3, indicating that 63% of students can add four arbitrary vectors to determine a resultant applied to wooden block with rubber bands (Fig. 1)

and its final movement. The graph shows that the vast majority of student can grasp the notion of vectors and add them together.

5.3. *Results from the programs "Atom Frenzy"*

The results from the program 4.4 are shown in Fig. 4. Despite the fact that the Australian curriculum stipulated that atoms should not be introduced until the age of 14, 40% of students had a basic understanding of atoms prior to the program. Figure 3 indicates that 83% of students were able to answer *what is an atom?* after the program, compared to only 40% of students before the program. In addition, 75% of students expanded their answers by referencing atom structure, naming subatomic particles, or thinking them to be a part of molecules. Also 87.5% of students correctly identified atom number six as a carbon atom, drew its structure, and presented it as a component of carbon dioxide.

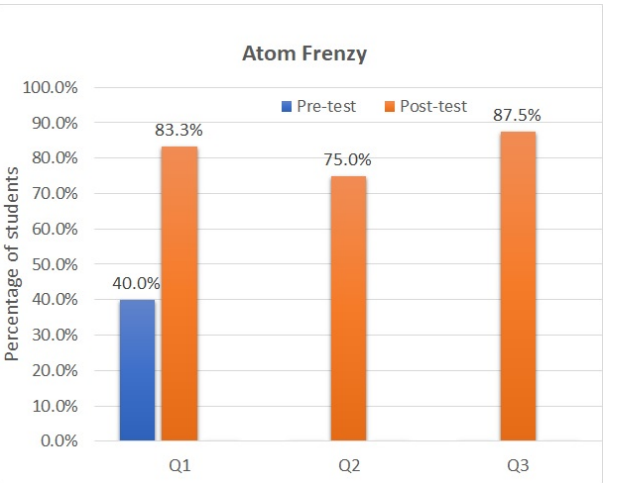

Fig. 4. The percentage of students, giving corrected answers on the questions about atoms before and after program Atom Frenzy?
Q1: Describe what you think an atom is.
Q2: Write down three things you know about atoms and the things they are made of.
Q3: Draw a picture of atom number 6.

Overall, outcomes of programs show that, the students demonstrated a considerable gain in their grasp of atoms, vectors, and the use of powers of ten as a technique of manipulating big and small numbers.

6. Conclusion

We have emphasized the vital necessity to rethink the science curriculum and mathematics associated with it. It has become obvious to introduce ideas that students

find interesting and engaging especially because of the widespread decline of students' attitude to science. Einstein-First is an innovative experimental education project rethinking the physical science curriculum by developing an innovative approach for introducing Einsteinian Physics in school starting at an early age. We have given the general principle of our approach and examples of methods used to make the physics accessible to teachers and students alike. We have presented some results from recent short interventions, that have shown that students aged 11 to 14 years have shown competency with power of ten notation. Secondly, we have demonstrated that students aged 10 obtain high scores in understanding the concept of vectors, including vectors addition. Within the larger Einstein-First project, learning progressions of curricula have been created, starting with Year 3 and going up to Year 10. Einstein-First also considers Year 2 to be the pre-learning stage for modern physics vocabulary. Models and analogies, drama plays, and mathematical support modules are suggested to make concepts of modern physics digestible and fun to learn. It has been demonstrated that even short interventions can bring high outcomes in learning Einsteinian physics in both primary and early-secondary schools.

Acknowledgments

We very much thank the anonymous teachers, who facilitated and taught in the programs presented here. This research was supported by Australian Research Council Linkage Grant LP 180100859.

Kundt spacetimes in the Einstein–Gauss–Bonnet theory

R. Švarc*, J. Podolský† and O. Hruška

Institute of Theoretical Physics, Faculty of Mathematics and Physics, Charles University, Prague, V Holešovičkách 2, 180 00 Praha 8, Czech Republic
*E-mail: *robert.svarc@mff.cuni.cz, †podolsky@mbox.troja.mff.cuni.cz*
www.mff.cuni.cz

Based on our recent results we present the complete class of vacuum solutions in the Einstein–Gauss–Bonnet gravity which admit non-expanding, shear-free and twist-free null geodesic congruence and thus form the Kundt family of geometries. We explicitly derive the field equations and classify their solutions into three distinct subfamilies. Algebraic structure of the Weyl tensor is determined and using the corresponding scalars entering the invariant form of geodesic deviation equation we discuss the specific local physical properties of the gravitational field constrained by the EGB theory. Moreover, we analyze interesting subclasses of such vacuum solutions, namely all geometries with constant-curvature transverse space, and the class of *pp*-waves admitting a covariantly constant null vector field.

Keywords: Einstein–Gauss Bonnet theory; Kundt spacetimes; exact solutions; *pp*-waves.

1. Introduction

The Einstein–Gauss–Bonnet (EGB) theory represents the first and simultaneously the simplest non-trivial contribution of the Lovelock gravities[1] extending the classic Einstein–Hilbert action into higher dimensions $D \geq 5$ and keeping the second order field equations. This theory also arises in various scenarios, e.g., as the heterotic string theory limit for low energies.[2,3]

In particular, the EGB vacuum action in D-dimensions reads

$$S = \int \left[\kappa^{-1}\,(R - 2\Lambda_0) + \gamma\, L_{GB}\right] \sqrt{-g}\;\mathrm{d}^D\mathrm{x}\,, \tag{1}$$

with the Gauss–Bonnet term defined as

$$L_{GB} \equiv R_{cdef}\,R^{cdef} - 4\,R_{cd}\,R^{cd} + R^2\,. \tag{2}$$

Here R stands for the Ricci scalar, R_{cdef} and R_{cd} are Riemann and Ricci tensors, respectively, Λ_0, κ and γ are theory constants. Obviously, for $\gamma = 0$ the standard Einstein–Hilbert action of the general relativity is restored. The least action principle, i.e., variation $\delta S = 0$, leads to the field equations in the form

$$R_{ab} - \tfrac{1}{2} R\, g_{ab} + \Lambda_0\, g_{ab} + 2k\, H_{ab} = 0 \qquad \text{where} \qquad k \equiv \kappa\gamma\,, \tag{3}$$

and

$$H_{ab} \equiv R\,R_{ab} - 2R_{acbd}\,R^{cd} + R_{acde}\,R_b{}^{cde} - 2R_{ac}\,R_b{}^{c} - \tfrac{1}{4}\,g_{ab}\,L_{GB}\,. \tag{4}$$

The aim of this proceeding contribution is to briefly summarize main results of Ref. 4, where we explicitly derived and analyzed the second order field equations (3)

in the case of so-called Kundt geometries,[5,6] see e.g. Ref. 7 for detail list of references, and compared properties of obtained EGB solutions with those extensively studied within general relativity.[8–11]

The Kundt geometries are defined via geometric assumption on existence of a specific affinely parametrized null geodesic congruence. In general, transverse deformations of such null congruence, generated by null vector field $\boldsymbol{k}$, are described by the optical scalars which characterize its twist, shear, and expansion, namely

$$A^2 = -k_{[a;b]}k^{a;b}\,, \qquad \sigma^2 = k_{(a;b)}k^{a;b} - \tfrac{1}{D-2}(k^{a}_{\ ;a})^2\,, \qquad \Theta = \tfrac{1}{D-2}k^{a}_{\ ;a}\,. \tag{5}$$

Then, the Kundt spacetimes are those which admit the congruence with all above optical scalars vanishing, i.e., we deal with the non-twisting, shear-free, and non-expanding geometries. Simultaneously, presence of the non-twisting vector field $\boldsymbol{k}$ implies existence of the spacetime null foliation[8] with $\boldsymbol{k}$ being normal (tangent). In such a case, it is straightforward to introduce adapted set of coordinates $\{r,\, u,\, x^p\}$ in D dimensions, where $u = \text{const}$ labels null hypersurfaces generated by $\boldsymbol{k}$, r is an affine parameter along the non-twisting null congruence, i.e., $\boldsymbol{k} = \partial_r$, and the $(D-2)$-dimensional transverse subspace with $u = \text{const}$ and $r = \text{const}$ is covered by spatial coordinates x^p with $p = 2, \ldots, D-1$. Using these adapted coordinates the general non-twisting line element can be written as

$$\mathrm{d}s^2 = g_{pq}(r,u,x)\,\mathrm{d}x^p\mathrm{d}x^q + 2g_{up}(r,u,x)\,\mathrm{d}x^p\mathrm{d}u - 2\mathrm{d}u\mathrm{d}r + g_{uu}(r,u,x)\,\mathrm{d}u^2\,, \tag{6}$$

where g_{pq} represents metric of the transverse space. Moreover, the shear-free condition implies

$$g_{pq} = \rho^2(r,u,x)\,g_{pq}(u,x) \qquad \text{with} \qquad \rho = \exp\Big(\int \Theta(r,u,x)\,\mathrm{d}r\Big)\,. \tag{7}$$

Finally, the non-expanding condition leads to the r-independent transverse space metric, i.e., $g_{pq} = g_{pq}(u,x)$. The most general Kundt line element can thus be expressed as

$$\mathrm{d}s^2 = g_{pq}(u,x)\,\mathrm{d}x^p\mathrm{d}x^q + 2g_{up}(r,u,x)\,\mathrm{d}x^p\mathrm{d}u - 2\mathrm{d}u\mathrm{d}r + g_{uu}(r,u,x)\,\mathrm{d}u^2\,. \tag{8}$$

Moreover, in our contribution[4] we assume simplification corresponding to $g_{up} = 0$, i.e., our metric ansatz takes the form

$$\mathrm{d}s^2 = g_{pq}(u,x)\,\mathrm{d}x^p\mathrm{d}x^q - 2\mathrm{d}u\mathrm{d}r + g_{uu}(r,u,x)\,\mathrm{d}u^2\,, \tag{9}$$

where the metric functions g_{pq} and g_{uu} have to be specified by the field equations (3).

Finally, let us briefly mention the most important members of the Kundt family of spacetimes studied within Einstein's general relativity. Definitely, the prominent role is played by spacetimes admitting a covariantly constant null vector field, which can be associated with $\boldsymbol{k}$, leading to all optical scalars vanishing. These *pp*-wave spacetimes were introduced by Brinkmann[12] in the context of conformal mapping. On the level of Kundt line element (8) this corresponds to all metric functions being r-independent. The spacetimes providing vanishing scalar curvature invariants of all

orders (VSI spacetimes)[13] also belong to the Kundt class and their metric functions have to be of the form

$$g_{pq} = \delta_{pq}\,, \quad g_{up} = e_p(u,x) + r\, f_p(u,x)\,, \quad g_{uu} = a(u,x)\, r^2 + b(u,x)\, r + c(u,x)\,. \tag{10}$$

Moreover, the Kundt geometries include also various direct product spacetimes such as Bertotti—Robinson, Nariai, and Plebanski—Hacyan backgrounds, see e.g. Chap. 7 in Ref. 9, or toy models for null particles with internal spin called gyratons independently discovered by Bonnor[14] and Frolov.[15]

2. EGB field equations in the Kundt case

Let us analyze the specific constraints on the Kundt geometry (9) implied by the EGB field equations (3). These can be rewritten in alternative form

$$R_{ab} = \frac{2\Lambda_0}{D-2} g_{ab} - 2k\left(H_{ab} - \frac{g_{ab}}{D-2} H\right) \qquad \text{with} \qquad H = g^{ab} H_{ab}\,. \tag{11}$$

Calculating all the curvature tensors we find that the rr and rp components of (11) are identically satisfied and the only conditions we have to discuss are

$$R_{ru} = -\tfrac{2\Lambda_0}{D-2} - 2k\left(H_{ru} + \tfrac{1}{D-2} H\right), \qquad R_{up} = -2k\, H_{up}\,,$$
$$R_{pq} = \tfrac{2\Lambda_0}{D-2}\, g_{pq} - 2k\left(H_{pq} - \tfrac{g_{pq}}{D-2} H\right), \qquad R_{uu} = \tfrac{2\Lambda_0}{D-2}\, g_{uu} - 2k\left(H_{uu} - \tfrac{g_{uu}}{D-2} H\right).$$

In particular, we obtain:

- ru-component connects the transverse space geometry described by the metric $g_{pq}(u,x)$ with the theory constants Λ_0 and k, namely

$$ {}^S\!R - 2\Lambda_0 + k\left({}^S\!R^2_{klmn} - 4\, {}^S\!R^2_{mn} + {}^S\!R^2 \right) = 0\,, \tag{12}$$

  where the superscript ^{S} denotes quantities calculated using the $(D-2)$-dimensional metric g_{pq}. Moreover, in the general relativity limit corresponding to $k = 0$ the transverse space Ricci scalar ${}^S\!R$ has to be a constant, i.e., ${}^S\!R = 2\Lambda_0$.

- pq-component generically provides relation between the transverse space geometry and the r-dependence of the metric function g_{uu} via relation

$$\begin{aligned} &Q_{pq}\, g_{uu,rr} + {}^S\!R_{pq} \\ &\quad + 2k\big({}^S\!R_{pq}\, {}^S\!R - 2\, {}^S\!R_{pmqn}\, {}^S\!R^{mn} \\ &\qquad + {}^S\!R_{pklm}\, {}^S\!R_q{}^{klm} - 2\, {}^S\!R_{pm}\, {}^S\!R_q{}^m \big) = 0\,, \end{aligned} \tag{13}$$

  where Q_{pq} is a *fundamental quantity* important for the further discussion defined as

$$Q_{pq} \equiv -\tfrac{1}{2}\, g_{pq} + k\left(2\, {}^S\!R_{pq} - {}^S\!R\, g_{pq}\right). \tag{14}$$

  To obtain a particular constraint we evaluate the *trace* of (13), namely

$$-Q\, g_{uu,rr} = 4\Lambda_0 - {}^S\!R \tag{15}$$

with

$$Q \equiv g^{pq}\, Q_{pq} = -\left[\tfrac{1}{2}(D-2) + k(D-4)\, {}^{S}R\right]. \tag{16}$$

Obviously, the further discussion has to be split into three distinct cases, namely $Q \neq 0$, and $Q = 0$ with $Q_{pq} \neq 0$, or $Q_{pq} = 0$. In Einstein's theory we have $Q \neq 0$ and the condition (15) can be simply integrated to obtain the specific r-dependence of g_{uu}.

- *up*-component represents constraint on the spatial dependence of the metric function g_{uu} combined with the admitted u-dependence of the transverse space metric g_{pq},

$$\begin{aligned} Q_{pn}\, g^{nm}\big(g_{uu,rm} - 2g^{kl} g_{k[m,u||l]}\big) \\ + 2k\big(-2\, {}^{S}R^{kl}\, \delta^{m}_{p} + {}^{S}R_{p}{}^{kml}\big) g_{k[m,u||l]} = 0\,, \end{aligned} \tag{17}$$

where the symbol $_{||}$ denotes covariant derivative on the transverse space.

- *uu*-component restricts the possible amplitudes of Kundt gravitational waves typically encoded in the second covariant derivative $g_{uu||pq}$. The condition becomes

$$\begin{aligned} Q^{pq}\big(g_{uu||pq} + g_{pq,uu} - \tfrac{1}{2} g_{uu,r}\, g_{pq,u} - \tfrac{1}{2} g^{kl} g_{kp,u}\, g_{lq,u}\big) \\ + 2k\left(g^{ko} g^{ls} - 2\, g^{kl} g^{os}\right) g^{pq}\, g_{k[p,u||l]}\, g_{o[q,u||s]} = 0\,. \end{aligned} \tag{18}$$

The above equations represent a complete set of the constraints on the Kundt spacetime geometry implied by the EGB theory which have to be satisfied. In the following subsections we will discuss three particular cases defined with respect to the values of quantities Q, and Q_{pq}, respectively.

2.1. *Case $Q \neq 0$ – generic case*

In this non-degenerate case the pq-equation determines r-dependence of g_{uu} to be polynomial. Subsequently, the remaining equations are decoupled with respect to power in r. In particular,

- pq-equation trace (15) can be integrated to obtain

$$g_{uu}(r,u,x) = b(u,x)\, r^2 + c(u,x)\, r + d(u,x)\,, \tag{19}$$

where

$$b = \frac{4\Lambda_0 - {}^{S}R}{(D-2) + 2k\,(D-4)\, {}^{S}R}\,. \tag{20}$$

With g_{uu} in hand the pq-equation restrict the transverse space geometry,

$$\begin{aligned} &\big[(D-2) + 4k(D-4)\big(1 + k\, {}^{S}R\big)\, {}^{S}R + 16k\Lambda_0\big]\, {}^{S}R_{pq} \\ &- \big(1 + 2k\, {}^{S}R\big)\big(4\Lambda_0 - {}^{S}R\big) g_{pq} \\ &- 2k\big[(D-2) + 2k(D-4)\, {}^{S}R\big]\big(2\, {}^{S}R_{pmqn}\, {}^{S}R^{mn} - {}^{S}R_{pklm}\, {}^{S}R_{q}{}^{klm} \\ &\qquad + 2\, {}^{S}R_{pm}\, {}^{S}R_{q}{}^{m}\big) = 0\,. \end{aligned} \tag{21}$$

In general relativity ($k = 0$) this condition implies that the transverse space has to be the Einstein space, i.e.,

$$ {}^{S}R_{pq} = \frac{2\Lambda_0}{D-2}\, g_{pq}\,. \tag{22} $$

- *up*-component has a non-trivial part which determines the spatial dependence of $c(u,x)$ in (19) and couples it to the u-dependence of the spatial metric g_{km},

$$ \begin{aligned} & Q_{pn}\, g^{nm}\left(c_{,m} - 2g^{kl} g_{k[m,u||l]}\right) \\ & \qquad + 2k\left(-2\,{}^{S}R^{kl}\,\delta^{m}_{p} + {}^{S}R_{p}{}^{kml}\right) g_{k[m,u||l]} = 0\,. \end{aligned} \tag{23} $$

  Basically, in general relativity this equation plays very similar role.
- *uu*-component gives two independent conditions implied by its parts linear in r, and r-independent, respectively,

$$ Q^{pq}\big(c_{||pq} - b\, g_{pq,u}\big) = 0\,, \tag{24} $$

$$ \begin{aligned} & Q^{pq}\big(d_{||pq} - \tfrac{1}{2}\, c\, g_{pq,u} + g_{pq,uu} - \tfrac{1}{2} g^{kl} g_{kp,u}\, g_{lq,u}\big) \\ & \qquad + 2k\big(g^{mo} g^{ns} - 2\, g^{mn} g^{os}\big) g^{pq} g_{m[p,u||n]}\, g_{o[q,u||s]} = 0\,. \end{aligned} \tag{25} $$

  These constraints can be understood as restrictions on the spatial dependence of g_{uu}. In particular, it gives a possible amplitudes $d_{||pq}$ of the Kundt gravitational waves.

2.2. *Case* $Q = 0$ *with* $Q_{pq} \neq 0$

In principal, there may occur a peculiar situation in which $Q_{pq} \neq 0$ and simultaneously $Q = 0$. In such a case the condition $Q = 0$ implies a strict constraint on the transverse-space scalar curvature, namely

$$ {}^{S}R = -\frac{D-2}{2k(D-4)}\,, \tag{26} $$

which is a non-vanishing and constant. This case is clearly *not allowed* in the Einstein theory. Moreover, the trace of pq-equation gives

$$ {}^{S}R = 4\Lambda_0\,. \tag{27} $$

These two conditions combined together represent an interesting coupling of all theory parameters in the form

$$ 8(D-4)k\Lambda_0 = -(D-2)\,. \tag{28} $$

We can thus conclude that for any Gauss–Bonnet parameter $\gamma = k/\kappa$ there is a unique value of Λ_0. Simultaneously, parameters k and Λ_0 must have opposite signs and none of them can be vanishing. Finally, since $Q_{pq} \neq 0$, the pq-equation has to be satisfied for every pair p and q which again implies at most quadratic r-dependence of g_{uu} and thus all remaining equations are similar to those of the previous case.

2.3. *Case $Q_{pq} = 0$ implying $Q = 0$*

As in the previous case $Q = 0$ implies relation between the theory constants,

$$8(D-4)k\Lambda_0 = -(D-2) \quad \text{and} \quad {}^{S}R = 4\Lambda_0\,. \tag{29}$$

However, the condition $Q_{pq} = 0$ strongly constraints the transverse-space geometry,

$${}^{S}R_{pq} = \frac{1}{4k}\,g_{pq} + \frac{1}{2}\,{}^{S}R\,g_{pq}\,, \quad \text{i.e.} \quad {}^{S}R_{pq} = \frac{4\Lambda_0}{D-2}\,g_{pq} \equiv -\frac{1}{2k(D-4)}\,g_{pq}\,. \tag{30}$$

In this degenerate case the $(D-2)$-dimensional transverse space has to be the Einstein space. Interestingly, this subclass of EGB vacuum solutions does not allowed a straightforward limit to the Einstein theory. The constraints implied by the field equations become:

- pq-equation restricts the transverse-space Riemann tensor as

$${}^{S}R_{pklm}\,{}^{S}R_{q}{}^{klm} = 2\big[2k(D-4)\big]^{-2}\,g_{pq} \equiv -\frac{1}{k(D-4)}\,{}^{S}R_{pq}\,, \tag{31}$$

  and the ru-equation becomes identically satisfied.
- up-equation significantly simplifies to the form

$$\big(-\tfrac{8\,\Lambda_0}{D-2}\,\delta^{m}_{p}\,g^{kl} + {}^{S}R_{p}{}^{kml}\big)\,g_{k[m,u||l]} = 0\,. \tag{32}$$

- uu-component constraints only the transverse metric g_{pq} and its u-dependence as

$$\big(g^{ko}g^{ls} - 2\,g^{kl}g^{os}\big)g^{pq}\,g_{k[p,u||l]}\,g_{o[q,u||s]} = 0\,. \tag{33}$$

Interestingly, the metric component $g_{uu}(r,u,x)$ remains *arbitrary function of all spacetime variables*. Moreover, for the spatial metric g_{pq} being u-independent the equations (32) and (33) are identically satisfied.

3. Analysis of the solution

In this section we summarize two methods employed in analysis of the general solution derived above. In particular, we discuss the structure of the Weyl tensor and describe relative motion of free test particles, respectively.

3.1. *Algebraic structure*

The higher-dimensional algebraic classification can be formulated in terms of the boost-weight irreducible components of any tensor with respect to a suitable null frame.[7,16] Such a frame in the case of Kundt geometries (9) takes the form

$$\boldsymbol{k} = \partial_r\,, \qquad \boldsymbol{l} = \tfrac{1}{2}\,g_{uu}\partial_r + \partial_u\,, \qquad \boldsymbol{m}_i = m_i^p\,\partial_p\,. \tag{34}$$

The Weyl tensor components sorted by their boost weights with respect to the generic null frame $\{\boldsymbol{k}, \boldsymbol{l}, \boldsymbol{m}_i\}$ are

$$\begin{aligned}
\Psi_{0^{ij}} &= C_{abcd}\, k^a\, m_i^b\, k^c\, m_j^d\,, & & \\
\Psi_{1^{ijk}} &= C_{abcd}\, k^a\, m_i^b\, m_j^c\, m_k^d\,, & \Psi_{1T^i} &= C_{abcd}\, k^a\, l^b\, k^c\, m_i^d\,, \\
\Psi_{2^{ijkl}} &= C_{abcd}\, m_i^a\, m_j^b\, m_k^c\, m_l^d\,, & \Psi_{2S} &= C_{abcd}\, k^a\, l^b\, l^c\, k^d\,, \\
\Psi_{2^{ij}} &= C_{abcd}\, k^a\, l^b\, m_i^c\, m_j^d\,, & \Psi_{2T^{ij}} &= C_{abcd}\, k^a\, m_i^b\, l^c\, m_j^d\,, \\
\Psi_{3^{ijk}} &= C_{abcd}\, l^a\, m_i^b\, m_j^c\, m_k^d\,, & \Psi_{3T^i} &= C_{abcd}\, l^a\, k^b\, l^c\, m_i^d\,, \\
\Psi_{4^{ij}} &= C_{abcd}\, l^a\, m_i^b\, l^c\, m_j^d\,. & &
\end{aligned} \tag{35}$$

Moreover, their irreducible components identifying specific algebraic subtypes are defined[16] as

$$\begin{aligned}
\tilde{\Psi}_{1^{ijk}} &= \Psi_{1^{ijk}} - \tfrac{2}{D-3}\delta_{i[j}\Psi_{1T^{k]}}\,, \\
\tilde{\Psi}_{2T^{(ij)}} &= \Psi_{2T^{(ij)}} - \tfrac{1}{D-2}\delta_{ij}\Psi_{2S}\,, \\
\tilde{\Psi}_{2^{ijkl}} &= \Psi_{2^{ijkl}} - \tfrac{2}{D-4}\big(\delta_{ik}\tilde{\Psi}_{2T^{(jl)}} + \delta_{jl}\tilde{\Psi}_{2T^{(ik)}} - \delta_{il}\tilde{\Psi}_{2T^{(jk)}} - \delta_{jk}\tilde{\Psi}_{2T^{(il)}}\big) \\
&\quad - \tfrac{4\,\delta_{i[k}\delta_{l]j}}{(D-2)(D-3)}\Psi_{2S}\,, \\
\tilde{\Psi}_{3^{ijk}} &= \Psi_{3^{ijk}} - \tfrac{2}{D-3}\delta_{i[j}\Psi_{3T^{k]}}\,.
\end{aligned} \tag{36}$$

The above quantities evaluated for the Kundt geometry (9) without employing any particular theory constraints imply:

- with respect to the natural null frame (34) the +2 and +1 boost-weight components Ψ_0 and Ψ_1 vanish identically and the analyzed spacetimes are *at least* of algebraic type II with $\boldsymbol{k} = \partial_r$ being a *double* degenerate Weyl aligned null direction (WAND),
- since $\Psi_{2^{ij}} = 0$, the geometry (9) is of the algebraic *subtype* II(d).

Moreover, the specific EGB theory restrictions derived in the previous section enter the discussion and may affect the Weyl tensor structure. We observe:

- in the generic case $Q \neq 0$ the type II(d) remains in general unchanged,
- the case $Q = 0$ with $Q_{pq} \neq 0$ specializes to II(ad) $\Leftrightarrow \Psi_{2S} = 0$, i.e.,

$$b = -\frac{{}^{S}R}{(D-2)(D-3)} = -\frac{4\Lambda_0}{(D-2)(D-3)} = \frac{1}{2k(D-3)(D-4)}\,, \tag{37}$$

- in the class $Q_{pq} = 0$ both the highest and the lowest non-trivial boost weights Ψ_2 and Ψ_4 contain *arbitrary* metric function g_{uu} and are thus in general non-vanishing. However, since the transverse space has to be the Einstein space we get $\tilde{\Psi}_{2T^{(ij)}} = 0$ which leads to the subtype II(bd).

Analogous discussion can be performed also for the Ricci tensor, see Ref. 4.

3.2. *Geodesic deviation*

To observe a physical nature of a given solution its useful to study relative motion of free test particles encoded in the geodesic deviation.[17] This is described the Jacobi equation

$$\frac{\mathrm{D}^2 Z^a}{\mathrm{d}\,\tau^2} = R^a{}_{bcd}\, u^b u^c Z^d\,, \tag{38}$$

where Z^a are components of the separation vector of nearby geodesics, $R^a{}_{bcd}$ is the Riemann curvature tensor, and u^b are components of the fiducial observer 4-velocity, i.e., $\boldsymbol{u} = \dot{r}\,\partial_r + \dot{u}\,\partial_u + \dot{x}^p\partial_p$. To obtain coordinate-independent information it is natural to project (38) onto a suitable orthonormal frame $\{\boldsymbol{e}_{(0)}, \boldsymbol{e}_{(1)}, \boldsymbol{e}_{(i)}\}$ associated with some particular observer where we assume $\boldsymbol{e}_{(0)} \equiv \boldsymbol{u}$. This leads to $\ddot{Z}^{(a)} = R^{(a)}{}_{(0)(0)(b)}\, Z^{(b)}$ with $\ddot{Z}^{(a)} \equiv e^{(a)}_b \frac{\mathrm{D}^2 Z^b}{\mathrm{d}\,\tau^2}$ and $Z^{(b)} \equiv e^{(b)}_a Z^a$, where $a, b = 0, 1, \ldots, D-1$, which gives $\ddot{Z}^{(0)} = 0$. Moreover, using decomposition of the Riemann tensor we obtain the invariant form of the geodesic deviation equation,

$$\ddot{Z}^{(\mathrm{i})} = \left[C_{(\mathrm{i})(0)(0)(\mathrm{j})} + \frac{1}{D-2}\left(R_{(\mathrm{i})(\mathrm{j})} - \delta_{\mathrm{ij}}\, R_{(0)(0)}\right) - \frac{R\,\delta_{\mathrm{ij}}}{(D-1)(D-2)}\right] Z^{(\mathrm{j})}\,, \tag{39}$$

where $\mathrm{i}, \mathrm{j} = 1, 2, \ldots, D-1$.

To explicitly analyze the specific effects of the EGB theory we restrict ourselves to the transversally static observers, i.e., we set $\sqrt{2}\,\dot{u} = 1$, $\dot{x}^p = 0$, which corresponds to the direct relation between observer's orthonormal frame $\{\boldsymbol{e}_{(0)}, \boldsymbol{e}_{(1)}, \boldsymbol{e}_{(i)}\}$ and the null frame (34), namely

$$\boldsymbol{k} = \tfrac{1}{\sqrt{2}}(\boldsymbol{u} + \boldsymbol{e}_{(1)})\,, \qquad \boldsymbol{l} = \tfrac{1}{\sqrt{2}}(\boldsymbol{u} - \boldsymbol{e}_{(1)})\,, \qquad \boldsymbol{m}_i = \boldsymbol{e}_{(i)}\,. \tag{40}$$

The straightforward evaluation of all projections in (39) and expression of the Ricci tensor components using the EGB field equations give the decomposed form of the geodesic deviation equation,

$$\begin{aligned}
\ddot{Z}^{(1)} =& \frac{2\,(\Lambda_0 + 2kH/D)}{(D-1)(D-2)} Z^{(1)} + \Psi_{2S}\, Z^{(1)} - \frac{1}{\sqrt{2}}\,\Psi_{3T^j}\, Z^{(j)} \\
&+ \frac{k}{D-2}\left(4\mathcal{H}_{ru}\, Z^{(1)} + \sqrt{2} m^p_j\, \mathcal{H}_{up}\, Z^{(j)}\right), \qquad (41) \\
\ddot{Z}^{(i)} =& \frac{2\,(\Lambda_0 + 2kH/D)}{(D-1)(D-2)} Z^{(i)} - \Psi_{2T^{(ij)}}\, Z^{(j)} - \frac{1}{\sqrt{2}}\,\Psi_{3T^i}\, Z^{(1)} - \frac{1}{2}\Psi_{4^{ij}}\, Z^{(j)} \\
&+ \frac{k}{D-2}\Big(- 2m^p_i m^q_j\, \mathcal{H}_{pq}\, Z^{(j)} + \sqrt{2} m^p_i\, \mathcal{H}_{up}\, Z^{(1)} \\
&\qquad + \left[(g_{uu} + 2)\mathcal{H}_{ru} + \mathcal{H}_{uu}\right] Z^{(i)}\Big), \qquad (42)
\end{aligned}$$

where the components of the traceless Gauss–Bonnet part $\mathcal{H}_{ab} \equiv H_{ab} - \frac{1}{D} H g_{ab}$ satisfy $2\mathcal{H}_{ru} = g^{pq}\,\mathcal{H}_{pq}$.

4. Example: Solutions with a constant-curvature transverse space

To explicitly demonstrate application of the above completely general constraints on the Kundt geometries within the EGB theory together with analysis of their properties we present a particular important case of (9) with an additional assumption that $(D-2)$-dimensional transverse space with the metric $g_{pq}(u,x)$ is of a *constant curvature*. In such a case the Riemann tensor can be written as

$$ {}^{S}R_{pqmn} = \frac{{}^{S}R}{(D-3)(D-2)} \left(g_{pm}g_{qn} - g_{pn}g_{qm}\right), \tag{43} $$

and the transverse metric becomes conformally flat, namely

$$ g_{pq} = \frac{\delta_{pq}}{P^2}, \quad \text{where} \quad P = 1 + \frac{{}^{S}R}{4(D-3)(D-2)} \left[\left(x^2\right)^2 + \cdots + \left(x^{D-1}\right)^2\right]. \tag{44} $$

The scalar curvature ${}^{S}R$ is then determined via the ru-equation (12) by generic theory parameters $k = \kappa\gamma$ and Λ_0,

$$ {}^{S}R = \frac{(D-2)(D-3)}{2k(D-4)(D-5)} \left(\pm\sqrt{1 + 8k\Lambda_0 \frac{(D-4)(D-5)}{(D-2)(D-3)}} - 1\right). \tag{45} $$

Immediately we can see that $D = 5$ and $D = 4$ are exceptional cases for which we have ${}^{S}R = 2\Lambda_0$ corresponding to the pure Einstein theory. Moreover, there are *two* branches of generic solutions in the EGB gravity where the " $+$ " case has a GR limit while the " $-$ " case is peculiar.

For generic values of the theory parameters we have $Q_{pq} \neq 0$ and the resulting line element becomes

$$ \begin{aligned} \mathrm{d}s^2 = {} & \left[1 + \frac{{}^{S}R\,\delta_{mn}\,x^m x^n}{4(D-2)(D-3)}\right]^{-2} \delta_{pq}\,\mathrm{d}x^p\,\mathrm{d}x^q - 2\,\mathrm{d}u\,\mathrm{d}r \\ & + \left[\frac{4\Lambda_0 - {}^{S}R}{(D-2) + 2k\,(D-4)\,{}^{S}R}\,r^2 + c(u)\,r + d(u,x)\right] \mathrm{d}u^2, \end{aligned} \tag{46} $$

where the scalar curvature ${}^{S}R$ is given by (45), $c(u)$ is arbitrary function, and $d(u,x)$ has to satisfy the Laplace equation,

$$ g^{pq} d_{||pq} = 0. \tag{47} $$

The Weyl tensor algebraic type of such solution is II(bcd). However, for the flat transverse space, i.e., with ${}^{S}R = 0$, $g_{pq} = \delta_{pq}$, we have $\Lambda_0 = 0$ and all the Gauss–Bonnet corrections vanish which means that we effectively deal with the Einstein theory (subclass of VSI spacetimes of the Weyl-type N). These spacetimes can be interpreted as exact type II gravitational waves propagating on the type D(bcd) background corresponding to the direct-product (anti-)Nariai universe.

This interpretation is simply supported by analysis of relative accelerations in terms of the geodesic deviation. For the transversally static observer associated with

the privileged null congruence we get a simple result,

$$\ddot{Z}^{(1)} = \frac{4\Lambda_0 - {}^{S}R}{(D-2) + 2k\,(D-4)\,{}^{S}R}\, Z^{(1)}\,, \qquad \ddot{Z}^{(i)} = -\frac{1}{2}\Psi_{4^{ij}}\, Z^{(j)}\,, \tag{48}$$

where the longitudinal spatial acceleration in the direction $\boldsymbol{e}_{(1)}$ is determined by the direct-product background corresponding to the non-trivial coefficient of r^2 term in g_{uu}, The transverse accelerations in $D-2$ directions $\boldsymbol{e}_{(i)}$ are given by $\Psi_{4^{ij}} = -\frac{1}{2} m_i^p m_j^q\, d_{||pq}$ and cause symmetric and traceless deformations representing the exact Kundt–EGB gravitational waves.

Finally, as a special case of the above solution we can set ${}^{S}R = 4\Lambda_0$ which makes the resulting metric r-independent and we are thus dealing with the *pp*-wave solution. Subsequently, the parameter Λ_0 can be vanishing, which leads to the classic solution analogous to the general relativity one, or it has to become

$$\Lambda_0 = -\frac{(D-2)(D-3)}{8k(D-4)(D-5)}\,. \tag{49}$$

This *new* non-trivial class is only allowed in the EGB theory with $D > 5$ and its metric takes the form

$$\mathrm{d}s^2 = \left(1 - \frac{\delta_{mn}\, x^m x^n}{8k(D-4)(D-5)}\right)^{-2} \delta_{pq}\, \mathrm{d}x^p\, \mathrm{d}x^q - 2\,\mathrm{d}u\,\mathrm{d}r + d(u,x)\,\mathrm{d}u^2\,, \tag{50}$$

where the Laplace equation (47) for the metric function $d(u,x)$ reflects the non-trivial transverse-space geometry corresponding to the Weyl-type II(bcd) solutions.

5. Conclusions

In this contribution we have summarized the main results of Ref. 4. In particular, we have described explicit class of the Kundt solutions to the Einstein–Gauss–Bonnet gravity. As the first step, the explicit form of the EGB field equations has been derived and geometrically distinct subclasses identified. We have also indicated differences in comparison with the classic solutions to the Einstein's general relativity. As a suitable tool characterizing the solutions we have briefly discussed the algebraic structure of the Weyl tensor and geodesic deviation. Finally, we have presented a particular example of the Kundt solutions with the constant-curvature transverse space including the EGB *pp*-waves.

This paper explores the extended gravitational decoupling procedure for a static sphere in the context of $f(\mathbb{R},T)$ theory where $\mathbb{R}$ denotes the scalar curvature and T represents the trace of the energy-momentum tensor. This method extends the domain of a seed solution by including a new gravitational source. Deformations in radial and temporal metric potentials split the set of field equations into two subsystems associated with isotropic and additional matter sources. We utilize the Korkina-Orlyanskii spacetime as a solution for the system describing the seed source and use some physical constraints to extend it to anisotropic domain. A linear gravity model, $f(\mathbb{R},T)=\mathbb{R}+2\chi T$ (where χ couples geometry to matter) is employed to interpret the influence of the decoupling parameter on the developed solutions. It is found that physically acceptable solutions can be formulated in the background of $f(\mathbb{R},T)$ gravity through the decoupling approach.

Keywords: $f(\mathbb{R},T)$ gravity; Extended gravitational decoupling; Anisotropy.

1. Introduction

Numerous fascinating astronomical discoveries have opened the gateway to the mysteries of cosmic origin and evolution. In this regard, one of the significant developments is Hubble's discovery of an expanding universe.[1] Observations based upon redshifts of Type Ia supernovae provide evidence that the rate of this expansion is accelerating.[2] An unknown energy field (known as dark energy) possessing large negative pressure is assumed to be the source of this acceleration.[3] Einstein's general theory of relativity has successfully been employed to describe different astrophysical phenomena. However, this theory supports a universe experiencing a receding rate of expansion owing to gravitational attraction. Consequently, the cosmological constant was added in the field equations of general relativity (GR) to construct the ΛCDM model which has been used to justify the current cosmic behavior.[4] Nevertheless, this model is unable to solve the problems of fine-tuning[5] and cosmic coincidence.[6] The fine-tuning problem is concerned with the large discrepancy between the observed and predicted values of the cosmological constant whereas the cosmic coincidence problem questions the equal densities of dark matter (nonbaryonic matter with strong gravitational field) and dark energy detected in the current era.

Modifications of GR are proposed to find a suitable explanation of these cosmic issues. The simplest modification replaced the Ricci scalar in the Einstein-Hilbert

action by its generic function and was put forward by Buchdal[7] as the $f(\mathbb{R})$ theory. Harko et al.[8] introduced $f(\mathbb{R},T)$ gravity by generalizing the $f(\mathbb{R})$ theory. The $f(\mathbb{R},T)$ theory incorporates a non-zero covariant derivative of the trace of the energy-momentum tensor. This causes test particles to execute non-geodesic motion and produces acceleration. Various models of $f(\mathbb{R},T)$ gravity have been developed to explore different cosmological events. The most widely used model is $f(\mathbb{R},T) = f_1(\mathbb{R}) + f_2(T)$ where $f_2(T)$ is often set equal to $2\chi T$.[8] Houndjo[9] inspected the matter-dominated phase and late-time acceleration of the universe for this minimally coupled $f(\mathbb{R},T)$ model. This theory also aids in understanding of gravitational effects at the quantum level.[10] Das et al.[11] used different equations of state to examine the properties of gravastar in the context of $f(\mathbb{R},T)$ theory. Effects of the trace on the state variables of a white dwarf were discussed by Carvalho et al.[12] Moreover, the viability of relativistic interiors has been analyzed in this theory.[13]

Solutions of the Einstein field equations represent feasible stellar interiors. Therefore, they help in investigating the essential properties of compact objects. Models portraying physically acceptable astrophysical structures with extremely dense matter have been suggested to exhibit anisotropy. Ruderman[14] studied the existence of anisotropy in high density pure neutron matter. Canuto[15] reviewed the effects of deviations from local isotropy on various stellar characteristics. Impact of anisotropy generated during the phase transition from normal to pion-condensed matter was analyzed by Lovas et al.[16] Gleiser and Dev[17] revealed a stability range for anisotropic stars that was wider in contrast to their isotropic counterparts. Paul and Deb[18] constructed a class of viable relativistic models composed of anisotropic fluid in hydrostatic equilibrium.

However, extraction of analytic anisotropic solutions of the non-linear field equations is often difficult. Therefore, new methods to formulate viable solutions have been developed. In this respect, the decoupling approach allows us to extend known solutions of the field equations to more complex domains. This minimizes the requirement of additional constraints and simplifies the system of equations. Ovalle[19] introduced decoupling through the minimal geometric deformation (MGD) approach by addition of new matter sources. The MGD technique splits the original system of equations into two sets by deforming the radial metric coefficient. Both sets are solved individually and the complete solution is obtained by the principle of superposition.

The MGD technique has been employed extensively for the derivation of anisotropic extensions of well-known solutions. Ovalle et al.[20] utilized this technique to devise stellar models from the isotropic Tolman IV metric. Sharif and Sadiq[21] found well-behaved solutions for spherically symmetric matter configurations. Singh et al.[22] considered the MGD approach in relation to the embedding class-one condition. Furthermore, Sharif and collaborators[23] adopted this procedure to obtain realistic solutions in modified theories of gravity. The use of MGD

decoupling has yielded several solutions of the $f(\mathbb{R},T)$ field equations. Maurya and Tello-Ortiz[24] computed charged anisotropic extensions of the isotropic Durgapal-Fuloria model. Recently, Maurya et al.[25] utilized a linear $f(\mathbb{R},T)$ model to develop a compact structure through the Korkina-Orlyanskii line element and ascertained its viability as well as stability through energy conditions and speed of sound criteria, respectively.

Despite the effectiveness of the MGD method, the scheme deforms only one metric function leading to a purely gravitational interaction between matter sources. Thus, Ovalle[26] proposed a technique incorporating transformations of both radial and temporal metric components known as the extended geometric deformation (EGD) approach. The continuity equation obtained through this procedure holds regardless of the absence or presence of matter sources. Contreras and Bargueño[27] developed a charged BTZ solution by implementing this technique in (1+2)-dimensional spacetime. Maurya et al.[28] extended an embedding class-one solution through the EGD approach. Sharif and Ama-Tul-Mughani[29] constructed viable solutions from the isotropic Krori-Barua metric under the influence of the electromagnetic field. Moreover, the EGD technique has also been employed with modified theories to produce feasible stellar interiors.[30]

In this work, we provide two anisotropic extensions of the Korkina-Orlyanskii spacetime using the EGD approach in connection to $f(\mathbb{R},T)$ gravity. The salient features of the generated models are analyzed through energy conditions and stability criteria. This paper has been arranged as follows. In section **2**, we apply the EGD technique to decouple the field equations of $f(\mathbb{R},T)$ theory. An anisotropic solution corresponding to certain constraints on the extra source is evaluated in section **3**. Physical relevance of the solution is also discussed in the same section. The last section summarizes the main results.

2. Basic Formalism in $f(\mathbb{R},T)$ Theory

The action for $f(\mathbb{R},T)$ theory incorporating the Lagrangian density (L_ϑ) of an additional source (ϑ) turns out to be[8]

$$S=\int\sqrt{-g}(\frac{f(\mathbb{R},T)}{16\pi}+L_m+\alpha L_\vartheta)d^4x, \tag{1}$$

where L_m, g and α indicate the matter Lagrangian, determinant of the metric tensor and dimensionless decoupling parameter, respectively. The energy-momentum tensors of the seed and additional sources are written as

$$T_{\omega\beta}=-\frac{2}{\sqrt{-g}}\frac{\delta(\sqrt{-g}L_m)}{\delta g^{\omega\beta}}=g_{\omega\beta}L_m-2\frac{\partial L_m}{\partial g^{\omega\beta}}, \tag{2}$$

$$\vartheta_{\omega\beta}=-\frac{2}{\sqrt{-g}}\frac{\delta(\sqrt{-g}L_\vartheta)}{\delta g^{\omega\beta}}=g_{\omega\beta}L_\vartheta-2\frac{\partial L_\vartheta}{\partial g^{\omega\beta}}. \tag{3}$$

while the field equations for $f(\mathbb{R},T)$ gravity are derived as

$$8\pi(T_{\omega\beta}+\alpha\vartheta_{\omega\beta})-f_T(\mathbb{R},T)(T_{\omega\beta}+\Theta_{\omega\beta})=(R_{\omega\beta}-\nabla_\omega\nabla_\beta+g_{\omega\beta}\Box)f_{\mathbb{R}}(\mathbb{R},T) - \frac{1}{2}g_{\omega\beta}f(\mathbb{R},T). \tag{4}$$

Here ∇_ω symbolizes the covariant derivative operator while $f_{\mathbb{R}}(\mathbb{R},T)$ and $f_T(\mathbb{R},T)$ are derivatives of the generic function with respect to $\mathbb{R}$ and T, respectively. Moreover, $\Box=g^{\omega\beta}\nabla_\omega\nabla_\beta$ and $\Theta_{\omega\beta}=g_{\omega\beta}L_m-2T_{\omega\beta}-2g^{\delta\gamma}\frac{\partial^2 L_m}{\partial g^{\omega\beta}\partial g^{\delta\gamma}}$.

Covariant differentiation of Eq.(4) yields

$$\nabla^\omega T_{\omega\beta}=\frac{f_T(\mathbb{R},T)}{8\pi-f_T(\mathbb{R},T)}\left[(T_{\omega\beta}+\Theta_{\omega\beta})\nabla^\omega lnf_T(\mathbb{R},T)+\nabla^\omega\Theta_{\omega\beta}-\frac{1}{2}g_{\omega\beta}\nabla^\omega T - \frac{8\pi\alpha}{f_T(\mathbb{R},T)}\nabla^\omega\vartheta_{\omega\beta}\right], \tag{5}$$

which shows the non-conserved energy-momentum tensor in $f(\mathbb{R},T)$ theory. The isotropic matter distribution is characterized by the following energy-momentum tensor

$$T_{\omega\beta}=(\rho+p)u_\omega u_\beta-pg_{\omega\beta}, \tag{6}$$

with isotropic pressure (p), matter density (ρ), four-velocity (u_ω) and $u_\omega u^\omega=1$. Since the matter Lagrangian appears explicitly in the field equations, in order to obtain the corresponding dynamics we set $L_m=-p$ corresponding to a perfect fluid.[31] This further leads to $\Theta_{\omega\beta}=-2T_{\omega\beta}-pg_{\omega\beta}$. We consider a minimally coupled $f(\mathbb{R},T)$ model of the form

$$f(\mathbb{R},T)=\mathbb{R}+2\chi T, \tag{7}$$

which provides

$$\begin{aligned}G_{\omega\beta}&=8\pi(T_{\omega\beta}+\alpha\vartheta_{\omega\beta})+\chi Tg_{\omega\beta}+2\chi(T_{\omega\beta}+pg_{\omega\beta})\\&=8\pi\widetilde{T}_{\omega\beta}+8\pi\alpha\vartheta_{\omega\beta}=8\pi T^{(eff)}_{\omega\beta},\end{aligned} \tag{8}$$

where $\widetilde{T}_{\omega\beta}=T_{\omega\beta}(1+\frac{\chi}{4\pi})+\frac{\chi}{8\pi}(T+2p)g_{\omega\beta}$.

To describe the interior configuration of the stellar object, we choose a line element given by

$$ds^2=e^\nu dt^2-e^\eta dr^2-r^2(d\theta^2+\sin^2\theta d\phi^2), \tag{9}$$

where ν and η are functions of the radial coordinate. The field equations can now be rewritten as

$$\frac{1}{r^2}-e^{-\eta}\left(\frac{1}{r^2}-\frac{\eta'}{r}\right)=8\pi(\bar{\rho}+\alpha\vartheta^t_t), \tag{10}$$

$$-\frac{1}{r^2}+e^{-\eta}\left(\frac{1}{r^2}+\frac{\nu'}{r}\right)=8\pi(\bar{p}-\alpha\vartheta^r_r), \tag{11}$$

$$\frac{e^{-\eta}}{4}\left(2\nu''+\nu'^2-\eta'\nu'+2\frac{\nu'-\eta'}{r}\right)=8\pi(\bar{p}-\alpha\vartheta^\theta_\theta). \tag{12}$$

Here prime denotes derivative with respect to r while $\bar{\rho}$ and $\bar{p}$ are identified as follows

$$\bar{\rho} = \rho + \frac{\chi}{8\pi}(3\rho - p), \tag{13}$$

$$\bar{p} = p - \frac{\chi}{8\pi}(\rho - 3p). \tag{14}$$

The physical variables (total density and radial/tangential pressure) are defined as

$$\rho^{(tot)}(r) = \rho(r) + \alpha\vartheta_t^t, \tag{15}$$

$$p_r^{(tot)}(r) = p(r) - \alpha\vartheta_r^r, \tag{16}$$

$$p_t^{(tot)}(r) = p(r) - \alpha\vartheta_\theta^\theta, \tag{17}$$

whereas the anisotropy generated from involvement of an extra source is obtained as

$$\Delta = p_t^{(tot)}(r) - p_r^{(tot)}(r) = \alpha(\vartheta_r^r - \vartheta_\theta^\theta). \tag{18}$$

Seven unknowns appear in the system of equations (10)-(12). Therefore, to reduce the degrees of freedom and close the undetermined system, we adopt the EGD scheme.

2.1. *The EGD Approach*

The EGD approach disintegrates the field equations into two distinct sets through deformations in the temporal and radial metric potentials. To proceed with this technique, we consider a line element corresponding to perfect fluid

$$ds^2 = e^{\xi(r)}dt^2 - \frac{dr^2}{\mu(r)} - r^2(d\theta^2 + \sin^2\theta d\phi^2). \tag{19}$$

Taking non-zero values of the parameter α incorporates the effects of the source $\vartheta_{\omega\beta}$ in $T_{\omega\beta}$. The metric components linked to (ν, η)-frame are segregated as

$$\nu = \xi + \alpha h(r), \tag{20}$$

$$e^{-\eta(r)} = \mu + \alpha f(r), \tag{21}$$

where $h(r)$ and $f(r)$ represent temporal and radial deformation functions, respectively. Substitution of above transformations in the field equations decomposes the system into two sets. We acquire an array for the seed distribution given as

$$8\pi\bar{\rho} = -\frac{\mu'}{r} - \frac{\mu}{r^2} + \frac{1}{r^2} = 8\pi\rho + \chi(3\rho - p), \tag{22}$$

$$8\pi\bar{p} = \frac{\mu\xi'}{r} + \frac{\mu}{r^2} - \frac{1}{r^2} = 8\pi p - \chi(\rho - 3p), \tag{23}$$

$$8\pi\bar{p} = \frac{\mu}{4}(2\xi'' + (\xi')^2 + 2\frac{\xi'}{r}) + \frac{\mu'}{4}(\xi' + \frac{2}{r}) = 8\pi p - \chi(\rho - 3p). \tag{24}$$

The isotropic density and pressure are evaluated from the above equations as

$$\rho=\frac{\chi(\mu\xi' r+\mu-1)+(8\pi+3\chi)(-\mu' r-\mu+1)}{r^2(8\pi+2\chi)(8\pi+4\chi)}, \tag{25}$$

$$p=\frac{\chi(-\mu' r-\mu+1)+(8\pi+3\chi)(\mu\xi' r+\mu-1)}{r^2(8\pi+2\chi)(8\pi+4\chi)}. \tag{26}$$

The second system, related to the source $\vartheta_{\omega\beta}$, is obtained as

$$8\pi\vartheta^t_t=-\frac{f'}{r}-\frac{f}{r^2}, \tag{27}$$

$$8\pi\vartheta^r_r=-\frac{\mu h'}{r}-f(\frac{\xi'}{r}+\frac{\alpha h'}{r}+\frac{1}{r^2}), \tag{28}$$

$$\begin{aligned}8\pi\vartheta^\theta_\theta=&-\frac{f}{4}\left(2\xi''+2\alpha h''+(\xi')^2+\alpha^2(h')^2+2\xi'\alpha h'+2\frac{\xi'}{r}+2\frac{\alpha h'}{r}\right)\\&-\frac{f'}{4}(\frac{2}{r}+\xi'+\alpha h')-\mu\left(\frac{h''}{2}+\frac{\alpha(h')^2}{4}+\frac{\xi' h'}{2}+\frac{h'}{2r}\right)-\frac{\mu' h'}{4}.\end{aligned} \tag{29}$$

The energy-momentum tensor corresponding to the line element (19) satisfies the Bianchi identity as

$$\nabla^{(\xi,\mu)}_\omega\widetilde{T}^\omega_\beta=-\frac{dp}{dr}-\frac{\xi'}{2}(\rho+p)+\frac{\chi}{2(4\pi+\chi)}\frac{d}{dr}(\rho-p)=0, \tag{30}$$

while the divergence $\nabla_\omega\widetilde{T}^\omega_\beta$ associated with the system (22)-(24) yields

$$\nabla_\omega\widetilde{T}^\omega_\beta=\nabla^{(\xi,\mu)}_\omega\widetilde{T}^\omega_\beta+\alpha\frac{h'}{2}(\rho+p)\delta^1_\beta. \tag{31}$$

Furthermore, conservation of the additional source $\vartheta_{\omega\beta}$ is provided as

$$\nabla_\omega\vartheta^\omega_\beta=\frac{d\vartheta^r_r}{dr}-\frac{\xi'}{2}(\vartheta^t_t-\vartheta^r_r)-\frac{2}{r}(\vartheta^\theta_\theta-\vartheta^r_r)=-\frac{h'}{2}(\rho+p)\delta^1_\beta. \tag{32}$$

Consequently, the continuity equation for the effective energy-momentum tensor is constructed as follows

$$-\frac{dp}{dr}-\frac{\xi'}{2}(\rho+p)+\frac{\chi}{2(4\pi+\chi)}\frac{d}{dr}(\rho-p)+\alpha\left[\frac{d\vartheta^r_r}{dr}-\frac{\xi'}{2}(\vartheta^t_t-\vartheta^r_r)-\frac{2}{r}(\vartheta^\theta_\theta-\vartheta^r_r)\right]=0. \tag{33}$$

An exchange of energy between the two sources ($\widetilde{T}_{\omega\beta}$ and $\vartheta_{\omega\beta}$) is evident from Eqs.(31) and (32) which allows successful implementation of the decoupling process. Meanwhile, decoupling in the case of MGD is possible only without a transfer of energy. Note that the system (22)-(24) consists of four unknowns (μ, ξ, ρ, p) whereas the system (27)-(29) comprises seven unknowns (μ, ξ, ρ, p, f, h, ϑ^t_t, ϑ^r_r, ϑ^θ_θ). The extraction of solutions can be simplified substantially by specifying a seed solution to the system of equations connected to the original energy-momentum tensor. As a result, the unknowns in the second array of equations decrease from seven to five. Hence, the EGD scheme facilitates the evaluation of anisotropic solutions by reducing the degrees of freedom.

3. Interior Anisotropic Solution

In this section, we use the Korkina-Orlyanskii solution for the system of equations (22)-(24). The metric coefficients of the Korkina-Orlyanskii spacetime have been previously utilized for the development of spherically symmetric static solutions to the Einstein-Maxwell system.[32] Moreover, this ansatz has helped examine the role of pressure anisotropy on charged stellar objects.[33] The metric components and corresponding physical variables in the framework of $f(\mathbb{R},T)$ theory read

$$\mu(r)=\frac{1+Ar^2}{1+2Ar^2}, \tag{34}$$

$$e^{\xi(r)}=C(1+Ar^2)\left[D+\frac{\sqrt{1+2Ar^2}}{1+Ar^2}-\sqrt{2}\ln\left(\sqrt{1+2Ar^2}+\sqrt{2+2Ar^2}\right)\right]^2, \tag{35}$$

$$\rho(r)=\frac{A}{8\chi^2+48\pi\chi+64\pi^2}\left[\frac{\chi}{2Ar^2+1}+\frac{(3\chi+8\pi)\left(2Ar^2+3\right)}{\left(2Ar^2+1\right)^2}-\frac{4\chi\left(A^2r^4+Ar^2\left(\sqrt{Ar^2+1}+2\right)+1\right)}{\left(2A^2r^4+3Ar^2+1\right)^{3/2}\left(D+\psi(r)\right)}\right], \tag{36}$$

$$p(r)=\frac{A}{8\chi^2+48\pi\chi+64\pi^2}\left[\frac{\chi\left(2Ar^2+3\right)}{\left(2\mathrm{Ar}^2+1\right)^2}+\frac{3\chi+8\pi}{2Ar^2+1}-\frac{4(3\chi+8\pi)\left(A^2r^4+Ar^2\left(\sqrt{Ar^2+1}+2\right)+1\right)}{\left(2A^2r^4+3Ar^2+1\right)^{3/2}\left(D+\psi(r)\right)}\right], \tag{37}$$

with $\psi(r)=\frac{\sqrt{1+2Ar^2}}{1+Ar^2}-\sqrt{2}\ln(\sqrt{1+2Ar^2}+\sqrt{2+2Ar^2})$. Here A, C and D are constants that are calculated by matching with the exterior Schwarzschild line element expressed as

$$ds^2=\left(1-\frac{2M}{r}\right)dt^2-\frac{1}{(1-\frac{2M}{r})}dr^2-r^2(d\theta^2+\sin^2\theta d\phi^2), \tag{38}$$

where M is the total mass of the exterior geometry.

To ensure a smooth junction between the interior and exterior regions at $r=R$, the matching conditions were introduced by Darmois.[34] These conditions are given as

$$[ds^2]_{r=R}=0, \tag{39}$$

$$[p_r^{(tot)}(r)]_{r=R}=0. \tag{40}$$

which provide

$$A=\frac{2M}{R^2(R-4M)}, \tag{41}$$

$$C=\frac{1-\frac{2M}{R}}{(AR^2+1)}\left[D-\sqrt{2}\ln\left(\sqrt{2AR^2+1}+\sqrt{2AR^2+2}\right)\right.\quad\left.+\frac{\sqrt{2AR^2+1}}{AR^2+1}\right]^{-2}, \tag{42}$$

$$D=\frac{\sqrt{2AR^2+1}\,(D_2(R)\chi+4\pi D_1(R))+D_3(R)}{(AR^2+1)^{3/2}\,(4AR^2\chi+8\pi AR^2+3\chi+4\pi)}, \tag{43}$$

where

$$\begin{aligned}
D_1(R)&=4+4A^2R^4-\sqrt{1+AR^2}+2AR^2(4+\sqrt{1+AR^2}),\\
D_2(R)&=6+6A^2R^4-3\sqrt{1+AR^2}+2AR^2(6+\sqrt{1+AR^2}),\\
D_3(R)&=(3\chi+4\pi+4\chi AR^2+8\pi AR^2)(1+AR^2)^{3/2}\sqrt{2}\ln\left[\sqrt{1+2AR^2}\right.\\
&\quad\left.+\sqrt{2+2AR^2}\right].
\end{aligned}$$

We now produce a solution of Eqs.(27)-(29) corresponding to the extra source ϑ_ω. Because the number of unknowns (f, h, ϑ_t^t, ϑ_r^r, ϑ_θ^θ) is greater than the number of equations, two additional constraints need to be applied to close the system and extend the isotropic sector to anisotropic domain. The matching condition in Eq.(40) is fulfilled if

$$\vartheta_r^r(r)=p(r). \tag{44}$$

Thus, the above equation is selected as the first constraint. Accordingly, the physical entities of the anisotropic configuration are acquired through Eqs.(15)-(17) as

$$\rho^{(tot)}(r)=\rho(r)+\frac{\alpha}{8\pi}(-\frac{f'}{r}-\frac{f}{r^2}), \tag{45}$$

$$p_r^{(tot)}(r)=p(r)(1-\alpha), \tag{46}$$

$$\begin{aligned}
p_t^{(tot)}(r)&=p(r)-\frac{\alpha}{8\pi}\left[-\frac{f}{4}\left(2\xi''+2\alpha h''+(\xi')^2+\alpha^2(h')^2+2\xi'\alpha h'+2\frac{\xi'}{r}\right.\right.\\
&\quad\left.+\,2\frac{\alpha h'}{r}\right)-\frac{f'}{4}\left(\frac{2}{r}+\xi'+\alpha h'\right)-\mu\left(\frac{h''}{2}+\frac{\alpha(h')^2}{4}+\frac{\xi' h'}{2}+\frac{h'}{2r}\right)\\
&\quad\left.-\,\frac{\mu' h'}{4}\right].
\end{aligned} \tag{47}$$

In the subsequent discussion, the respective anisotropic extension is generated by means of a second constraint.

3.1. *Solution*

Along with the mimic constraint stated in Eq.(44), we impose a condition on the anisotropy of the system developed through the conservation equation by Bowers

and Liang.[35] The Bowers-Liang constraint takes the following precise form

$$\vartheta_\theta^\theta - \vartheta_r^r = jr\frac{\xi'}{2}(\vartheta_t^t + \vartheta_r^r). \tag{48}$$

Here j is an arbitrary constant for which we have defined a value of 2. This constraint has been used extensively with gravitational decoupling in search of feasible star models.[36,37] The geometric deformations $f(r)$ and $h(r)$ are obtained from Eqs.(44) and (48), respectively as

$$\begin{aligned} f(r) = {} & \frac{1}{(\chi+2\pi)(\chi+4\pi)\left(\alpha r h(r) + r\xi'(r) + 1\right)}\left(-r\chi^2 h(r)\mu(r)\right. \\ & + \pi r\chi\mu'(r) - 6\pi r\chi h(r)\mu(r) - 8\pi^2 r h(r)\mu(r) - 3\pi r\chi\mu(r)\xi'(r) \\ & \left. - 8\pi^2 r\mu(r)\xi'(r) - 2\pi\chi\mu(r) - 8\pi^2\mu(r) + 2\pi\chi + 8\pi^2\right), \end{aligned} \tag{49}$$

$$\begin{aligned} & \frac{1}{r}\left(r\left(h(r)\left(r\left(\alpha f'(r) + \mu'(r)\right) - 2\mu(r)\left((j-1)r\xi'(r) + 1\right)\right) + f'(r)\left((r\right.\right.\right. \\ & - 2jr)\xi'(r) + 2) + 2r\mu(r)h'(r) + \alpha r h(r)^2\mu(r)\big) + f(r)\left(2\alpha r^2 h'(r)\right. \\ & - 2\alpha r h(r)\left((j-1)r\xi'(r) + 1\right) + \alpha^2 r^2 h(r)^2 - 2jr^2\xi'(r)^2 - 4jr\xi'(r) \\ & \left. + 2r^2\xi''(r) + r^2\xi'(r)^2 - 2r\xi'(r) - 4\right)\big) = 0. \end{aligned} \tag{50}$$

A numerical solution of the deformation function $h(r)$ is revealed by applying the initial condition $h(0) = 0$ to Eq.(50).

The deformed temporal and radial metric components are derived as

$$\begin{aligned} \nu(r) = {} & \ln\left(C(1+Ar^2)\left[\frac{\sqrt{1+2Ar^2}}{1+Ar^2} - \sqrt{2}\ln\left(\sqrt{1+2Ar^2}\right.\right.\right. \\ & \left.\left.\left. + \sqrt{2+2Ar^2}\right) + D\right]^2\right) + \alpha h(r), \end{aligned} \tag{51}$$

$$\begin{aligned} e^{-\eta} = {} & \frac{1+Ar^2}{1+2Ar^2} + \alpha\left[\frac{1}{(\chi+2\pi)(\chi+4\pi)\left(\alpha r h(r) + r\xi'(r) + 1\right)}\left(\pi r\chi\mu'(r)\right.\right. \\ & - r\chi^2 h(r)\mu(r) - 6\pi r\chi h(r)\mu(r) - 8\pi^2 r h(r)\mu(r) - 3\pi r\chi\mu(r)\xi'(r) \\ & \left.\left. - 8\pi^2 r\mu(r)\xi'(r) - 2\pi\chi\mu(r) - 8\pi^2\mu(r) + 2\pi\chi + 8\pi^2\right)\right], \end{aligned} \tag{52}$$

while the matter variables are formulated through Eqs.(45)-(47). After the inclusion of anisotropy in the solution, matching of interior and exterior line elements yields

the following expressions

$$\ln\left(1-\frac{2M}{R}\right)=\ln\left(C(1+AR^2)\left[\frac{\sqrt{1+2AR^2}}{1+AR^2}-\sqrt{2}\ln\left(\sqrt{1+2AR^2}\right.\right.\right.$$
$$\left.\left.\left.+\sqrt{2+2AR^2}\right)+D\right]^2\right)+\alpha h(R), \tag{53}$$

$$1-\frac{2M}{R}=\frac{1+AR^2}{1+2AR^2}+\alpha\left[\frac{1}{(\chi+2\pi)(\chi+4\pi)\left(\alpha Rh(R)+R\xi'(R)+1\right)}\right.$$
$$\times\left(\pi R\chi\mu'(R)-R\chi^2h(R)\mu(R)-6\pi R\chi h(R)\mu(R)-8\pi^2\mu(R)\right.$$
$$-\left.8\pi^2Rh(R)\mu(R)-3\pi R\chi\mu(R)\xi'(R)-8\pi^2R\mu(R)\xi'(R)\right.$$
$$-\left.\left.2\pi\chi\mu(R)+2\pi\chi+8\pi^2\right)\right]. \tag{54}$$

which cannot determine the constants A and C. Hence, they are considered as free parameters and acquired from Eqs.(41) and (42). On the other hand, the condition $[p_r^{(tot)}(r)]_{r=R}=0$ provides the constant D as computed in Eq.(43).

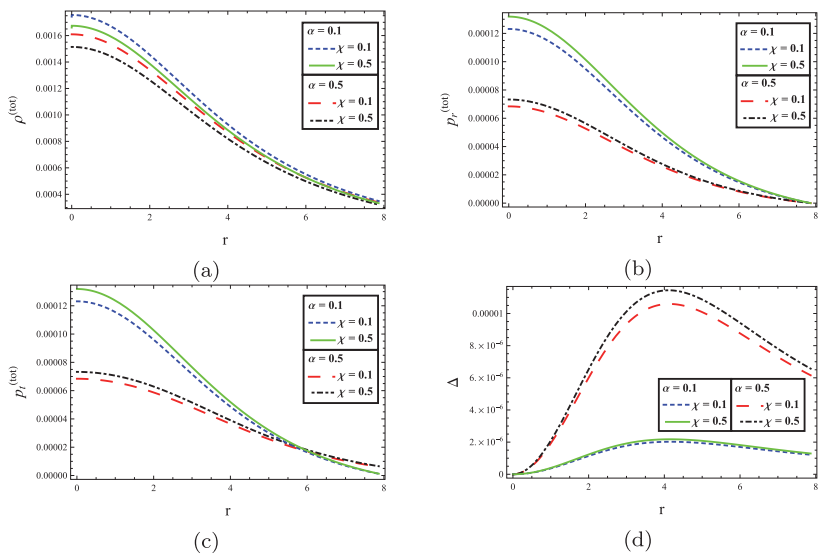

Fig. 1. Behavior of (a) density, (b) radial pressure, (c) tangential pressure and (d) anisotropy factor relative to radial coordinate.

The physical entities of the constructed setup are analyzed graphically for the star 4U 1538-52 with a mass of 1.28325km and a radius 7.866km.[38] The density and pressure components must be positive and decreasing from a maximum at the core. Figure 1 exhibits variations of these physical attributes relative to the radial coordinate. It is evident that the total energy density as well as both pressure components decrease continually from the center towards the surface. Moreover, the radial pressure vanishes at $r=R$ while the anisotropy displays a null value at

Table 1. State determinants of the stellar model corresponding to 4U 1538-52 ($M = 1.28325$ km and $R = 7.866$ km).

$r = 0$. The positive anisotropy factor suggests the presence of an outward-directed force. Higher values of χ cause the radial/tangential pressure and anisotropy to increase. Furthermore, the energy density declines as α and χ increase. Table 1 shows values of A, C and D along with the state determinants for different values of α and χ. The subscripts $\mathcal{C}$ and $\mathcal{S}$ denote that the quantity has been evaluated at the center and surface of the star, respectively.

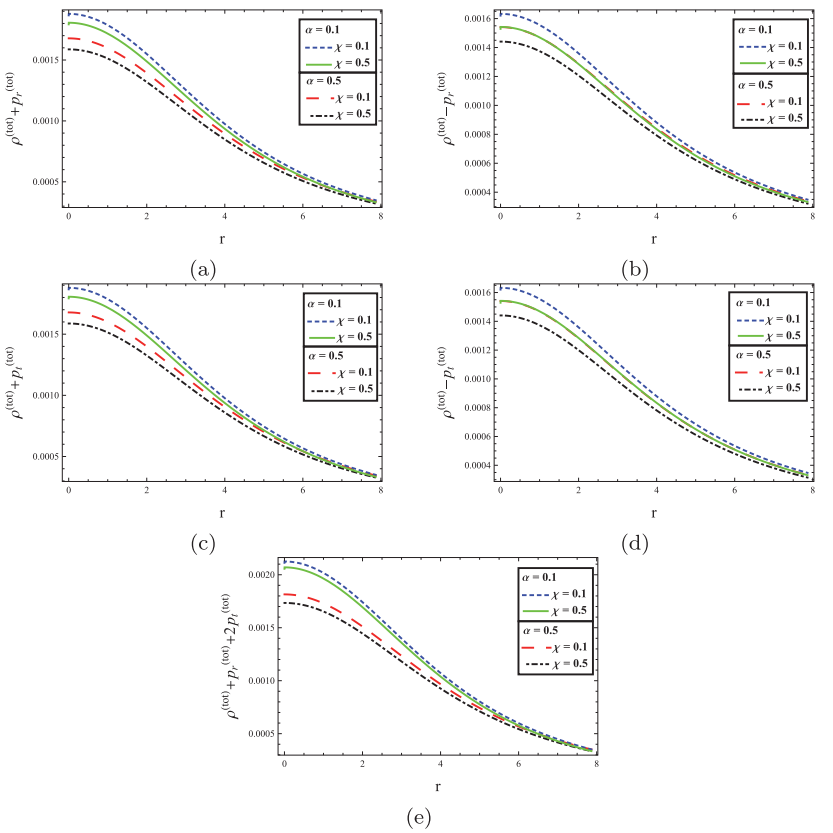

Fig. 2. Plots of energy conditions ((a)-(e)) against radial coordinate.

To verify the viability of the constructed solution, we place some bounds on the physical parameters called the energy conditions. These conditions, classified as null (NEC), weak (WEC), strong (SEC) and dominant (DEC), are presented as

$$\text{NEC: } \rho^{(tot)}+p_r^{(tot)}\geq 0, \quad \rho^{(tot)}+p_t^{(tot)}\geq 0,$$
$$\text{WEC: } \rho^{(tot)}\geq 0, \quad \rho^{(tot)}+p_r^{(tot)}\geq 0, \quad \rho^{(tot)}+p_t^{(tot)}\geq 0,$$
$$\text{SEC: } \rho^{(tot)}+p_r^{(tot)}\geq 0, \quad \rho^{(tot)}+p_t^{(tot)}\geq 0, \quad \rho^{(tot)}+p_r^{(tot)}+2p_t^{(tot)}\geq 0,$$
$$\text{DEC: } \rho^{(tot)}-p_r^{(tot)}\geq 0, \quad \rho^{(tot)}-p_t^{(tot)}\geq 0.$$

Figure 2 demonstrates positive behavior of above inequalities. Therefore, the solution is viable for the considered values of α and χ.

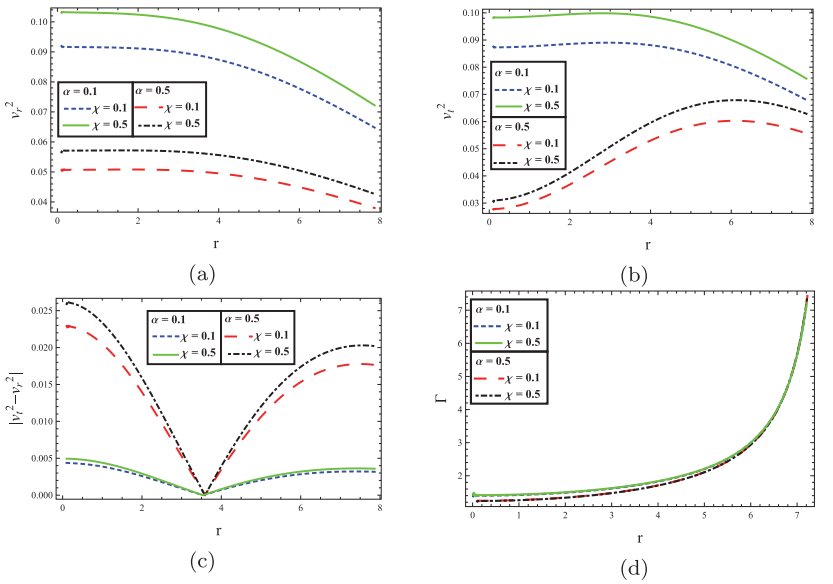

Fig. 3. Graphical representation of (a) v_r^2, (b) v_t^2, (c) $|v_t^2-v_r^2|$ and (d) Γ.

Another important feature of anisotropic stellar models is stability to fluctuations in the physical variables. The causality constraint is one of the stability criteria which limits the radial ($v_r^2=\frac{dp_r^{(tot)}}{d\rho^{(tot)}}$) and tangential ($v_t^2=\frac{dp_t^{(tot)}}{d\rho^{(tot)}}$) sound speeds inside the static configuration as follows

$$0\leq v_r^2\leq c, \quad 0\leq v_t^2\leq c,$$

where $c=1$ is the speed of light. Herrera[39] devised another approach to examine stability known as cracking. Cracking is caused by a sudden change in the direction of the radial force within a stellar configuration as a result of perturbations in density and anisotropy. Later, Abreu et al.[40] defined the potentially stable and

unstable regions within a compact object through differences of sound speeds given as

$$\begin{aligned} -1 \leq & v_t^2 - v_r^2 \leq 0 \Rightarrow \text{Potentially stable}, \\ 0 < & v_t^2 - v_r^2 \leq 1 \Rightarrow \text{Potentially unstable}. \end{aligned}$$

The above inequalities can be combined in to a single relation of the form $0 \leq |v_t^2 - v_r^2| \leq 1$.

In addition to the above constraints, an alternative tool to establish the stability of compact spheres is the adiabatic index which measures the resistance offered by a stellar configuration to perturbations in density. It is obtained as

$$\Gamma = \frac{p_r^{(tot)} + \rho^{(tot)}}{p_r^{(tot)}} v_r^2.$$

An adiabatic index greater than $4/3$ is proposed to indicate stable relativistic structures.[41] Figure 3 displays graphs of radial and temporal sound speeds as well as the adiabatic index for the developed solution. The sound speeds lie between 0 and 1 whereas the adiabatic index remains greater than $4/3$. Hence, we deduce that the resulting stellar model is stable.

4. Conclusions

In this paper, we have derived an anisotropic solution depicting the interior of a self-gravitating system in connection to $f(\mathbb{R}, T)$ gravity. The set of field equations (10)-(12) has been decoupled into two sets through the EGD scheme. These arrays separately describe the seed and anisotropic distributions. The Bianchi identity has been employed to examine energy transfer between the matter sources. We have considered the Korkina-Orlyanskii metric as a solution to the array corresponding to the isotropic configuration. Matching conditions on the hypersurface have been used to calculate the constants appearing in the solution. In order to extend the seed solution to anisotropic domain, we require two additional constraints. Thus, we have implemented the mimic constraint on ϑ_r^r along with the Bowers-Liang constraint. Physical relevance of the acquired solution has been investigated by employing the mass and radius of the star 4U 1538-53. For this purpose, we have performed graphical examination of the state determinants corresponding to $\alpha = 0.1,\ 0.5$ with $\chi = 0.1,\ 0.5$.

Plots for effective energy density, radial and tangential pressures have been found to monotonically decrease from the core. The anisotropy increases steadily from the center where $\Delta = 0$. The solution is viable and stable since all required quantities are in agreement with the energy bounds and speed of sound criteria. Furthermore, smaller values of the parameters α and χ give rise to denser, more compact and stable stellar models. Maurya et al.[25] evaluated an anisotropic, stable interior solution corresponding to a mimic constraint on pressure through the MGD technique. When compared to the solution obtained via the MGD approach, the EGD scheme

has yielded a denser star model with higher anisotropy. Hence, we conclude that the construction of anisotropic and ultra-dense stellar interiors is attainable using the EGD approach in the framework of $f(\mathbb{R}, T)$ theory.

The TOV equation is usually interpreted as the relativistic counterpart of the classical condition for hydrostatic equilibrium, and characterises the static equilibrium of bound, spherical distributions of matter such as stars. In the present work we aim at showing that a generalised TOV equation also determines the equilibrium of models endowed with other symmetries besides spherical. We resort to the dual null formalism applied to spacetimes with two dimensional spherical, planar and hyperbolic symmetries, and consider a perfect fluid as the source. Static configurations assume the existence of a time-like Killing vector field orthogonal to the surfaces of symmetry, and homogeneous dynamical solutions arise when the Killing field is space-like. In order to treat equally all the aforementioned cases, we discuss the definition of a quasi-local energy for the spacetimes with planar and hyperbolic foliations, since the Hawking-Hayward definition only applies to compact foliations. This procedure enables us to translate our geometrical formalism to the fluid dynamics language in a unified way, to find the generalised TOV equation, for the three cases when the solution is static, and to obtain the evolution equation, for the homogeneous spacetime cases. Remarkably, we show that the static solutions which are not spherically symmetric violate the weak energy condition (WEC). We also show that the counterpart of the TOV equation $\rho + P = 0$, defines a cosmological constant-type behaviour, both in the hyperbolic and spherical cases. This implies a violation of the strong energy condition in both cases, added to the above mentioned violation of the weak energy condition in the hyperbolic case. We illustrate our unified treatment obtaining analogs of Schwarzschild interior solution, for an incompressible fluid $\rho = \rho_0$ constant.

Keywords: Gravitational collapse; hydrostatic equilibrium.

1. Introduction

The Tolman-Oppenheimer-Volkoff (TOV) equation[1,2] characterises spherical objects in equilibrium in the framework of General Relativity. It appears as the

relativistic counterpart of the classical condition for hydrostatic equilibrium. Given the relevance of the spherical configurations in astrophysics, many solutions were investigated,[3–15] and more specifically, different formalisms[16–20] and solutions generating techniques have been developed.[21,22] Extensions of the TOV equation have also been investigated in the framework of modified gravity theories.[23–29]

Yet a unified characterization of the underlying features of the TOV equation has attracted little attention, and this is what concerns us in the present work. There is a widespread perception of the TOV equation as being restricted to the spherically symmetric case, but this is a misled assumption. So, in the present work we derive a generalised TOV equation that also characterises the equilibrium of models endowed with other symmetries besides the spherical.[a]

We adopt the dual null formalism[b] that offers a description of the spacetime based on the properties of the optical flow, and has the significant advantage of being a coordinate free formalism. In the literature it has been considered in connection with the behaviour of dynamical black holes,[35,36] the definition of energy in more general geometries,[37] the gravitational collapse of fluids,[38] and even with the definition of generalized horizons in modified gravity.[39] The dual null formalism has also been useful to explicit the "linear" behavior of gravity for sources that satisfy the hypotheses of the Birkhoff theorem.[31]

Here, we apply the dual null formalism to analyse, in a unified way, the spacetimes which admit a codimension-two foliation with constant curvature leaves.[40] This comprises the spherical, planar and hyperbolic symmetries, sourced by a perfect fluid. Aside from the Killing vector fields that are tangent to those surfaces of symmetry, we assume the existence of an additional symmetry generated by a Killing vector field orthogonal to those surfaces at each event. A particular case of this setup, where the symmetry is spherical and the Killing vector is timelike, corresponds to the spherically symmetric perfect fluid in hydrostatic equilibrium, which leads us to the well-known TOV equation. As we will show this celebrated equation arises most naturally in the dual-null framework which, moreover, allows us to generalize it for the planar and hyperbolic cases. This generalisation of the geometry underlying the TOV equation, stepping beyond spherical symmetry, is novel and leads to consequences which are far from trivial.[40]

Since in planar and hyperbolic geometries the spatial hypersurfaces are open, this extension requires the novel introduction of a mass-energy "parameter". In fact one needs to promote a generalization of the Misner-Sharp/Hawking-Hayward definitions of the mass-energy distribution, which overcomes the problem of the divergence of the latter quantities due to the natural threading with infinite surfaces.

[a] A similar prejudice applying to the Birkhoff theorem, has been addressed with its generalization to more general geometries by C. Bona,[30] and more recently by us in.[31]

[b] We follow here the nomenclature coined by Sean A. Hayward[32–34] although in some references this formalism is referred to as double-null.

Finally, our investigation of the planar and hyperbolic geometries reveals the violation of the weak energy condition in order to maintain hydrostatic equilibrium. This takes the form of negative effective mass, physically translating repulsive curvature effects, which suggest a link to repulsive source models, as those proposed to mimic dark energy, generate bouncing universes, or support classical wormholes.[41,42]

For completness, when the metric is characterised by a spacelike, rather than a timelike Killing vector, we have spatially homogeneous spacetimes that correspond to some of the Bianchi spacetimes, or Kantowski-Sachs, as expected. The hydrostatic equilibrium on those spacetimes is only possible when their source is a cosmological constant in the non flat cases, also implying the violation of energy conditions.

2. The dual null formalism

We consider metrics that have a codimension-two maximally symmetric foliation, and can be written as

$$\mathrm{d}s^2 = N_{ab}\mathrm{d}x^a\mathrm{d}x^b + Y^2(x^c)\left(\mathrm{d}\theta^2 + S_\epsilon^2\mathrm{d}\phi^2\right) , \tag{1}$$

where

$$S_\epsilon = \begin{cases} \sin\theta, \text{ for } \epsilon = 1 \\ 1, \text{ for } \epsilon = 0 \\ \sinh\theta, \text{ for } \epsilon = -1 \end{cases} ,$$

and where we divide the tangent space $\mathcal{T}$ at each event in two orthogonal subspaces $\mathcal{T} = \mathcal{N} \oplus \mathcal{S}$. Here $\mathcal{S}$ is the subspace generated by the orbits of (θ, ϕ) and $\mathcal{N}$, the subspace of $\mathcal{T}$ orthogonal to $\mathcal{S}$. The x^a coordinates are chosen orthogonal to $\mathcal{S}$, which gives the metric in the warped sum form of Eq. (1).

We denote $s_{ab} = Y^2\gamma_{ab}$ the induced metric in each leaf of the foliation where $Y(x^c)$ is the warp factor. Evidently, $\gamma_{ab} := \delta^\theta_a\delta^\theta_b + S^2_\epsilon\delta^\phi_a\delta^\phi_b$ has constant curvature and does not depend on the coordinates x^a which identify each leaf Σ_{x^c}, defined as the locus spanned by the orbits of θ and ϕ for fixed x^c. We define an orthonormal two dimensional basis $(n^a\,, e^a)$ for $\mathcal{N}$, whose induced metric is N_{ab}, according to Eq. (1). This basis satisfies

$$-n^a n_a = e^a e_a = 1\,, \quad n^a e_a = n^a s_{ab} = e^a s_{ab} = 0\,. \tag{2}$$

We may also define a dual null basis for the same subspace from n^a and e^a by

$$\begin{aligned} k^a &= \frac{1}{2}\left(n^a + e^a\right) , \quad l^a = \frac{1}{2}\left(n^a - e^a\right) , \\ n^a &= k^a + l^a\,, \quad e^a = k^a - l^a\,, \end{aligned} \tag{3}$$

which satisfies

$$k^a k_a = l^a l_a = 0\,, \quad k^a l_a = -\frac{1}{2}\,. \tag{4}$$

The metric g_{ab} can be written as

$$g_{ab} = \frac{2}{k^c l_c} k_{(a} l_{b)} + s_{ab} \,. \tag{5}$$

We associate the null expansion for each null vector as follows

$$\Theta_k = \frac{1}{2} s^{ab} \mathcal{L}_k s_{ab} = \frac{1}{2} Y^{-2} \gamma^{ab} \mathcal{L}_k Y^2 \gamma_{ab} = \frac{2}{Y} k^a \partial_a Y \,. \tag{6}$$

We may extend the definition of null expansion to timelike and spacelike vectors in $\mathcal{N}$, calling it the two-expansion, since it measures the rate of variation of area, as in the null case. We may define the mean curvature form $\mathcal{K}_a = \partial_a \ln Y^2$, such that, we obtain for the two-expansion $\Theta_{(u)}$ of any vector u^a in $\mathcal{N}$

$$\Theta_{(u)} = u^a \mathcal{K}_a \,. \tag{7}$$

We describe our spacetimes by means of the behaviour of the null expansion, casting the Einstein equations, $G_{ab} = 8\pi T_{ab}$ in terms of expansions, i.e., by writing the Raychaudhuri equations and constraint equations[35,43–45]

$$\mathcal{L}_k \Theta_{(k)} = \nu_k \Theta_{(k)} - \frac{\Theta^2_{(k)}}{2} - 8\pi T_{ab} k^a k^b \,, \tag{8a}$$

$$\mathcal{L}_l \Theta_{(l)} = \nu_l \Theta_{(l)} - \frac{\Theta^2_{(l)}}{2} - 8\pi T_{ab} l^a l^b \,, \tag{8b}$$

$$\mathcal{L}_k \Theta_{(l)} + \mathcal{L}_l \Theta_{(k)} = -\Theta_{(l)} \nu_k - \Theta_{(k)} \nu_l - 2\,\Theta_{(k)}\,\Theta_{(l)} + \epsilon \frac{2\,k^a l_a}{Y^2} + 16\pi\, T_{ab} k^a l^b \,, \tag{8c}$$

where we included the inaffinities ν_k and ν_l, defined as

$$\nu_k = \frac{1}{k^c l_c} l^b k^a \nabla_a k_b \qquad \nu_l = \frac{1}{k^c l_c} k^b l^a \nabla_a l_b \,. \tag{9}$$

In the latter equations, for T_{ab}, if we take the source to be a perfect fluid[c], then the energy momentum tensor reduces to

$$T_{ab} = \rho n_a n_b + P(e_a e_b + s_{ab}) \,. \tag{10}$$

where we adapt our vector basis to the fluid source, such that n^a gives its flow. In the latter decomposition ρ is the energy density, and P is the isotropic pressure, both measured by an observer moving with 4-velocity n^a. By construction, the flow n^a is always orthogonal to the surfaces of symmetry and will be characterized by two quantities

$$\mathcal{A} = e^a \dot{n}_a = e^a n^b \nabla_b n_a \,, \qquad \mathcal{B} = e^a n'_a = e^a e^b \nabla_b n_a \,. \tag{11}$$

The scalar $\mathcal{A}$ gives us the acceleration of the flow, a positive sign meaning that the acceleration is outwards in the spherical, compact case. The scalar $\mathcal{B}$ gives the

[c]The equations in the case of a general fluid are given by us in Ref.[46].

change of direction of n^a as we travel along e^a. It is the $e-e$ component of the extrinsic curvature K_{ab} of the 3-space orthogonal to this flow, since

$$K_{ab} = \frac{1}{2}\mathcal{L}_n h_{ab}\,, \tag{12}$$

where $h_{ab} = g_{ab} + n_a n_b$. We may also write

$$h_{ab} = e_a e_b + Y^2 \gamma_{ab}\,, \tag{13}$$

which gives

$$K_{ab} = \mathcal{B}\, e_a e_b + \frac{\Theta_{(n)}}{2}\, Y^2 \gamma_{ab}\,. \tag{14}$$

The trace of Eq. (14) gives us the flow volumetric expansion $\Theta_3 = \nabla_a n^a = K^a_a$ as

$$\Theta_3 = \mathcal{B} + \Theta_{(n)}\,. \tag{15}$$

In order to relate our quantities with the flow scalars, we compute the shear scalar σ, by taking the symmetric traceless part of K_{ab}. We obtain

$$\sigma = \frac{\Theta_{(n)}}{6} - \frac{\mathcal{B}}{3}\,, \tag{16}$$

which implies

$$\frac{\Theta_3}{3} + \sigma = \frac{\Theta_{(n)}}{2}\,, \tag{17}$$

in agreement with the result obtained in Ref.[38].

Using the inaffinities of the null basis vectors, $\mathcal{A}$ and $\mathcal{B}$ can be expressed as

$$\mathcal{A} = \nu_k - \nu_l\,, \qquad \mathcal{B} = \nu_k + \nu_l\,. \tag{18}$$

Contracting the conservation of the energy-momentum tensor with e_b (Euler equation in[47]) we get

$$e_b \nabla_a T^{ab} = (\rho + P)\dot{n}^b e_b + e^a \nabla_a P = 0 \Rightarrow$$
$$\mathcal{A} = -\frac{e^a \partial_a P}{\rho + P}\,. \tag{19}$$

3. Orthogonal Killing vector

We now assume that our metric has a Killing vector orthogonal to maximally symmetric surfaces, as we are interested in static configurations. Our symmetry requirements imply that it commutes with the symmetry generators on the foliation. We denote this hypersurface orthogonal Killing vector field χ^a. It satisfies the Killing equation,

$$\mathcal{L}_\chi g_{ab} = 0\,. \tag{20}$$

Proposition 1. If a spacetime is described by a metric of the form (1) and admits an orthogonal Killing vector $\chi^a \in \mathcal{N}$, then $\Theta_\chi = 0$.

Proof. We may write, from Eq. (6), $\Theta_\chi = \frac{1}{2}s^{ab}\mathcal{L}_\chi s_{ab} = \frac{1}{2}Y^{-2}\gamma^{ab}\mathcal{L}_\chi Y^2\gamma_{ab}$, and

$$g_{ab} = N_{ab} + Y^2\gamma_{ab}\,. \tag{21}$$

Then

$$\begin{aligned} 0 = Y^{-2}\gamma^{ab}\mathcal{L}_\chi g_{ab} &= Y^{-2}\gamma^{ab}\mathcal{L}_\chi N_{ab} + 2\Theta_\chi \\ &= -Y^{-2}N^{ab}\mathcal{L}_\chi\gamma_{ab} + 2\Theta_\chi\,. \end{aligned} \tag{22}$$

However

$$\mathcal{L}_\chi\gamma_{ab} = 0\,, \tag{23}$$

since χ^a does not admit components in $\mathcal{S}$ and γ_{ab} doesn't depend on coordinates along $\mathcal{N}$. Therefore, Eq. (22) implies that $\Theta_\chi = 0$. □

Consequently, if there is an extra symmetry with orbits orthogonal to those of the maximally symmetric leaves of the foliation, the two-expansion of its generator vanishes. This also implies that if $\mathrm{d}Y$ is spacelike, then χ_a is timelike and vice-versa. If $\mathrm{d}Y$ is null, the Killing vector will also be null.

4. Extension of the mass-energy parameter to open geometries

There is a widely known mass-energy definition suitable to the spherically symmetric case, namely the Misner-Sharp mass-energy,[48,49] that is defined regardless of asymptotic assumptions. However, as we also intend to analyze nonspherical spacetimes in this work, we are led to consider a more general mass-energy definition, namely the Hawking-Hayward's (hereafter HH).[37,50] The HH mass-energy gives the mass-energy content inside a closed compact surface in terms of an integral over that surface, in a manner similar to the Gauss law in Newtonian gravity. This quasilocal mass-energy has been explored in different contexts, such as seen in Refs.[51–53].

Under our symmetry assumptions the Hawking-Hayward mass-energy enclosed by Σ is reduced to

$$M_\Sigma = \frac{1}{8\pi}\sqrt{\frac{A}{16\pi}}\int_\Sigma\left[\mathcal{R} - \frac{1}{k^a l_a}\Theta_{(k)}\Theta_{(l)}\right]\mathrm{d}\Sigma \tag{24}$$

where $\mathcal{R}$ is the two-dimensional Ricci scalar and A is the area of Σ. We have included a factor of $-\dfrac{1}{k^a l_a}$ in the optical scalars part of the mass-energy, compared with the formula present in Ref.[37], in order to take account of our different normalization of the null normals. Our symmetry assumptions imply that the only non-vanishing optical scalar on Σ is the null expansion.

Since we assume that Σ is maximally symmetric, we have $\mathcal{R} = \frac{2\epsilon}{Y^2}$. We also have

$$\Theta_{(k)}\Theta_{(l)} = k^{(a}l^{b)}\partial_a \ln Y^2 \partial_b \ln Y^2 = \frac{k^c l_c}{2} g^{ab}\partial_a \ln Y^2 \partial_b \ln Y^2 =$$

$$\frac{1}{2}k^c l_c ||\mathrm{d}\ln Y^2||^2 = k^c l_c \frac{2}{Y^2}||\mathrm{d}Y||^2 \Rightarrow \frac{\Theta_{(k)}\Theta_{(l)}}{k^c l_c} = \frac{2}{Y^2}||\mathrm{d}Y||^2\,, \tag{25}$$

where we used Eq. (5) in the second step.

For the spherical case $\epsilon = 1$ and $A = 4\pi Y^2$, we obtain the known interpretation of $||\mathrm{d}Y||$ in terms of the Misner-Sharp mass-energy, which coincides with the Hawking-Hayward one

$$M_\Sigma = \frac{Y}{2}\left(1 - ||\mathrm{d}Y||^2\right) \Leftrightarrow ||\mathrm{d}Y||^2 = 1 - \frac{2M_\Sigma}{Y}\,. \tag{26}$$

In this work, we aim at treating all three symmetry types in the same manner. In the planar and hyperbolic cases ($\epsilon = 0$ and $\epsilon = -1$, respectively), the Hawking-Hayward mass is not conveniently defined for the integration domain set by our preferred foliation, as it requires a closed compact surface which is absent in the latter cases. Therefore, we need a mass-energy definition which might be equivalent to the HH mass-energy, but suitable to deal with (instead of adapted for) non compact domains in order to take advantage of the planar or hyperbolic symmetry.

We can make such an extension of the HH mass-energy, as long as their boundary correspond to a pair of symmetric two-surfaces of symmetry Σ corresponding to the same warp factor Y. Of course, those domains are infinite and have an infinite mass-energy content in general. However, as they are homogeneous along the surfaces of symmetry, we can successfully adapt the HH mass-energy definition in order to obtain a finite *mass-energy parameter* with those cases. They then describe an infinite mass-energy distribution, homogeneous along the surfaces of symmetry, with a finite density.

We proceed by first making the replacement

$$\frac{1}{8\pi}\sqrt{\frac{A}{16\pi}} \to \frac{Y}{4\pi\kappa}, \tag{27}$$

in order to keep its dimensionality, and eliminating the explicit dependence on the area of Σ. Evidently, by setting $\kappa = 4$ we recover the Hawking-Hayward mass-energy in the spherical case. This step is justified by the fact that originally this factor was introduced to correct the dimensionality of the mass-energy, and to make it match the Arnowitt-Deser-Misner (ADM) mass,[54] where both are well defined. Since our symmetric spacetimes allow an "areal scalar" as the warp factor Y, we can replace $\sqrt{A}$ by Y as the quantity with dimension of length associated to each surface of symmetry.

We then define the quasi-local mass-energy parameter $\mu(Y)$ by

$$M_\Sigma = \frac{\mu(Y)}{4\pi} \int S_\epsilon(\theta)\, \mathrm{d}\theta \mathrm{d}\phi\,, \tag{28}$$

and we write

$$\frac{Y}{4\pi\kappa}\left[\mathcal{R} - \frac{\Theta_{(k)}\Theta_{(l)}}{k^c l_c}\right]\int_\Sigma \mathrm{d}\Sigma = \frac{Y}{4\pi\kappa}\left[2\epsilon - 2||\mathrm{d}Y||^2\right]\int S_\epsilon(\Theta)\mathrm{d}\theta\mathrm{d}\phi\,. \tag{29}$$

Equating Eqs. (28) and (29) and eliminating the improper area integral on both sides we derive

$$||\mathrm{d}Y||^2 = \epsilon - \frac{\kappa\mu(Y)}{2Y}\,. \tag{30}$$

Equation (30) coincides with the known mass function [see Eq. (15.7a) in[55]] which appears as we integrate the Einstein equations of specific spacetimes with metrics of the form (1) for planar and hyperbolic symmetries. From now on, we will consider Eq. (30) with the choice $\kappa = 4$ as the mass-energy definition.

An alternative route to Eq. (30) can be obtained by computing the HH mass-energy in a finite domain, symmetric with respect to the central plane or wire, $Y = 0$, and taking the limit where the domain tends to be the whole surface. The finite integration domain consist of the union of

(1) a subset of the Σ_Y, that we denote Γ_r, bounded by a circle γ_r of radius r on the (θ, ϕ) coordinate plane and
(2) a compact surface given by the surfaces Δ_r defined by γ_r transported along Y orbits.

It forms a closed surface, corresponding to a part of a cylinder bounded by $Y =$ constant surfaces in the space of coordinates (Y, θ, ϕ). Therefore, the HH mass-energy enclosed by those surfaces will by finite, and given by

$$M_r = \frac{1}{8\pi}\sqrt{\frac{A_r}{16\pi}}\left(\int_{\Gamma_r}(\dots)S_\epsilon \mathrm{d}\theta\mathrm{d}\phi + \int_{\Delta_r}(\dots)\mathrm{d}\Delta\right) \tag{31}$$

where (...) replaces the integrand of Eq. (24). In the limit $r \to \infty$, the first integral in Eq. (31) scales as r^2 while the second one scales as r. This means that, in the limit $r \to \infty$, and repeating the replacement in Eq. (27) we obtain

$$\frac{M_r}{A_r} \to \frac{\mu(Y)}{4\pi Y^2}\,. \tag{32}$$

This relation is particularly adequate to obtain the extension of the TOV equation for the open geometries, as it will become apparent in the following section.

5. Evolution equations

5.1. *Timelike Killing vector*

We assume $\chi^a\chi_a < 0$. In this case, the spacetime is static, and $n^a \sim \chi^a$. Therefore, from Proposition 1, $\Theta_{(n)} = 0$ everywhere, and $\mathrm{d}Y$ is spacelike, since it is orthogonal to n^a. If $\Theta_{(n)}$ vanishes everywhere, this means that the fluid has no radial velocity, therefore we are dealing with a static fluid with a flow parallel to the Killing vector field.

In order to characterize its static equilibrium, we realise the derivative of the flow 2-expansion along the flow itself is vanishing

$$\mathcal{L}_n\Theta_{(n)} = 0\,, \tag{33}$$

since $\Theta_{(n)} = 0$ everywhere.

We may write $\mathcal{L}_n\Theta_{(n)}$ in terms of the null expansions as

$$\mathcal{L}_n\Theta_{(n)} = \mathcal{L}_k\Theta_{(k)} + \mathcal{L}_l\Theta_{(l)} + \mathcal{L}_l\Theta_{(k)} + \mathcal{L}_k\Theta_{(l)}\,. \tag{34}$$

Substituting the Eqs. (8a), (8b), and (8c), we obtain

$$\begin{aligned}\mathcal{L}_n\Theta_{(n)} = &-\frac{(\Theta_{(k)} + \Theta_{(l)})^2}{2} - \\ &\Theta_{(k)}\Theta_{(l)} - \frac{\epsilon}{Y^2} - 8\pi T_{ab}e^a e^b + \mathcal{A}(\Theta_{(k)} - \Theta_{(l)})\,.\end{aligned} \tag{35}$$

Recall that we are assuming $\Theta_{(n)} = \Theta_{(k)} + \Theta_{(l)} = 0$, and that $\Theta_{(k)} - \Theta_{(l)} = \Theta_{(e)}$, using Eqs. (7) and (3). We identify here $\Theta_{(k)}\Theta_{(l)}$ as the mass term, since it equals $\frac{2}{Y^2}||\mathrm{d}Y||^2 = \frac{2}{Y^2}\left(\epsilon - \frac{2\mu(Y)}{Y}\right)$.

Taking the source to be a perfect fluid, (10), and contracting the divergence of the energy-momentum tensor with e_b (Euler equation in[47]) we get

$$\begin{aligned}e_b\nabla_a T^{ab} = (\rho + P)\dot{n}^b e_b + e^a\nabla_a P = 0 \Rightarrow \\ \mathcal{A} = -\frac{e^a\partial_a P}{\rho + P}\,.\end{aligned} \tag{36}$$

Since $\Theta_{(n)} = 0$, e^a is proportional to ∂_Y, and as e^a is normalized, we have

$$e_a = \frac{1}{||\mathrm{d}Y||}\partial_a Y\,, \quad e^a = ||\mathrm{d}Y||(\partial_Y)^a\,, \tag{37}$$

which gives us

$$\mathcal{A}\Theta_e = -||\mathrm{d}Y||^2\,\frac{2}{Y}\frac{\partial_Y P}{\rho + P}\,. \tag{38}$$

Therefore, replacing $||\mathrm{d}Y||^2$ by its meaning in terms of mass, $\mathcal{L}_n\Theta_{(n)} = 0$ corresponds to[40]

$$\left(\frac{\epsilon}{Y^2} - \frac{2\mu(Y)}{Y^2}\right)\frac{\partial_Y P}{\rho + P} = -\frac{1}{Y}\frac{\mu(Y)}{Y^2} - 4\pi P\,, \tag{39}$$

that reveals that the generalization of the concept of mass-energy given by (32) is particularly suited to avoid the caveats of the divergence of that quantity if it were defined in accordance to the canon of the spherically symmetric models.

Of course the latter equation (39) can alternatively be cast under a more familiar form as

$$\frac{\partial_Y P}{\rho + P} = -\left(\frac{\mu(Y)}{Y^2} + 4\pi P Y\right)\left(\epsilon - \frac{2\mu(Y)}{Y}\right)^{-1}, \tag{40}$$

which is what we denote as *the unified TOV equation*. It reduces to the well-know TOV equation for spherically symmetric spacetimes when $\epsilon = 1$, and it corresponds to the equation of hydrostatic equilibrium for planar and hyperbolic geometries, in the cases where $\epsilon = 0$ and $\epsilon = -1$, respectively. This underlines the fact that the TOV equation is a hydrostatic equilibrium equation, and not an equation of state, as it is sometimes erroneously stated.

In order to determine $\mu(Y)$ we consider the $\mathcal{L}_e\Theta_{(e)}$ Raychaudhuri equation

$$\begin{aligned}\mathcal{L}_e\Theta_{(e)} = \mathcal{B}\Theta_{(n)} - \frac{\Theta^2_{(e)}}{2} + \frac{1}{4}\left(\Theta^2_{(n)} - \Theta^2_{(e)}\right) \\ + \frac{\epsilon}{Y^2} - 8\pi T_{ab} n^a n^b\,,\end{aligned} \tag{41}$$

which, by using $\Theta_{(n)} = 0$, and Eq. (37) lead us to

$$||\mathrm{d}Y||\partial_Y\left(\frac{2}{Y}||\mathrm{d}Y||\right) = -\frac{3}{Y^2}||\mathrm{d}Y||^2 + \frac{\epsilon}{Y^2} - 8\pi\rho\,. \tag{42}$$

Substituting Eq. (30) into Eq. (42), we obtain

$$\partial_Y \mu = 4\pi\rho Y^2\,, \tag{43}$$

which looks like the mass-energy equation of spherical symmetry. Here, it should be interpreted as the mass-energy equation in the spherical case, and as a mass-energy parameter equation in the planar and hyperbolic cases. Furthermore, Eqs. (43) and (30) imply that, if the *weak energy condition (WEC)*[56] *holds*, only the spherically symmetric case admits static regular solutions. Indeed, as those solutions require $||\mathrm{d}Y||^2 > 0$, that implies $\mu < 0$ for $\epsilon \leq 0$ and, as in regular spacetimes,

$$\mu(Y) = 4\pi\int_0^Y \rho(y) y^2 \mathrm{d}y\,, \tag{44}$$

this imposes $\rho < 0$.

With Eq. (43), the last requirement to solve Eq. (40) is the equation of state of the fluid, $f(\rho, P) = 0$ which should come from specific physical considerations.

5.2. *Spacelike Killing vector: The cosmological cases*

In the case of a spacelike Killing vector, $\mathrm{d}Y$ is timelike, the flow n_a is orthogonal to the Killing vector, and the unitary base vector e^a is parallel to it. This imposes no constraint on the sign of μ according to Eq. (30), and thus there is no need to

violate energy conditions in order to consider these solutions, thorougly studied in cosmology.[57]

Combining the dynamical equation given by $\mathcal{L}_e\Theta_{(e)} = 0$, and Proposition 1, we have $\Theta_{(e)} = 0$. Replacing Eq. (16) in Eq. (41), we derive

$$\frac{3}{4}\Theta^2_{(n)} - 3\sigma\Theta_{(n)} + \frac{\epsilon}{Y^2} = 8\pi\rho\,, \tag{45}$$

and, using Eq. (17), we can express this Eq. (45) in terms of the volume expansion Θ_3 obtaining

$$\frac{\Theta_3^2}{3} - 3\sigma^2 = 8\pi\rho - \frac{\epsilon}{Y^2}\,, \tag{46}$$

which corresponds to the generalised Friedmann constraint equation for the evolution of a homogeneous and anisotropic universe. In the case $\sigma = 0$, we may identify $\Theta_3 = 3H$, and we recover the usual Friedmann equation for the flat ($\epsilon = 0$) and open ($\epsilon = -1$) spatially isotropic universes. Notice though that $\sigma = 0$ also yields anisotropic, cosmological solutions when the matter content is not a perfect fluid.[58]

The $\mathcal{L}_n\Theta_{(n)}$ Raychaudhuri equation gives the evolution of $\Theta_{(n)}$. Using Eq. (35) we obtain

$$\mathcal{L}_n\Theta_{(n)} = -\frac{3}{4}\Theta^2_{(n)} - \frac{\epsilon}{Y^2} - 8\pi T_{ab}e^a e^b\,, \tag{47}$$

so that subtracting Eq. (45) from Eq. (47), we further derive

$$\mathcal{L}_n\Theta_{(n)} = -3\sigma\Theta_{(n)} - 8\pi\left(\rho + P\right)\,, \tag{48}$$

which, together with an equation of state relating ρ and P closes our system. By adding half of the Eq. (48) with one third of Eq. (46), we obtain:

$$\begin{aligned}\mathcal{L}_n\left(\frac{\Theta_3}{3}\right) + \left(\frac{\Theta_3}{3}\right)^2 = \\ - 2\sigma\left(\frac{\Theta_3}{3} + \sigma\right) - \frac{\epsilon}{3Y^2} - \frac{4\pi}{3}\left(\rho + 3P\right)\,.\end{aligned} \tag{49}$$

Those homogeneous and anisotropic spacetimes belong to a subclass of Bianchi models,[59,60] with the case $\epsilon = 0$ corresponding to Bianchi type I universes, $\epsilon = -1$ corresponding to the Bianchi type III models, and $\epsilon = 1$ to the Kantowski-Sachs spacetimes.[61]

In this work we are mainly focused on the hydrostatic equilibrium situations. Thus, our interest will be directed to understanding whether it is possible to find a correspondence between the TOV equation of static equilibrium, and some condition applying to the spatially homogeneous models.

Imposing staticity amounts in the present case to have $\Theta_3 = 0$, $\mathcal{L}_n\Theta_3 = 0$, and $\sigma = 0$ in Eqs. (46) and (49). Reconciling the reduced equations simply requires

$$\rho + P = 0\,, \tag{50}$$

in the $\epsilon = \pm 1$ cases, and has no realisation when $\epsilon = 0$, as $\rho = 0$ from Eq.(46). Hence we conclude that the TOV condition interpreted as a cornerstone of stability yields the well-known equation of state characterising a cosmological constant in the non flat cases. In hindsight, one could have anticipated this result which emerges here in a self-consistent way. Moreover we see that strong energy condition (SEC) is violated for both cases $\epsilon = \pm 1$, whilst the WEC is additionally violated for the $\epsilon = -1$ case, as follows from Eq. (46).

6. An illustration: Incompressible fluid solutions

Using our unified TOV equation, Eq. (40), we may look for static perfect fluid solutions for all three symmetries considered here. By choosing a timelike coordinate T along the flow, making $n_a = -\alpha(Y)\mathrm{d}T$, and the warp factor Y, we obtain the following line element in the (T, Y) coordinates:

$$\mathrm{d}s^2 = -\alpha^2(Y)\mathrm{d}T + \frac{\mathrm{d}Y^2}{\epsilon - \frac{2\mu(Y)}{Y}} + Y^2\mathrm{d}\Omega_\epsilon\,, \tag{51}$$

where $\mathrm{d}\Omega_\epsilon = \left(\mathrm{d}\theta^2 + S_\epsilon^2\mathrm{d}\phi^2\right)$ and the functions α and μ will be given by solving Einstein equations, i.e., Eqs. (40) and (30).

Here, we will apply our unified treatment to find the analogs of Schwarzschild interior solution, that is, we will use the equation of state of an incompressible fluid $\rho = \rho_0$ constant. It is important to note that, as we have discussed in Sec. 5.1, the static solutions with $\epsilon \neq 1$ violate the WEC, therefore we should take $\rho_0 < 0$ in those cases.

Equation (36) implies

$$\frac{\alpha'}{\alpha} = -\frac{P'}{\rho + P} \Rightarrow \alpha = \frac{c_0}{\rho_0 + P}\,, \tag{52}$$

where c_0 is an integration constant that can be set by rescaling the time coordinate and the prime denotes Y differentiation.

Equation (43) gives us

$$\mu(Y) = \frac{4\pi\rho_0 Y^3}{3}\,, \tag{53}$$

which we replace in Eq. (40) to obtain

$$P(Y) = \rho_0 \left(\frac{2\sqrt{|\epsilon - \frac{Y_s}{Y_g}|}}{3\sqrt{|\epsilon - \frac{Y_s}{Y_g}|} - \sqrt{|\epsilon - \frac{Y_s Y^2}{Y_s^3}|}} - 1 \right)\,. \tag{54}$$

where Y_g is the analog of the radius of the object and is the least positive number that satisfy $P(Y_g) = 0$, $Y_s = \dfrac{8\pi\rho_0 Y_g^3}{3}$ is the analog of the Schwarzschild radius,

although it can not be interpreted as a location since it will be a negative number. This gives

$$\alpha = \frac{1}{2}\left(3\sqrt{\left|\epsilon - \frac{Y_s}{Y_g}\right|} - \sqrt{\left|\epsilon - \frac{Y_s Y^2}{Y_g^3}\right|}\right) \tag{55}$$

which has a similar form to the interior Schwarzschild solution, where we only change the sign of the mass-energy parameter and change the value of ϵ in the formula. Of course the physical properties are very distinct, since the solutions violate the WEC.

In Fig. 1 we compare the pressure for the three cases. From the slope of the curves, we notice that only the hyperbolic case presents $P' > 0$, compensating the repulsive gravity force in this setup. This is the opposite of the more familiar situations presented in the spherical and planar cases, where gravity is attractive, with $P' < 0$ sustaining the weight of the configuration. We can also see that the planar case admits a positive pressure for $0 < Y < Y_g$. That means that, as long as mass-energy is negative, we may have static plane configurations over a finite Y interval. On the other hand, the hyperbolic solution only admits positive pressure for $Y > Y_g$, so there is no analog of the Schwarzschild interior solution for this foliation, although it can be interpreted as an exterior fluid solution to an internal void. It can thus be matched to a hyperbolic vacuum solution for $Y < Y_g$, found as a particular case in Ref.[31]:

$$\mathrm{d}s^2 = -\left(\frac{2m}{Y} - 1\right)\mathrm{d}t^2 + \frac{\mathrm{d}Y^2}{\frac{2m}{Y} - 1} + Y^2(\mathrm{d}\theta^2 + \sinh^2\theta \mathrm{d}\phi^2)\,, \tag{56}$$

where the parameter $m = |\mu|$. The peculiarities of the hyperbolic solutions with regard to the energy conditions are also found in the work.[42]

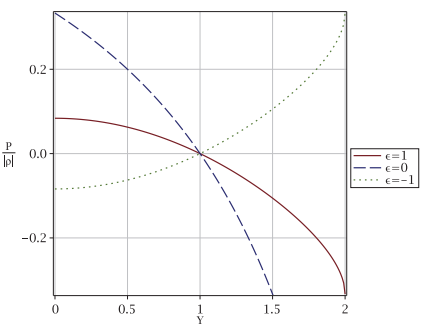

Fig. 1. Pressure as function of Y for $Y_g = 1$ and $|Y_s| = 0.25$ for $\epsilon = 1$, $\epsilon = 0$ and $\epsilon = -1$.

The equation of state consisting of a negative energy density with a positive pressure might be achieved by some kind of phantom field, but a Lagrangian description of the fluid is beyond the scope of this work. However, our simple incompressible

model, with constant energy density, but varying pressure, is reminiscent of a constant time surface of a McVittie or Shah-Vaidya spacetime, which admits a Lagrangian scalar field as source.[62,63] This suggests the possibility that there exist field models in the literature which can source the solutions presented in this paper.

We notice that the planar solutions may also represent a subclass of cylindrical solutions (see Refs.[64,65]) if we select one coordinate along the plane to be periodic. Thus, our planar solution may be interpreted as a static cylinder of fluid with boundary given by $Y = Y_g$. At this surface, the solution must be matched with a vacuum solution.

Actually, all fluid configurations found can be matched with the corresponding static solutions presented in Ref.[31] which arise from applying Birkhoff theorem for external fluid sources that satisfy the hypotheses of the theorem. In those cases there is a matter content present outside, the most common examples being an electromagnetic field, and a cosmological constant. Therefore the matching surface will correspond to a surface where $P(Y)$ matches the pressure of the exterior solution, in a manner similar to the way in which an uncompressible charged sphere is matched to a Reissner-Nordström solution in Ref.[66].

7. Conclusion

In this paper we analysed spacetimes with a two-dimensional maximally symmetric foliation sourced by a perfect fluid. We proved that in those cases, if there is a Killing vector orthogonal to the leaves, its two-expansion vanishes, which allows us to simplify our dynamical equations in terms of the two-expansion of a unit vector orthogonal to the Killing field.

When the Killing vector χ^a is timelike, we find that the flow lines must be tangent to χ^a, and as this is true at all times, the equations describe a hydrostatic equilibrium, governed by a (generalised) TOV equation. When the Killing vector is spacelike, we have instead a spatially homogeneous dynamical spacetime. The result is a subclass of Bianchi universes, with only one shear degree of freedom. The corresponding equation gives the evolution of expansion and shear scalars.

Our approach relates the mass parameter to the geometrically defined quasi-local mass-energies of Misner-Sharp and Hawking-Hayward by slightly changing its definition in order to apply it to our infinite mass-energy distributions. This innovation is in itself a step towards addressing the open issue of defining mass/energy in gravitation and cosmology, c.f the recent works of,[67] and others[68,69] on this subject.

Using these concepts we could recover the physical interpretation of the geometrical quantities appearing in the equilibrium/evolution equations, translate the dual null formalism to the more usual relativistic fluid dynamics framework, and show that the TOV equation arises as a particular case of those equations. Henceforth the generalizations of the TOV equation appear automatically by just setting $\epsilon = 0$ or -1 accordingly.

From this treatment it emerges the fact that the only static fluid solutions that satisfy the WEC are the spherical ones, as the other two cases require a negative energy density.

In what regards the spatially homogeneous spacetimes, the hydrostatic equilibrium condition also implies a violation of the SEC[70, 71] for the non planar solutions, constraining the equation of state for the perfect fluid to be that of a cosmological constant[d].

In order to illustrate the analogy between the planar, hyperbolic and spherical cases we studied the static solutions for an incompressible fluid. We found that, besides the known case of spherically symmetric spacetimes, we can obtain a static interior fluid configuration only in the case of planar symmetric spacetimes. In the hyperbolic case, the static configuration is an exterior solution that can surround an inner vacuum region.

Our unified way to describe three classes of spacetimes foliated with codimension-two leaves of constant curvature leads the way to further generalizations that we will address elsewhere.

A spherically symmetric stiff fluid spacetime in light of cosmic structure formation

School of Science, Jiangsu University of Science and Technology, Zhenjiang 212003, China
E-mail: danielegregoris@libero.it

We will report here a critical inspection of the Penrose conjecture according to which the gravitational entropy should be quantified via the Weyl curvature, with the Clifton-Ellis-Tavakol entropy being one specific realization of this proposal. In fact, we will show that in some exact inhomogeneous and anisotropic cosmological models which arise as exact solutions in general relativity with either closed and open topologies, the Clifton-Ellis-Tavakol gravitational entropy is increasing in time despite the decrease of the magnitude of the Weyl curvature: this is possible thanks to the growth of the spatial shearing effects. The matter content driving the dynamics of this class of models comes in the form of a stiffened fluid which can be relevant in the early universe. We choose the values of the free parameters entering the metric tensor consistently with the holographic principle and the second law of thermodynamics. Our study can be of interest in light of the modeling of the formation of some primordial structures, like the Large Quasar Groups, as suggested by the growth of gravitational entropy, and whose existence cannot be accounted for by standard perturbation methods over a homogeneous background.

Keywords: Exact solution; stiff matter; gravitational entropy.

1. Introduction

Our Universe contains a plethora of different astrophysical structures with different sizes such as galaxies, clusters of galaxies, filaments, voids,... The formation process for cosmic structures of sizes smaller than 150 Mpc, which is the length scale above which the universe is considered to be homogeneous,[1] can be described with perturbation schemes applied to a homogeneous background as the Friedman-Lemaître-Robertson-Walker one.[2,3] However, there is observational evidence of the existence of astrophysical structures like the one known as the "axis of evil"[4] which challenge the Copernican principle because they come with an alignment of matter along a preferred direction and their sizes are larger than 150 Mpc. Other examples are the Large Quasar Groups with sizes in the range of 70-350 Mpc.[5–8] Accounting for their existence by means of perturbation methods is problematic because the cosmic material would not cluster quickly enough for forming a bound system of this size: this is one among few other open questions affecting the standard model of cosmology.[12] Inhomogeneous cosmology may offer an alternative route for developing theoretical frameworks which can describe the evolution of matter perturbations undergoing a local collapse which can lead to the formation of an astrophysical structure. For example, in a dust Szekeres spacetime the density contrast grows eight times quicker

than in the linear perturbation regime making the process of formation of astrophysical structures more efficient.[13] There is also observational evidence of exotic astrophysical structures with non-standard size which should have formed in the early universe, as a supermassive black hole at redshift $z \sim 10$,[9,10] and the Huge Quasar Group at redshift $z \sim 1.27$,[11] whose existence cannot be explained by invoking effects played by an inhomogeneous spacetime supported by dust (which can be interpreted as pressureless dark matter). Therefore, the issue becomes to provide an appropriate theoretical framework in which spatial shear effects and tidal effects can trigger a local collapse in an overall expanding background supported by a matter content consistent with the early stages of evolution of the universe.

In the primordial universe shearing effects may play an important role, as compared to the one of the matter content, even though they are almost negligible at the present day.[14] Moreover, it has been argued that in early cosmic epochs the matter content may come in the form of a stiff fluid[a],[15–19] which is the effective hydrodynamical realization of a massless scalar field according to the canonical formalism.[20,21] More in detail, in[18,19] it has been argued that the early universe should be filled with cold baryons which fulfill the equation of state $p = \rho$, and that if cosmic matter is described as a relativistic self-gravitating Bose-Einstein condensate, then the cosmic evolution would experience a stiff-matter dominated era. Indeed the development of specific algorithms for integrating the Einstein field equations when the matter content is a stiff fluid has received attention in the literature;[22–28] then a number of exact and analytical solutions expressible in terms of elementary functions has been found obeying to a variety of symmetry groups,[29–32] just to mention a few examples.

One specific solution to the Einstein equations that we have adopted in our own research,[33] and which was found and investigated from the mathematical perspective by a number of different authors,[34–38] reads as (see also page 261 in[39]):

$$ds^2 = -\left(\frac{r}{2}\right)^2 dt^2 + \frac{dr^2}{\epsilon + Cr^2} + r^2\left[\frac{\epsilon}{2} + h(t)\right](d\theta^2 + \sin^2\theta d\phi^2), \tag{1}$$

where the "generalized scale factor" can either be

$$h(t) = A\sin(t) + B\cos(t) \qquad \text{if} \qquad \epsilon = -1\,, \tag{2}$$

$$h(t) = -\left(\frac{t}{2}\right)^2 + 2At + B \qquad \text{if} \qquad \epsilon = 0\,, \tag{3}$$

$$h(t) = Ae^t + Be^{-t} \qquad \text{if} \qquad \epsilon = 1\,, \tag{4}$$

according to the topology of the spacetime. We can note that the model (1) depends on three free parameters A, B, and C, and that only its angular part, and not the

[a] A stiff fluid is a perfect fluid, e.g. it is fully described by its adiabatic pressure p and energy density ρ, whose equation of state in natural units is $p = \rho$, and with matter-energy tensor $T^{\mu}{}_{\nu} = \mathrm{diag}[-\rho, p, p, p]$.

radial one, is expanding. The spacetime is supported by a fluid obeying to a stiffened equation of state

$$p = \rho + \frac{3C}{4\pi}\,. \tag{5}$$

which reduces to the case of a stiff fluid, i.e. of a massless scalar field, in the limit of $C \to 0$. Thus, this latter parameter, which does not affect directly the time evolution of the generalized scale factor $h(t)$ as we can appreciate from (2)-(3)-(4), would instead make the cosmic fluid pressure to be non-zero but equal to a constant in an empty space for which $\rho = 0$; more in general th equation of state (5) can be written in the form $p = \omega(\rho)\rho$ in which the density-dependent equation of state parameter can be interpreted as a chameleon field.[40,41] The Hubble function, invariant shear, cosmic energy density and Weyl curvature of the spacetime (1) are given by

$$H = \frac{4\dot{h}(t)}{3(\epsilon + 2h(t))r}\,, \tag{6}$$

$$\sigma^2 = \frac{4\dot{h}(t)^2}{3(\epsilon + 2h(t))^2 r^2} = \frac{3H^2}{4}\,, \tag{7}$$

$$\rho = -\frac{c^2(R + 18C)}{16\pi G}\,, \qquad R = -2\frac{\epsilon + \mathcal{R} + 6Cr^2(\epsilon + 2h(t))^2}{r^2(\epsilon + 2h(t))^2}\,, \tag{8}$$

$$\Psi_2 = -\frac{\mathcal{R} + \epsilon}{3r^2(2h(t) + \epsilon)^2}\,, \tag{9}$$

where an overdot denotes a derivative with respect to the cosmic time. In the computation of the latter quantity we have applied the Newman-Penrose formalism,[42] and the following notation has been introduced:

$$\begin{aligned} &\mathcal{R} = 4(A^2 + B^2) \qquad \text{for} \qquad \epsilon = -1\,, \\ &\mathcal{R} = 4(4A^2 + B) \qquad \text{for} \qquad \epsilon = 0\,, \\ &\mathcal{R} = -16AB \qquad \text{for} \qquad \epsilon = 1\,. \end{aligned} \tag{10}$$

Since we have a nonzero Weyl scalar Ψ_2, some tidal forces are present in the cosmological model (1),[43] and they can trigger a local gravitational collapse whose evolution then experiences the non-standard spatial shearing effects described by σ^2, potentially taming the previously mentioned problems of accounting for the existence of some astrophysical structures observed in the early universe. For exploring this topic, in our research[33] we have computed the gravitational entropy for the cosmology (1) by following the Clifton-Ellis-Tavakol proposal,[44] in which we have implemented some numerical values for the free parameters A, B, and C which are consistent with the thermodynamical requirements formulated through the cosmological holographic principle and the second law of thermodynamics. We have obtained that the gravitational entropy can be increasing even in the time intervals in which the strength of the Weyl curvature is decreasing, and therefore we have claimed that *Thermodynamics of shearing massless scalar field spacetimes*

is inconsistent with the Weyl curvature hypothesis according to which the conformal curvature can be adopted as a measure for the gravitational entropy.[45] Our result is due to the effects played by the spatial shear which accounts for the spatial anisotropies.

This *MG16 conference proceeding* is organized as follows: in Sect. 2 we impose the holographic principle and the second law of thermodynamics to the spacetime (1) showing how they can set some constraints on the behavior of various relevant physical quantities. In Sect. 3 we introduce the Clifton-Ellis-Tavakol entropy, discuss its importance in the modeling of the formation of astrophysical structures, and report on our specific results for the spacetime under investigation. In Sect. 4 we formulate the two messages that according to us the reader should take at home regardless the technicalities involved in this project. Finally in Sect. 5 we put our research into the larger perspective of the studies of gravitational entropy in inhomogeneous cosmology.

2. Imposing the thermodynamical requirements

According to the cosmological holographic principle, as formulated by Bousso, the matter entropy S_m inside a region bounded by a "horizon" should be smaller than the area A_H of the horizon itself, or more precisely $S_m \leq A_H/4$.[46] We can see that the celebrated Bekenstein-Hawking entropy for static black holes[47,48] constitutes the limiting case of this more general principle. For a dynamical spacetime we consider appropriate to work with the dynamical apparent horizon as the boundary of the region we are interested in; by introducing the areal radius

$$\tilde{r} = r\sqrt{\frac{\epsilon}{2} + h(t)}\,, \tag{11}$$

the location $\tilde{r}_H$ of the dynamical apparent horizon is such that[49]

$$||\nabla\tilde{r}||^2_{\tilde{r}=\tilde{r}_H} = 0\,. \tag{12}$$

In a time-evolving configuration, the dynamical apparent horizon is not the unique choice for the boundary of the region to which the cosmological holographic principle can be imposed; however in the homogeneous and isotropic Friedman universe assuming the space to be filled with some form of dark energy the first and second law of thermodynamics have been shown to hold for the dynamical apparent horizon, but not if one works with the cosmic horizon,[50] providing a motivation for choosing our route.[51,52]

Since the fluid energy density should be non-negative all along the time evolution of the system, we found that C should be non-positive; under this restriction, equation (12) admits a solution only for the topology $\epsilon = 1$. Setting the parameters A and B to be positive guarantees both a well-defined cosmic energy density and the existence of a solution for the equation determining the location of the dynamical apparent horizon. Taking into account that $A_H = 4\pi\tilde{r}_H^2$ and that $S_m = \alpha\tilde{r}_H^3$, with

α an overall proportionality constant, it can be seen after some computations that the holographic principle is further constraining the value of C, i.e. of the deviations of the equation of state of the cosmic matter from a stiff fluid. The cosmological consequences of these restrictions on the values of the arbitrary model parameters are:

- If we compute the deceleration parameter as in,[53] it would be negative;
- Since $\epsilon + 2h(t) \neq 0$, there would be no initial singularity in this cosmology because there would not exist a time t_B at which the energy density (8) would diverge.

On the other hand, imposing the second law of thermodynamics to the matter content would require $\dot{S}_m > 0$, which can be translated into the equivalent condition $\frac{d\tilde{r}_H}{dt} > 0$. After some algebraic manipulations, we could recast this condition as $Ae^t - Be^{-t} > 0$; thus, the cosmological consequences within the model (1) of imposing the second law are:

- The lower limit on the size of the universe $h(t) > 2Be^{-t}$ is established;
- The lower limit on the age of universe $t > \frac{1}{2}\ln\frac{B}{A}$ is established;
- The Weyl curvature Ψ_2 is a time-decreasing quantity.

3. Computing the gravitational entropy

"Entropy" can be naively regarded as a measure of the disorder within a system (as related to the existence of an arrow of time), or as a quantification of the number of different microscopic realizations compatible with the same macroscopic system (statistical entropy). Therefore, in cosmology, as astrophysical structures form in one specific spatial regions rather than in others with the whole universe remaining homogeneous on large enough length scales, the gravitational entropy should increase. Since when an observer looks at the universe from its location it may or may not detect an astrophysical structure, the growth of gravitational entropy should be accompanied by an increase of the spatial anisotropy. One specific way of computing the density $s_{\rm grav}$ of gravitational entropy in Petrov type D spacetime, as for example (1), is due to Clifton-Ellis-Tavakol[44]:

$$T_{\rm grav}\dot{s}_{\rm grav} = -dV\sigma_{\mu\nu}\left(\pi^{\mu\nu}_{\rm grav} + \frac{(\rho+p)}{3\rho_{\rm grav}}E^{\mu\nu}\right). \tag{13}$$

The ingredients of this formula are the following:

- The temperature of the free gravitational field defined as

$$T_{\rm grav} = \frac{|u_{a;b}l^a n^b|}{\pi} = \frac{r}{8\pi\sqrt{Cr^2+\epsilon}}, \tag{14}$$

  where u^a is the matter-comoving observer four-velocity, and l^a and n^a are part of the null coframe containing the dt and dr contributions.

- The volume element
$$dV = \frac{r^2 \sin\theta(\epsilon + 2h(t))}{2\sqrt{Cr^2+\epsilon}}\, dr d\theta d\phi\,. \tag{15}$$
- The shear tensor $\sigma_{\mu\nu}$ which describes the rate of distortion of a given region with fixed volume during the cosmic evolution.
- The gravitational energy defined in terms of the Weyl curvature as:
$$\rho_{\rm grav} := 16\pi|\Psi_2|\,. \tag{16}$$
- The gravitational anisotropic pressure also defined in terms of the Weyl curvature as:
$$\pi^{\rm grav}_{\mu\nu} := \frac{|\Psi_2|}{16\pi}(-x_a x_b + y_a y_b + z_a z_b + u^a u^b)\,, \tag{17}$$
in which x_a, y_a, z_a constitute the spacelike vectors in the orthonormal base for the metric (1).
- The gravito-electric tensor $E_{\mu\nu}$ which accounts for tidal effects, which are indeed necessary for having a gravitational collapse.

We have considered the approach (13) to be a sound proposal for computing the gravitational entropy because, as pointed out in,[44] it delivers a non-negative entropy, it is consistent with the Hawking-Bekenstein entropy of black holes, it provides a vanishing entropy in and only in conformally flat spacetimes (as for example in the homogeneous and isotropic Friedman-Lemaître-Robertson-Walker universe in which astrophysical structures cannot form due to the lack of any matter density contrast), and it is related to the growth of anisotropies in the spacetime (as they indeed increase during the structure formation phase).

Thus, it does not come as a surprise that the conjecture of a connection between gravitational entropy and Weyl curvature has been regarded as a useful tool for the description of the formation of astrophysical structures in various inhomogeneous models. For example, in[54] a relationship between the growth of gravitational entropy and the amplitude of initial fluctuations of spatial curvature at the last scattering time has been found, while the possible saturation of its value at a certain time has been investigated in[55] for the Lemaître-Tolman-Bondi universe, in[56] more in general for the class of silent universes for which the gravitomagnetic part of the Weyl curvature vanishes, and in[57] for a perturbed Friedman spacetime. Furthermore, a gravitational entropy quantified via the Weyl curvature is consistent with the generalized second law in the void Lemaître-Tolman-Bondi universe,[58] and the specific Clifton-Ellis-Tavakol entropy has been shown to be a time increasing function in a number of cosmological models.[59]

Our explicit computations for the Clifton-Ellis-Tavakol gravitational entropy delivered the result
$$T_{\rm grav}\dot{s}_{\rm grav} = dV\frac{64\pi\dot{h}(t)(1-16AB)}{3(2h(t)+\epsilon)^3 r^3}\,. \tag{18}$$

Here we have restricted ourselves to the spacetime (4) because, as mentioned in Sect. 2, it is the only case within (1) for which a thermodynamical investigation based on the cosmological holographic principle was possible. Then, implementing the constraints on the free parameters obtained from such analysis and those arising from the second law of thermodynamics, we have found that a challenge to the Weyl curvature conjecture proposed by Penrose[45] is posed. In fact, the gravitational entropy is increasing even when the gravito-electric curvature as measured by Ψ_2 in (9) is not, and thus the latter cannot be considered too naively as a measure of the former.

4. Discussion

Quantifying the effects that the interactions between small-scale inhomogeneities (e.g. galaxies, galaxy clusters, voids, filaments, etc...) have on the large-scale evolution of the Universe is not a trivial task, and the debate in the literature about their importance is still open.[61] There exists in fact a range of completely different claims from that they have no effects at all to the one that they can bring an energy budget which can be responsible for the observed accelerated expansion of the universe without the need of a cosmological constant; see[62] for a review of different approaches and their predictions. Once endowed with a cosmological model formulated in terms of a metric tensor solution of the field equations of the underlying gravitational theory, it is necessary to investigate its physical applicability. Some widely applied cosmological tests which can assess the suitability of a mathematical solution of the Einstein equations as a cosmological model rely on supernovae data,[63–65] cosmic microwave background data,[66,67] or baryon acoustic oscillations data,[68,69] and clearly require data-analysis skills. For example, the inhomogeneous dust Lemaître-Tolman-Bondi model has been shown to be in tension with the kinematic Sunyaev-Zel'dovich effect[70] although it is not with observations related to the luminosity distance of supernovae, without the need of dark energy but assuming that the observer is located inside a giant void;[71] more in general the development of "model independent" tests for inhomogeneous cosmology constitutes a line of current research.[72–74] However, in Sect. 2 we have explained how "theoretical" requirements can also be exploited for constraining the values of the free model parameters and for extracting cosmological information about the model under investigation. We had previously applied the same way of thinking to the Stephani cosmological model by estimating the strength of spatial inhomogeneities, the matter abundance and the size of the universe by imposing the cosmological holographic principle and the second law of thermodynamics[75] (however this latter spacetime is conformally flat and therefore it does not offer any viable possibility for an investigation of the gravitational entropy). Thus, the first take at home message from our research is:

- By working with solely pen and paper, we can constrain a given cosmological model known in terms of its metric tensor by imposing the

thermodynamical requirements which follow from the cosmological holographic principle and the second law of thermodynamics.

In Sect. 3 we have mentioned that the Clifton-Ellis-Tavakol gravitational entropy is increasing in time for the spacetime (1) although the Weyl curvature is not thanks to the presence of a term given by shear tensor which is inserted by hands in its formulation. The fact that spatial shearing effects are developing in the same time interval in which the gravitational entropy is increasing is a fundamental consistency check for the mathematical formula adopted for the latter. In fact, both these quantities are expected to increase during the structure formation phase because the universe is becoming anisotropic and inhomogeneous, with the former being measured by the shear tensor while the latter can be regarded as an increase of the level of "disorder" of the system which should be quantified via an appropriate entropy quantity. Thus, our second take at home message, whose consequences will be further explored in the next Sect. 5 is:

- Implementing the Weyl curvature conjecture according to which the Weyl curvature should serve as a measure for the gravitational entropy is not as simple as it may look like at a first sight and other ingredients may be necessary in the construction of a mathematical formula for the gravitational entropy.

5. Outlook

The search for an appropriate inhomogeneous cosmological model which can provide a viable framework for addressing the issue of the formation of astrophysical structures with sizes larger than 150 Mpc (and which is also in agreement with other datasets), and the formulation of an appropriate measure for the "gravitational entropy" in the spirit of the Weyl curvature conjecture are two related problems. Therefore, we consider appropriate to investigate various notions of gravitational entropy as the following:

- $$S = \frac{C_{\mu\nu\rho\sigma}C^{\mu\nu\rho\sigma}}{R_{\mu\nu}R^{\mu\nu}} \tag{19}$$

  where $C_{\mu\nu\rho\sigma}$ and $R_{\mu\nu}$ are respectively the Weyl and Ricci tensor, and its spatially integrated version

  $$\tilde{S} = \int dV S\,. \tag{20}$$

  This formula has arisen in the context of cosmologies exhibiting an anisotropic singularity.[76] However this proposal cannot be applied to vacuum spacetimes because of the vanishing of the Ricci tensor.

- Eq. (19) but multiplied by the square root of the determinant of the spatial metric h as suggested in[77]:

$$S = \sqrt{h}\frac{C_{\mu\nu\rho\sigma}C^{\mu\nu\rho\sigma}}{R_{\mu\nu}R^{\mu\nu}}\,, \tag{21}$$

  which would be something in between the two proposals of the previous step.
- Applying a spatially averaging scheme and writing the entropy as[78,79]

$$S = V_{\mathcal{D}}\left\langle \rho \ln \frac{\rho}{\langle\rho\rangle_{\mathcal{D}}} \right\rangle_{\mathcal{D}}\,, \tag{22}$$

  where angular brackets denote an average over the spatial domain of interest $\mathcal{D}$.
- The Clifton-Ellis-Tavakol entropy that we have already talked about in Sect. 3.

These inequivalent ways of computing the gravitational entropy should be applied to the general line element describing a spherically symmetric dynamical spacetime (see page 251 in[39])

$$ds^2 = -e^{2\nu(t,r)}dt^2 + e^{2\lambda(t,r)}dr^2 + Y^2(t,r)(d\theta^2 + \sin^2\theta d\phi^2) \tag{23}$$

in a set of future projects. Intuitively, we expect that demanding the simultaneous growth of shear, Weyl curvature and gravitational entropy would provide some information on the increasing/decreasing and concavity properties of the functions $\nu(t,r)$, $\lambda(t,r)$ and $Y(t,r)$, which then will be implemented into the Einstein equations for understanding which types of matter content permit to achieve this goal.

All the previously mentioned proposals for computing the gravitational entropy are directly sensitive to the matter content of the spacetime. In fact in some of them the energy density (Hosoya-Buchert-Morita) and possibly also the pressure (Clifton-Ellis-Tavakol) appear explicitly; in other cases as in (19)-(20)-(21) they are inserted via the Ricci tensor, which is connected to the matter content of the universe as we can see from the Einstein equations written in the form

$$R_{\mu\nu} = 8\pi\left(T_{\mu\nu} - \frac{1}{2}g_{\mu\nu}T\right)\,. \tag{24}$$

A more conservative proposal which has been formulated recently in the context of black hole physics argues that it is possible to write the density s of gravitational entropy just in terms of the frame component of the Weyl tensor W and of its Newman-Penrose derivative DW as[80]

$$s = \left|\frac{DW}{W}\right|. \tag{25}$$

The applicability of such formalism in inhomogeneous cosmology and in particular the investigation of its relationship to the spatial anisotropies quantified by the shear tensor would constitute a subject of future studies.

The null-surface formuation (NSF) of general relativity is equivalent to standard general relativity but uses families of null surfaces rather than the metric or connection. The NSF can be constructed in dimension 3+1, in any dimension higher, and also in dimension 2+1, which is a special case: In 2+1 dimensions, the main NSF field equation is equivalent to Cartan's metricity condition. The latter arose in differential equation theory to address the problem of classifying solutions of 4 third-order ordinary differential equations. Solving the NSF/Cartan equation has proved challenging, and only three solutions are known to date. This talk presents a fourth solution, which depends upon three independent parameters. Two of the previously known solutions are included as special cases. Energy conditions and possible source terms are examined. The physical interpretation is discussed in detail.

Keywords: Null-surface formulation; NSF; metricity condition; low dimensional gravity; imperfect fluid.

1. Introduction

The NSF[1–3] uses families of null surfaces, rather than a metric, and can be presented in terms of a function Z that specifies the families. More commonly, the NSF is described in terms of a function Λ that is related to Z by differentiation. If required, a metric can be constructed up to a conformal factor from a knowledge of either Z or Λ and an auxiliary function Ω. Forni, Iriondo, Kozameh and Parisi,[4,5] Tanimoto,[6] and Silva-Ortigoza[7] have constructed a (2+1)-dimensional version of the NSF. A brief summary of the 2+1 NSF is given in the remainder of this section. The sections that follow will present a new solution and list its properties.

The equation $u = Z(x^a; \varphi)$ defines a surface, with x^a $(a = 0, 1, 2)$ being spacetime coordinates and $\varphi \in S^1$ being an angular variable. The role of φ is to label the surfaces. For the surfaces to be *null* with respect to a spacetime metric $g_{bc}(x^a)$,

the gradient of Z must satisfy

$$g^{bc}(x^a)Z_{,b}(x^a;\varphi)\,Z_{,c}(x^a;\varphi) \;=\; 0, \tag{1}$$

where $Z_{,a} \equiv \partial_a Z \equiv \partial Z/\partial x^a$. Equation (1) and its derivatives with respect to φ lead to the *metricity conditions*, which ensure that the nullness requirement is satisfied. The metricity conditions are most easily expressed in terms of coordinates that are naturally adapted to the surfaces.[4–6] Such coordinates are called *intrinsic* coordinates,[2] and are denoted

$$\begin{aligned} u &:= Z(x^a;\varphi), \\ \omega &:= \partial u \;\equiv\; \partial Z(x^a;\varphi), \\ \rho &:= \partial\omega \;=\; \partial^2 u \;\equiv\; \partial^2 Z(x^a;\varphi), \end{aligned}$$

where $\partial := \partial/\partial\varphi$ is the derivative with respect to φ when the x^a are held fixed. In principle, the above equations can be inverted to give

$$x^a \;=\; x^a(u,\omega,\rho,\varphi).$$

The third derivative of Z (i.e. of u) is denoted by Λ:

$$\Lambda(u,\omega,\rho,\varphi) := \partial^3 Z(x^a(u,\omega,\rho,\varphi);\varphi).$$

If Λ is known, then Z can be determined by integration. The intrinsic coordinates u, ω and ρ are φ-dependent and it can be shown that the action of the differential operator ∂ on a function $f(u,\omega,\rho,\varphi)$ is given by[4,6]

$$\partial \;=\; \partial' + \omega\,\partial_u + \rho\,\partial_\omega + \Lambda\,\partial_\rho,$$

where ∂' denotes the derivative with respect to φ when u, ω and ρ are held fixed.

Equation (1) leads to the following form for the inverse metric g^{ij},[4,6] expressed in terms of the u,ω,φ coordinates, with the signature of g^{ab}, and hence of g^{ij}, being chosen to be $(-++)$:

$$[\,g^{ij}\,] = \Omega^2\,[\,\gamma^{ij}\,] = \Omega^2 \begin{pmatrix} 0 & 0 & -1 \\ 0 & 1 & \frac{1}{3}\partial_\rho\Lambda \\ -1 & \frac{1}{3}\partial_\rho\Lambda & \frac{1}{3}\partial(\partial_\rho\Lambda) - \frac{1}{9}(\partial_\rho\Lambda)^2 - \partial_\omega\Lambda \end{pmatrix}.$$

It follows that the components of the metric g_{ij} are

$$[\,g_{ij}\,] = \Omega^{-2}\,[\,\gamma_{ij}\,] = \Omega^{-2} \begin{pmatrix} -\frac{1}{3}\partial(\partial_\rho\Lambda) + \frac{2}{9}(\partial_\rho\Lambda)^2 + \partial_\omega\Lambda & \frac{1}{3}\partial_\rho\Lambda & -1 \\ \frac{1}{3}\partial_\rho\Lambda & 1 & 0 \\ -1 & 0 & 0 \end{pmatrix}, \tag{2}$$

where γ_{ij} is called the *unphysical* metric. Equations (1) and (2) can be used to derive the following metricity conditions.[4,6]

$$2[\partial(\partial_\rho\Lambda) - \partial_\omega\Lambda - \tfrac{2}{9}(\partial_\rho\Lambda)^2]\partial_\rho\Lambda - \partial^2(\partial_\rho\Lambda) + 3\,\partial(\partial_\omega\Lambda) - 6\,\partial_u\Lambda = 0, \tag{3}$$

$$3\,\partial\Omega \;=\; \Omega\,\partial_\rho\Lambda. \tag{4}$$

Equations (3) and (4) ensure that Λ will determine a null surface with respect to *some* spacetime metric $g_{bc}(x^a)$. Equation (3) is the main metricity condition. Equation (4) is the secondary metricity condition. If the two metricity conditions are satisfied, then the Einstein equations, $G_{ij} = \kappa T_{ij}$, will be satisfied if the following equation holds:[4]

$$\partial_\rho^2 \Omega \;=\; \kappa T_{\rho\rho} \Omega. \tag{5}$$

Finding a solution in the NSF approach requires solving the coupled set of NSF field equations, Eqs (3), (4) and (5), for Λ and Ω. In 2+1 dimensions, only three nontrivial solutions of the NSF equations have been found to date.[8–10] The present paper introduces a new family of solutions.

2. Solution

The form of the differential operator ∂ suggests looking for solutions that are additively separable. Consider solutions that take the form

$$\Lambda(u, \omega, \rho) = -a\omega + h(\rho + au) = -a\omega + h(x), \tag{6}$$

where a is a constant. Writing $x := \rho + au$, will convert the main metricity condition, Eq. (3), into an ordinary differential equation with x as the independent variable:

$$h^2 \frac{d^3h}{dx^3} - h \frac{dh}{dx} \frac{d^2h}{dx^2} + \frac{4}{9} \left(\frac{dh}{dx} \right)^3 + 4a \frac{dh}{dx} = 0. \tag{7}$$

The solution of Eq. (7), together with Eq. (6), represents a solution of the main metricity condition. After introducing a new dependent variable $y := h^{2/3}$, and replacing h by $y^{3/2}$, Eq. (6) becomes

$$\Lambda(u, \omega, \rho) \;=\; -a\omega + [y(\rho + au)]^{3/2} \;\equiv\; -a\omega + [y(x)]^{3/2}, \tag{8}$$

and Eq. (7) becomes

$$\frac{d^3y}{dx^3} + 4a\, y^{-3} \frac{dy}{dx} \;=\; 0,$$

which can be rewritten

$$\frac{d}{dx} \left(\frac{d^2y}{dx^2} - 2ay^{-2} \right) \;=\; 0,$$

and leads to

$$\frac{d^2y}{dx^2} - 2ay^{-2} \;=\; k,$$

where k is a constant. A further integration can be achieved by multiplying by dy/dx to give

$$\frac{dy}{dx} \frac{d^2y}{dx^2} - 2ay^{-2} \frac{dy}{dx} - k \frac{dy}{dx} \;=\; 0,$$

which leads to

$$\left(\frac{dy}{dx}\right)^2 + 4ay^{-1} - 2ky \;=\; -A,$$

where A is a constant. The minus sign in front of A has been inserted for later convenience. It follows that

$$\frac{dy}{dx} \;=\; \pm\left(2ky - A - 4ay^{-1}\right)^{1/2},$$

and so

$$x = \pm \int \frac{dy}{\sqrt{2ky - A - 4ay^{-1}}},$$

$$\pm \int \frac{y\,dy}{\sqrt{y\,(2ky^2 - Ay - 4a)}}. \tag{9}$$

Equation (9) expresses y as an implicit function of x and, together with Eq. (8), represents an exact solution of the main metricity condition, Eq. (3). Although the right side of Eq. (9) can be evaluated in terms of elliptic integrals of the first and second kinds, the result is too complicated for the equation to be inverted to give y as an explicit function of x. Simplifications arise when some of the constants, A, a, and k, are zero. For example, if $A \neq 0, k \neq 0$, and $a = 0$, the solution becomes the perfect fluid, Petrov-type D, solution that the present authors reported in an earlier paper.[8] The special case where $k \neq 0, a \neq 0$, and $A = 0$ was also reported in an earlier paper, where the spacetime was determined to be of Petrov-type I and the source was represented by a minimally coupled scalar field.[9]

Now consider the secondary metricity condition, Eq. (4),

$$3\,\partial\Omega \;=\; \Omega\,\partial_\rho\Lambda.$$

As with Λ, assume that Ω depends upon u and ρ through the combination $\rho + au$, but assume that Ω is independent of ω. Thus $\Omega = \Omega(\rho + au)$. Using $\Lambda = -a\omega + h = -a\omega + y^{3/2}$, it follows that

$$\Omega = h^{1/3} = y^{1/2}.$$

The third NSF equation, Eq. (5),

$$\partial_\rho^2\Omega \;=\; \kappa T_{\rho\rho}\,\Omega,$$

then implies

$$T_{\rho\rho} = \frac{1}{2\kappa\,y^2}\left\{y\,\frac{d^2y}{dx^2} - \frac{1}{2}\left(\frac{dy}{dx}\right)^2\right\}.$$

It follows that

$$T_{\rho\rho} = \frac{1}{4\kappa\,y^2}\left(A + 8ay^{-1}\right) = \frac{1}{4\kappa\,y^2}\,W,$$

where W is defined by

$$W := A + 8ay^{-1}. \tag{10}$$

For any null vector V, the null energy condition requires $R_{ij}\,V^iV^j \geq 0$, which is equivalent to $G_{ij}\,V^iV^j \geq 0$. The vector $V^\rho = \partial_\rho \equiv (0,0,1)$ is null and so $T_{\rho\rho} \geq 0$, or equivalently $W \geq 0$, is a *necessary* condition for the null energy condition to hold. Henceforth, it will be assumed that $W \geq 0$.

3. Metric and Curvature

The form of the solution given in Section 2 implies

$$\partial_\rho^2 y = 2a\,y^{-2} + k, \tag{11}$$

and

$$(\partial_\rho y)^2 = 2k\,y - A - 4a\,y^{-1}. \tag{12}$$

Equations (11) and (12), together with the fact that $\Omega = y^{1/2}$, lead to the following expression for the metric g_{ij}:

$$[\,g_{ij}\,] = \Omega^{-2}\,[\,\gamma_{ij}\,] = \begin{pmatrix} -\left(\frac{1}{4}A + 3ay^{-1}\right) & \frac{1}{2}y^{-1/2}\,\partial_\rho y & -y^{-1} \\ \frac{1}{2}y^{-1/2}\,\partial_\rho y & y^{-1} & 0 \\ -y^{-1} & 0 & 0 \end{pmatrix}. \tag{13}$$

Hence $g := \det g_{ij} = -y^{-3}$. The inverse metric is

$$[\,g^{ij}\,] = \Omega^2\,[\,\gamma^{ij}\,] = \begin{pmatrix} 0 & 0 & -y \\ 0 & y & \frac{1}{2}y^{3/2}\,\partial_\rho y \\ -y & \frac{1}{2}y^{3/2}\,\partial_\rho y & \frac{1}{2}ky^3 + 2ay \end{pmatrix}.$$

Equations (11), (12), and (13) can be used to find the Christoffel symbols and the Ricci tensor R_{ij}, which are listed in the appendix. The scalar curvature is constant:

$$R = \frac{1}{32}\,A^2 + ka. \tag{14}$$

If the constants A. a, and k, are all assumed to be positive (which is consistent with $W > 0$), then it is straightforward to show that the matrix $[\,R_{ij}\,]$ is positive definite. This implies that the null, weak, and strong energy conditions are all satisfied.

Being a theory of null surfaces,the NSF does not distinguish between conformally related spacetimes. Thus NSF solutions that correspond to conformally flat spacetimes are considered to be trivial. In 2+1 dimensions, the Cotton-York tensor is defined by[11]

$$C^i_{\ j} \;:=\; \varepsilon^{ikp}\left(R_{pj} - \frac{1}{4}R\,g_{pj}\right)_{;\,k}$$

and provides a test for conformal flatness: A (2+1)-dimensional spacetime is conformally flat if and only if $C^i_j = 0$. For the solution considered in the present paper, $C^i_j \neq 0$ (except for the trivial case where the constants A, k, and a are all zero). Thus the spacetime is not conformally flat. The components C^i_j are listed in the appendix.

4. Fluid Source: Kinematics

Begin by assuming that the source is a fluid. Equation (10) and the discussion around the null-energy condition gave $W := A + 8ay^{-1} \geq 0$. Make the further assumption that $W + 4ay^{-1} > 0$ so that

$$\frac{1}{4}\,A + 3ay^{-1} > 0.$$

It follows from Eq. (13) that $g_{uu} < 0$. The form of the Ricci tensor, R_{ij}, given in the appendix then suggests the following convenient choice for the fluid velocity vector U,

$$(U^u,\, U^\omega,\, U^\rho) := a^{-1/2} y^{1/2}\,(1,\, 0,\, -\tfrac{1}{8} W y),$$

$$(U_u,\, U_\omega,\, U_\rho) \;=\; a^{-1/2} y^{-1/2}\,(-\tfrac{1}{8} W y - a,\, \tfrac{1}{2} y^{1/2}\,\partial_\rho y,\, -1),$$

which, using the R_{ij} given in the appendix, leads to

$$R_{ij} U^i U^j = \frac{1}{8} A R a^{-1} y. \tag{15}$$

Note that $U^i U_i = -1$, as required. The covariant derivative $U_{i\,;\,j}$ can be written as a sum[12] (p. 85)

$$U_{i\,;\,j} \;=\; \omega_{ij} + \sigma_{ij} + \frac{1}{2}\,\theta\, h_{ij} - \dot{U}_i\, U_j,$$

where the projection tensor h_{ij}, the acceleration vector $\dot{U}_i$, the vorticity tensor ω_{ij}, the expansion θ, and the shear tensor σ_{ij} are defined by

$$h_{ij} := g_{ij} + U_i U_j,$$

$$\dot{U}_i := U_{i\,;\,j}\, U^j,$$

$$\omega_{ij} := \frac{1}{2}\,(U_{i\,;\,k}\, h^k_j - U_{j\,;\,k}\, h^k_i),$$

$$\theta := U^i_{\,;\,i},$$

$$\sigma_{ij} := \frac{1}{2}\,(U_{i\,;\,k}\, h^k_j + U_{j\,;\,k}\, h^k_i) - \frac{1}{2}\,\theta\, h_{ij}.$$

The coefficient of θ, both in the expression for $U_{i\,;\,j}$ and in the expression for σ_{ij}, is $\frac{1}{2}$ (instead of $\frac{1}{3}$, as would be the case in 3+1 dimensions). This follows because the trace $h^i_{\ i}$ of the projection tensor is 2 (instead of 3). The components of $U_{i\,;\,j}$ and other kinematic quantities, including the acceleration vector $\dot{U}^i$, are listed in the appendix. The divergence of the acceleration vector, $\dot{U}^i_{\ ;\,i}$, is

$$\dot{U}^i_{\ ;\,i} = \frac{1}{8}(A - 4ky)Ra^{-1}y. \tag{16}$$

The expansion scalar, θ, measures the isotropic volume expansion of the fluid and is found to be zero:

$$\theta = 0. \tag{17}$$

The scalar vorticity ω and the scalar shear σ are given by

$$\omega^2 := \frac{1}{2}\omega^{ij}\,\omega_{ij} \ = \ \frac{1}{4}R^2a^{-2}y^2, \tag{18}$$

$$\sigma^2 := \frac{1}{2}\sigma^{ij}\,\sigma_{ij} \ = \ \frac{1}{128}A^2Ra^{-2}y^2. \tag{19}$$

Raychaudhuri's equation can be written[13] (p. 5295)

$$\dot{\theta} = -\frac{1}{2}\theta^2 - R_{ij}U^iU^j - 2\left(\sigma^2 - \omega^2\right) + \dot{U}^i_{\ ;\,i}.$$

Using Eqs (15) to (19), it is straightforward to verify that Raychaudhuri's equation holds.

5. Fluid Source: Dynamics

In analysing the Einstein field equations, $G_{ij} = R_{ij} - \frac{1}{2}R\,g_{ij}$, the velocity U^i and the projection tensor h_{ij} can be used to write the stress energy tensor as a sum of separate terms[12] (p. 91)

$$T_{ij} \ = \ \mu\,U_iU_j + p\,h_{ij} + q_iU_j + U_iq_j + \pi_{ij},$$

where $q_iU^i = 0$, $\pi_{ij}U^j = 0$, and $\pi^i_{\ i} = 0$. The function μ denotes the total mass-energy density, p the isotropic pressure (which may include a contribution from the bulk viscosity), q^i the heat-flux vector, and π_{ij} the trace-free anisotropic pressure due to processes such as dynamic viscosity. It follows that

$$T^i_{\ i} = 2p - \mu,$$

and

$$\kappa\,(2p - \mu) = -\frac{1}{2}\,R.$$

Hence the Einstein field equations can be rewritten

$$R_{ij} = \kappa\,[\,T_{ij} - (2p - \mu)g_{ij}\,]$$

and then decomposed using U^i and $h^j{}_k$ to produce the following equivalent set of equations:

$$R_{ij}\,U^iU^j = 2\kappa\,p,$$

$$R_{ij}\,U^ih^j{}_m = -\kappa\,q_m,$$

$$R_{ij}\,h^i{}_m\,h^j{}_n = \kappa\,(\mu - p)\,h_{mn} + \kappa\,\pi_{mn}.$$

It follows that the pressure p is given by

$$p = \frac{1}{16\kappa}a^{-1}yAR,$$

and that the mass-energy density μ is given by

$$\mu = \frac{1}{8\kappa}a^{-1}yAR + \frac{1}{2\kappa}\,R.$$

The components q_i of the heat-flux vector are given by

$$q_u = \frac{1}{64\kappa}a^{-3/2}y^{3/2}AWR,$$

$$q_\omega = -\frac{1}{16\kappa}a^{-3/2}yAR\,\partial_\rho y,$$

$$q_\rho = \frac{1}{8\kappa}a^{-3/2}y^{1/2}AR.$$

Heat flow is related to temperature and acceleration by the temperature gradient law[12] (p. 96),

$$q^i \;=\; -\,\lambda\,h^{ij}\left(T_{,\,j} + T\,\dot{U}_j\right),$$

where λ denotes the coefficient of thermal conductivity. It can be checked that this law is satisfied identically. However, the usual phenomenological equation of state relating anisotropic pressure to the shear is *not* satisfied: $\pi_{ij} \neq -2\eta\sigma_{ij}$ (η being the coefficient of shear viscosity). Situations where this equation of state may not hold have been considered by MacCallum, Stewart, and Schmidt.[14]

6. Summary and Conclusions

A family of (2+1)-dimensional null-surface formulation solutions has been introduced and involves three parameters, A, a, and k. Since the solutions that make up the family all satisfy the NSF main metricity condition, they automatically satisfy Cartan's metricity condition.[15–17] The family of solutions led to a metric and to the Einstein equations being satisfied. An imperfect fluid was presented as a possible source. The mass-energy density and the pressure were shown to be positive. The scalar expansion was found to be zero. The scalar vorticity and scalar shear were

found to be nonzero, and simple formulas were derived. The temperature gradient law was satisfied. It was pointed out that the special choices $\{A \neq 0, k \neq 0, a = 0\}$ and $\{k \neq 0, a \neq 0, A = 0\}$ correspond to two solutions that were reported earlier by the present authors.[8,9]

Acknowledgements

The authors would like to thank Dr. Alan Coley for a number of helpful comments. We would also like to acknowledge the generous hospitality of Dr. Ted Newman during our visits to the University of Pittsburgh.

Appendix

The Christoffel symbols are

$$\Gamma^{u}_{uu} = -a\Gamma^{u}_{\omega\omega} = -a\Gamma^{\omega}_{\omega\rho} = 2^{-1}ay^{-1}\,\partial_\rho y,$$

$$\Gamma^{u}_{u\omega} = 8^{-1}Ay^{-1/2} + ay^{-3/2},$$

$$\Gamma^{u}_{u\rho} = \Gamma^{u}_{\omega\rho} = \Gamma^{u}_{\rho\rho} = \Gamma^{\omega}_{\rho\rho} = 0,$$

$$\Gamma^{\omega}_{uu} = 2^{-1}Aay^{-1/2} + 3a^2y^{-3/2} - 2^{-1}kay^{1/2},$$

$$\Gamma^{\omega}_{u\omega} = -(16^{-1}A + ay^{-1})\,\partial_\rho y,$$

$$\Gamma^{\omega}_{u\rho} = 8^{-1}Ay^{-1/2} + ay^{-3/2},$$

$$\Gamma^{\omega}_{\omega\omega} = -4^{-1}Ay^{-1/2} - ay^{-3/2} + 2^{-1}ky^{1/2},$$

$$\Gamma^{\rho}_{uu} = -2^{-1}a\,(-4^{-1}A + 3ay^{-1} + 2^{-1}ky)\,\partial_\rho y,$$

$$\Gamma^{\rho}_{u\omega} = -(16^{-1}Aky^{3/2} + a^2y^{-3/2} + kay^{1/2}),$$

$$\Gamma^{\rho}_{u\rho} = (16^{-1}A - ay^{-1})\,\partial_\rho y,$$

$$\Gamma^{\rho}_{\omega\omega} = (2^{-1}\,ay^{-1} + 4^{-1}\,ky)\,\partial_\rho y,$$

$$\Gamma^{\rho}_{\omega\rho} = 8^{-1}Ay^{-1/2} - 2^{-1}ky^{1/2},$$

$$\Gamma^{\rho}_{\rho\rho} = -y^{-1}\,\partial_\rho y.$$

Using the abbreviation $W := A + 8a\,y^{-1}$, the Ricci tensor can be written as a matrix, $[R_{ij}]$:

$$[\,R_{ij}\,] = \begin{pmatrix} \frac{1}{256}\,(A^3+W^3) + \frac{1}{8}\,Aka & -\frac{1}{64}\,AW\,y^{-1/2}\,\partial_\rho y & \frac{1}{32}\,W^2\,y^{-1} \\ -\frac{1}{64}\,AW\,y^{-1/2}\,\partial_\rho y & -\frac{1}{32}\,A^2\,y^{-1} + \frac{1}{8}\,Ak & -\frac{1}{8}\,A\,y^{-3/2}\,\partial_\rho y \\ \frac{1}{32}\,W^2\,y^{-1} & -\frac{1}{8}\,A\,y^{-3/2}\,\partial_\rho y & \frac{1}{4}\,W\,y^{-2} \end{pmatrix}.$$

The scalar curvature, R, is given in Eq. (14).

The covariant derivatives of the velocity can be written as a matrix, $[\,U_{i\,;\,j}\,]$:

$$\begin{pmatrix} -\frac{1}{8}a^{1/2}y^{-1/2}\,W\,\partial_\rho y & -\frac{1}{64}a^{-1/2}\,W^2 & -\frac{1}{16}a^{-1/2}y^{-1/2}\,W\,\partial_\rho y \\ a^{-1/2}\left(\frac{1}{2}ka - \frac{1}{64}W^2 + a^2y^{-2}\right) & \frac{1}{16}a^{-1/2}y^{-1/2}\,A\,\partial_\rho y & \frac{1}{2}a^{-1/2}y^{-1}\left(ky - \frac{1}{4}A\right) \\ -a^{1/2}y^{-3/2}\,\partial_\rho y & -\frac{1}{8}a^{-1/2}y^{-1}\,W & -\frac{1}{2}a^{-1/2}y^{-3/2}\,\partial_\rho y \end{pmatrix}$$

The acceleration vector, $\dot{U}_i$, is defined by $\dot{U}_i := U_{i\,;\,j}\,U^j$, and its components are

$$\dot{U}^u = \left(1 - \frac{1}{16}Wa^{-1}y\right)\,\partial_\rho y,$$

$$\dot{U}^\omega = \frac{1}{4}Wy^{1/2}\left(1 - \frac{1}{16}Wa^{-1}y\right) - \frac{1}{2}Ra^{-1}y^{3/2},$$

$$= a^{-1}y^{3/2}\left(-R + \frac{1}{2}ka + a^2y^{-2}\right),$$

$$\dot{U}^\rho = -a\left(1 - \frac{1}{16}Wa^{-1}y\right)\,\partial_\rho y - \frac{1}{4}Ra^{-1}y^2\,\partial_\rho y.$$

The only nonzero components of the vorticity tensor, ω_{ij}, are

$$\omega_{u\omega} = -\omega_{\omega u} = -\frac{1}{16}WRa^{-3/2}y,$$

$$\omega_{\omega\rho} = -\omega_{\rho\omega} = \frac{1}{2}Ra^{-3/2}.$$

The components of the shear tensor, σ_{ij}, are

$$\sigma_{uu} = -\frac{1}{1024}AW^2a^{-3/2}y^{3/2}\,\partial_\rho y,$$

$$\sigma_{u\omega} = \sigma_{\omega u} = \frac{1}{128}W^2ka^{-3/2}y^2 - \frac{1}{16}WRa^{-3/2}y,$$

$$\sigma_{u\rho} = \sigma_{u\rho} = -\frac{1}{128} AWa^{-3/2} y^{1/2}\, \partial_\rho y,$$

$$\sigma_{\omega\omega} = -\frac{1}{32} Aka^{-3/2} y^{3/2}\, \partial_\rho y,$$

$$\sigma_{\omega\rho} = \sigma_{\rho\omega} = \frac{1}{16} Wka^{-3/2} y - \frac{1}{2} Ra^{-3/2},$$

$$\sigma_{\rho\rho} = -\frac{1}{16} Aa^{-3/2} y^{-1/2}\, \partial_\rho y.$$

The components of the Cotton-York tensor, $C^i_{\ j}$, are

$$C^u_{\ u} = -\frac{1}{4} W \left(R + \frac{1}{32} AW \right),$$

$$= -\frac{1}{4} A \left(R + \frac{1}{32} W^2 \right) - 2Ray^{-1},$$

$$C^u_{\ \omega} = y^{-1/2} \left(\frac{1}{2} R + \frac{1}{32} A^2 \right) \partial_\rho y,$$

$$C^u_{\ \rho} = -Ry^{-1} - \frac{1}{16} AWy^{-1},$$

$$C^\omega_{\ u} = ay^{-1/2} \left(\frac{1}{2} R + \frac{1}{32} AW \right) \partial_\rho y,$$

$$C^\omega_{\ \omega} = \frac{1}{128} A^2 W + Ray^{-1},$$

$$C^\omega_{\ \rho} = \frac{1}{4} Aay^{-3/2}\, \partial_\rho y,$$

$$C^\rho_{\ u} = \frac{1}{128} AW^2 a - 2Ra^2 y^{-1} + \frac{1}{2} RWa,$$

$$C^\rho_{\ \omega} = -ay^{-1/2} \left(\frac{1}{2} R + \frac{1}{32} A^2 \right) \partial_\rho y,$$

$$C^\rho_{\ \rho} = \frac{1}{2} Aa^2 y^{-2} - 2ka^2 y^{-1} + \frac{1}{4} AR + 3Ray^{-1},$$

$$= \frac{1}{16} AWay^{-1} + \frac{1}{4} AR + Ray^{-1}.$$

New exact stationary cylindrical anisotropic fluid solution of GR

M.-N. Célérier

Laboratoire Univers et THéories, Observatoire de Paris,

5, Place Jules Janssen, Meudon, 92190, France
E-mail: marie-noelle.celerier@obspm.fr

In a previous paper, the properties of interior spacetimes sourced by stationary cylindrical anisotropic fluids have been analytically studied for both nonrigid and rigid rotation. The gravito-electromagnetic features of different classes of such GR solutions have been described. Their regularity conditions and those for their junction to a vacuum exterior have also been provided. A new class of rigidly rotating exact solutions to Einstein's field equations satisfying a physically consistent equation of state for anisotropic fluids is displayed here. Its physical properties are discussed.

Keywords: General Relativity; exact solution; cylindrical symmetry; anisotropic fluids

1. Introduction

Cylindrically symmetric spacetimes have attracted much attention and have been extensively investigated in General Relativity (GR) for a number of purposes.[1,2] A recent review has been displayed in.[3]

The results presented here have been obtained as a continuation of a couple of previous works. The rigid rotation of stationary spacetimes sourced by a cylindrically symmetric anisotropic fluid has been considered in.[4] This study has been subsequently extended to nonrigidly rotating fluids,[5] while the analysis of the rigid case proposed in[4] has been supplemented, with a focuss on its Weyl tensor gravito-electromagnetic properties. Both were matched to a stationary vacuum exterior of the Lewis type.[6]

The new results displayed here consist of a class of exact interior solutions to the Einstein field equations for a rigidly rotating cylindrically symmetric anisotropic fluid bounded by a cylindrical hypersurface through which it is matched to an exterior Lewis vacuum of the Weyl class.[7] The particular case of an axially directed principal stress is considered here as a first step towards the analysis of anisotropy in this framework.[8] The main physical properties of these spacetimes are also discussed.

This contribution is organized as follows: in Section 2, the stress-energy tensor and the stationary cylindrically symmetric line element to be used in the following are set up. In Section 3, the new exact solution is constructed, from the field equations first displayed, through its regularity and junction conditions, up to its final form. A number of mathematical and physical properties pertaining to this solution are analyzed in Section 4. The conclusions are displayed in Section 5.

2. Cylindrical spacetime inside the source

A rigidly rotating stationary cylindrically symmetric anisotropic nondissipative fluid bounded by a cylindrical surface Σ whose principal stresses P_r, P_z and P_ϕ obey the equation of state $P_r = P_\phi = 0$ is considered. Its stress-energy tensor can be written as

$$T_{\alpha\beta} = \rho V_\alpha V_\beta + P_z S_\alpha S_\beta, \tag{1}$$

where ρ is the energy density of the fluid, V_α is its timelike 4-velocity, and S_α is a spacelike 4-vector, satisfying

$$V^\alpha V_\alpha = -1, \quad S^\alpha S_\alpha = 1, \quad V^\alpha S_\alpha = 0. \tag{2}$$

It is assumed, for the inside Σ spacetime, that the spacelike ∂_z Killing vector is hypersurface orthogonal, such as to ease its subsequent matching to the exterior Lewis metric. Hence, its stationary cylindrically symmetric line element reads

$$\mathrm{d}s^2 = -f\mathrm{d}t^2 + 2k\mathrm{d}t\mathrm{d}\phi + \mathrm{e}^\mu(\mathrm{d}r^2 + \mathrm{d}z^2) + l\mathrm{d}\phi^2, \tag{3}$$

where f, k, μ and l are real functions of the radial coordinate r only. Owing to cylindrical symmetry, the coordinates satisfy the following ranges

$$-\infty \leq t \leq +\infty, \quad 0 \leq r, \quad -\infty \leq z \leq +\infty, \quad 0 \leq \phi \leq 2\pi. \tag{4}$$

Now, still due to cylindrical symmetry, the two limits of the ϕ coordinate are topologically identified. These coordinates are numbered $x^0 = t$, $x^1 = r$, $x^2 = z$ and $x^3 = \phi$.

3. Rigidly rotating new solution

3.1. *Equation of state and 4-velocity of the fluid*

Choosing a corotating frame for the stationary fluid source,[4,5,8] the fluid 4-velocity can be written as

$$V^\alpha = v\delta^\alpha_0, \tag{5}$$

where v is a function of r only. The timelike condition for V^α, provided in (2), thus becomes

$$fv^2 = 1. \tag{6}$$

The spacelike 4-vector verifying conditions (2) can be chosen as

$$S^\alpha = \mathrm{e}^{-\mu/2}\delta^\alpha_2, \tag{7}$$

and a function $D(r)$, which will proved useful for the calculations, is defined as

$$D^2 = fl + k^2. \tag{8}$$

3.2. *Field equations*

With the above choices, and using (5)-(8) into (1), one obtains the stress-energy tensor components corresponding to the five non-vanishing Einstein tensor components and the five field equations for the inside Σ spacetime follow.

A new function $h(r)$ defined as $h(r) \equiv P_z(r)/\rho(r)$, allows to write them as

$$G_{00} = \frac{\mathrm{e}^{-\mu}}{2}\left[-f\mu'' - 2f\frac{D''}{D} + f'' - f'\frac{D'}{D} + \frac{3f(f'l' + k'^2)}{2D^2}\right] = \kappa\rho f, \tag{9}$$

$$G_{03} = \frac{\mathrm{e}^{-\mu}}{2}\left[k\mu'' + 2k\frac{D''}{D} - k'' + k'\frac{D'}{D} - \frac{3k(f'l' + k'^2)}{2D^2}\right] = -\kappa\rho k, \tag{10}$$

$$G_{11} = \frac{\mu' D'}{2D} + \frac{f'l' + k'^2}{4D^2} = 0, \tag{11}$$

$$G_{22} = \frac{D''}{D} - \frac{\mu' D'}{2D} - \frac{f'l' + k'^2}{4D^2} = \kappa\rho h\mathrm{e}^{\mu}, \tag{12}$$

$$G_{33} = \frac{\mathrm{e}^{-\mu}}{2}\left[l\mu'' + 2l\frac{D''}{D} - l'' + l'\frac{D'}{D} - \frac{3l(f'l' + k'^2)}{2D^2}\right] = \kappa\rho\frac{k^2}{f}, \tag{13}$$

where the primes stand for differentiation with respect to r.

3.3. *Bianchi identity*

The stress-energy tensor conservation is analogous to the Bianchi identity that reads

$$T^{\beta}_{1;\beta} = 0. \tag{14}$$

From (1), we have

$$T^{\alpha\beta} = \rho V^{\alpha} V^{\beta} + P_z S^{\alpha} S^{\beta}, \tag{15}$$

with V^{α} given by (5), and the space-like vector S^{α} given by (7), inserted into (15). Using (3) and (6), the Bianchi identity (14) reduces to

$$T^{\beta}_{1;\beta} = \frac{1}{2}\rho\frac{f'}{f} - \frac{1}{2}P_z\mu' = 0, \tag{16}$$

which, when the $h(r)$ function defined above is inserted, becomes

$$\frac{f'}{f} - h\mu' = 0. \tag{17}$$

3.4. *Solving the field equations*

Since only five independent differential equations are available for six unknowns, i.e., the four metric functions f, k, e^{μ} and l, the energy density ρ, and the pressure defined by h, the set of equations needs to be closed by an additional one. The particular assumption displayed in[5] as Eq. (111), and amounting to make a particular choice of coordinates issued from an arbitrary constraint on the Weyl tensor components, is chosen for this purpose as

$$\mu' = \frac{2h'}{1-h} + \frac{2h'}{h}, \tag{18}$$

which can be integrated as

$$\mathrm{e}^{\mu} = c_{\mu}\frac{h^2}{(1-h)^2}, \tag{19}$$

where c_{μ} is an integration constant. Inserting (18) into the Bianchi identity (17), one obtains

$$\frac{f'}{f} = \frac{2h'}{1-h}, \tag{20}$$

which can be integrated as

$$f = \frac{c_f}{(1-h)^2}, \tag{21}$$

c_f being another integration constant.

Now, (9) combined with (10), gives

$$\left(\frac{kf' - fk'}{D}\right)' = 0, \tag{22}$$

which can be integrated as[4]

$$kf' - fk' = 2cD, \tag{23}$$

where $2c$ is an integration constant, the factor 2 being chosen here for further convenience. Considered as a first order ordinary differential equation for $k(r)$, (23) possesses as a general solution

$$k = f\left(c_0 - 2c\int_{r_0}^{r}\frac{D(v)}{f(v)^2}\mathrm{d}v\right), \tag{24}$$

where c_0 and r_0 are new integration constants. With (21) inserted, it can be written as

$$k = \frac{c_f}{(1-h)^2}\left[c_0 - \frac{2c}{c_f^2}\int_{r_0}^{r}(1-h(v))^4\,D(v)\mathrm{d}v\right]. \tag{25}$$

The last metric function l follows from (8) as

$$l = \frac{(1-h)^2}{c_f}\left\{D^2 - \frac{c_f^2}{(1-h)^4}\left[c_0 - \frac{2c}{c_f^2}\int_{r_0}^{r}(1-h(v))^4\,D(v)\mathrm{d}v\right]^2\right\}. \tag{26}$$

3.5. *Interim results*

The field equations (9), (11) and (12), or, equivalently, (10), (11) and (12), give an expression for D'/D as a function of h and of its first and second derivatives. Then, inserting (19), (21), (25), (26) and the expression found for D'/D into (11) gives an expression for ρ depending on the same function h and its derivatives. Then inserting the same expressions into (9), or equivalently into (13), one obtains another expression for ρ still using h and derivatives

Equalizing both expressions for ρ yields a second order ordinary differential equation for h whose general solution allows one to calculate both the first and second derivatives of this h function. They are thus inserted into the previously obtained expressions for ρ and D'/D which can be integrated as

$$D^2 = c_f^2 c_k^2 \frac{(-2\ln h + 4h - h^2 + c_\beta)}{(1-h)(1+h)}. \tag{27}$$

Now (27) inserted into (25) gives, after integration,

$$k = \frac{c_f}{(1-h)^2}\left[c_0 + c_k(-2\ln h + 4h - h^2 + c_\beta)\right]. \tag{28}$$

Finally, the last metric function l emerges from inserting f, k and D into (8), which gives

$$l = c_f c_k^2 \frac{(1-h)}{(1+h)}(-2\ln h + 4h - h^2 + c_\beta) - \frac{c_f}{(1-h)^2}\left[c_0 + c_k(-2\ln h + 4h - h^2 + c_\beta)\right]^2. \tag{29}$$

3.6. *Regularity conditions*

The regularity conditions on the symmetry axis for metric (3) have already been displayed in.[4,5] However, since they will be needed in the following, their main outcomes are recalled briefly here.

To impose elementary flatness in the rotation axis vicinity, the norm X of the Killing vector ∂_ϕ must satisfy[2]

$$\lim_{r\to 0} \frac{g^{\alpha\beta} X_{,\alpha} X_{,\beta}}{4X} = 1, \tag{30}$$

where $X = g_{\phi\phi}$. Eqs. (3) and (30) yield

$$\lim_{r\to 0} \frac{e^{-\mu} l'^2}{4l} = 1. \tag{31}$$

The requirement that $g_{\phi\phi}$ vanishes on the axis implies

$$l \overset{0}{=} 0, \tag{32}$$

where $\overset{0}{=}$ means that the values are taken at $r = 0$.

Since there cannot be singularities along the axis, spacetime is forced to tend there to flatness. The coordinates are thus scaled such that, for $r \to 0$, the metric should be written as

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + 2\omega r^2 \mathrm{d}t\mathrm{d}\phi + \mathrm{d}r^2 + \mathrm{d}z^2 + r^2\mathrm{d}\phi^2, \tag{33}$$

implying

$$f \overset{0}{=} \mathrm{e}^{\mu} \overset{0}{=} 1, \qquad k \overset{0}{=} 0, \tag{34}$$

giving

$$D \overset{0}{=} 0, \tag{35}$$

and, from (31) and (33),

$$l' \overset{0}{=} 0. \tag{36}$$

Then, the addition of the requirement that the Einstein tensor components in (9)-(13) do not diverge, implies

$$f' \overset{0}{=} k' \overset{0}{=} k'' - k'\frac{D'}{D} \overset{0}{=} 0, \tag{37}$$

Inserting (19), (21) and (28) into (34) one obtains

$$c_f \overset{0}{=} (1-h)^2, \tag{38}$$

$$c_\mu \overset{0}{=} \frac{c_f}{h^2}, \tag{39}$$

$$c_0 = 0, \tag{40}$$

$$c_\beta \overset{0}{=} 2\ln h - 4h + h^2. \tag{41}$$

All the other regularity conditions are verified provided (40) and (41) are satisfied.

3.7. *Junction conditions*

These conditions have also been displayed in[4,5] for metric (3). For completeness, and also since they will be partially needed further on, they are recalled here briefly.

Since the system is stationary, the Lewis vacuum metric[6] is used to represent the exterior spacetime, and the Weyl class[7] is here chosen for real junction condition purpose. Its metric is

$$\mathrm{d}s^2 = -F\mathrm{d}t^2 + 2K\mathrm{d}t\mathrm{d}\phi + \mathrm{e}^M(\mathrm{d}R^2 + \mathrm{d}z^2) + L\mathrm{d}\phi^2, \tag{42}$$

where

$$F = aR^{1-n} - a\delta^2 R^{1+n}, \tag{43}$$

$$K = -(1-ab\delta)\delta R^{1+n} - abR^{1-n}, \tag{44}$$

$$\mathrm{e}^{M} = R^{(n^2-1)/2}, \tag{45}$$

$$L = \frac{(1-ab\delta)^2}{a} R^{1+n} - ab^2 R^{1-n}, \tag{46}$$

with

$$\delta = \frac{c}{an}, \tag{47}$$

where a, b, c and n are the real constants determining the Weyl class of the metrics.

In accordance with Darmois' junction conditions,[9] metric (3) and metric (42)'s coefficients and their derivatives must be continuous across the Σ surface. It has been shown in[4] that, for the most general anisotropic fluid, these conditions imply $P_r \overset{\Sigma}{=} 0$, which is in agreement with the equation of state of the here studied fluid which imposes $P_r = 0$ everywhere.

Hence the conditions for a smooth junction to a Lewis vacuum of the Weyl class are fulfilled by this solution.

3.8. *Final form of the solution*

The constraints (38)–(41) on the integration constants, imposed by the regularity conditions, and inserted into the metric functions as given in (21), (19), (28) and (29) lead to their final form which can be displayed as

$$f = \left(\frac{1-h_0}{1-h}\right)^2, \tag{48}$$

$$\mathrm{e}^{\mu} = \left(\frac{1-h_0}{h_0}\right)^2 \left(\frac{h}{1-h}\right)^2, \tag{49}$$

$$k = (1-h_0)^2 c_k \frac{\left[2\ln\frac{h_0}{h} + 4(h-h_0) - (h^2-h_0^2)\right]}{(1-h)^2}, \tag{50}$$

$$l = (1-h_0)^2 c_k^2 \left[2\ln\frac{h_0}{h} + 4(h-h_0) - (h^2-h_0^2)\right] \times \left\{\frac{1-h}{1+h} - \frac{\left[2\ln\frac{h_0}{h} + 4(h-h_0) - (h^2-h_0^2)\right]}{(1-h)^2}\right\}. \tag{51}$$

An implicit integral equation for $h(r)$ reads

$$r = \frac{(1-h_0)^2}{c} \int_{h_0}^{h} \left\{\frac{1+u}{u^2(1-u)^3\left[2\ln\frac{h_0}{u} + 4(u-h_0) - (u^2-h_0^2)\right]}\right\}^{\frac{1}{2}} \mathrm{d}u, \tag{52}$$

where h_0 denotes the h value on the symmetry axis, i.e., $h_0 \equiv h(r=0)$. And the expression for ρ follows as

$$\rho = \frac{2c^2h_0^2}{\kappa(1-h_0)^4}\frac{(1-h)^4}{h^2(1+h)^2}\left\{\frac{h\left[2\ln\frac{h_0}{h}+4(h-h_0)-(h^2-h_0^2)\right]}{(1+h)}+2(1-h)^2\right\}. \tag{53}$$

Notice that the constant c_k appearing in (50) and (51) can be absorbed by a rescaling of the ϕ coordinate.

4. Physical properties of the solution

4.1. *Hydrodynamical scalars, vectors and tensors*

The timelike 4-vector V_α can be invariantly decomposed through the genuine tensor $V_{\alpha;\beta}$ into three independent parts such as

$$V_{\alpha;\beta} = -\dot{V}_\alpha V_\beta + \omega_{\alpha\beta} + \sigma_{\alpha\beta}, \tag{54}$$

where

$$\dot{V}_\alpha = V_{\alpha;\beta}V^\beta, \tag{55}$$

$$\omega_{\alpha\beta} = V_{[\alpha;\beta]} + \dot{V}_{[\alpha}V_{\beta]}, \tag{56}$$

$$\sigma_{\alpha\beta} = V_{(\alpha;\beta)} + \dot{V}_{(\alpha}V_{\beta)}. \tag{57}$$

These three quantities are, respectively, the acceleration vector, the rotation tensor, and the shear tensor. For the timelike 4-vector given by (5), their nonzero components[5] are

$$\dot{V}_1 = \frac{1}{2}\frac{f'}{f}, \tag{58}$$

which becomes, with (48) inserted,

$$\dot{V}_1 = \frac{c}{(1-h_0)^2}h\left\{\frac{(1-h)}{(1+h)}\left[2\ln\frac{h_0}{h}+4(h-h_0)-(h^2-h_0^2)\right]\right\}^{\frac{1}{2}} \tag{59}$$

and

$$2\omega_{13} = -(2kv'+k'v). \tag{60}$$

From (58), the acceleration vector modulus is therefore

$$\dot{V}^\alpha\dot{V}_\alpha = \frac{1}{4}\frac{f'^2}{f^2}\mathrm{e}^{-\mu}, \tag{61}$$

which becomes, with (48) and (49) inserted, and with (52) differentiated with respect to r

$$\dot{V}^\alpha\dot{V}_\alpha = \frac{c^2h_0^2}{(1-h_0)^6}\frac{(1-h)^3}{(1+h)}\left[2\ln\frac{h_0}{h}+4(h-h_0)-(h^2-h_0^2)\right]. \tag{62}$$

The rotation scalar, ω, defined by

$$\omega^2 = \frac{1}{2}\omega^{\alpha\beta}\omega_{\alpha\beta}, \tag{63}$$

follows as

$$\omega^2 = \frac{1}{4\mathrm{e}^{\mu}D^2}\left(k\frac{f'}{f} - k'\right)^2. \tag{64}$$

Inserting (23) into (64), one obtains

$$\omega^2 = \frac{c^2}{f^2\mathrm{e}^{\mu}}, \tag{65}$$

As already stressed in,[4,5] the shear tensor vanishes for any rigidly rotating fluid.

4.2. *Singularities*

The solution exhibits three possible singularities.

One would occur for $h = +1$ where the whole metric function set diverges, which is not the case for the density ρ. Indeed, from its expression (53), the energy density is merely seen to vanish. Since a more complete analysis should be needed to conclude definitively, the question whether this locus is or not a mere coordinate singularity remains open.

For $h = -1$, l is the only metric function which diverges. However, at this location, ρ also happens to diverge and would change sign if h was allowed to reach values below -1, which is not the case as it is shown elsewhere.[8] However, this behaviour would imply a curvature singularity if such a value of h should be reachable.

A third singularity might occur for $h = 0$. Here, the density diverges and is no more defined if the h sign happens to become different from the h_0 sign, owing to the presence of $\ln h_0/h$ in its expression. We would be therefore confronted to another curvature singularity. However, as it is shown elsewhere,[8] such a singularity lies outside the domain of definition of these spacetimes

4.3. *Integration constants and metric signature*

Among the three integration constants, c, c_k and h_0, one, c_k, can be suppressed by a rescaling of the azimuthal coordinate ϕ.

Now, h_0 possesses an obvious physical interpretation from the consideration of the expression for $h(r)$ given by (52). Since the integral in the right hand side vanishes for $h = h_0$, such does r on the left hand side, and therefore, h_0 must be interpreted as the value of h on the axis. Notice that $h_0 = 1$, implying the vanishing of the whole set of metric functions, lies thus outside the domain of definition of the solution.

The parameter c is shown elsewhere[8] to represent the amplitude of the rotation scalar of the fluid on the axis.

Finally, the signature of the metric $(-+++)$ implies sign constraints on the components of the metric tensor, which, in turn, impose restrictions on the validity ranges of $h(r)$.[8]

5. Conclusions

Following the investigations of stationary cylindrical anisotropic gravitational fluids initiated in,[4,5] the case of rigidly rotating fluids with particular equation of state $P_r = P_\phi = 0$ has been considered here. A new exact solution of the field equations has thus been exhibited under the form of $h(r)$ functions for the metric and the density, with h defined as $h(r) = P_z(r)/\rho(r)$, and of an integral expression for h as a r function. As usual, this solution is valid in a given coordinate system which has been chosen such as to ease a direct physical interpretation. To allow any future use for astrophysical purposes, this solution has been forced to satisfy the regularity conditions on the symmetry axis and it has been matched to the Weyl class of the Lewis vacuum solution through a cylindrical Σ hypersurface.

A number of important physical properties have been analysed. The hydrodynamical scalars, vectors and tensors of the fluid have been computed such as to be used for further interpretation purpose. Three singularities have been identified and discussed. However, they will prove to be located outside the definition domain of the solution, which will thus appear as singularity-free.

The solution depends on two independent parameters, h_0, the value of the function $h(r)$ on the axis of symmetry, and c which represents the amplitude of the rotation scalar of the fluid on the axis.[8] It has been stressed that the signature of the metric implies constraints on the signs of the components of the metric tensor and this has been shown, in turn, to restrict the validity domain of the solution.

In,[8] the properties of the constant parameters h_0 and c have been analysed and the different classes of solutions which might be associated to these properties have been identified.

Now, the present display of this first particular class of solutions for a fluid with axially directed stress will be followed, in the future, by the study of other complementary cases which would hopefully provide us with a deeper understanding of stationary rotating cylinders of matter in GR.

Laboratoire de Physique Théorique, Université de Toulouse, CNRS, UPS, France

Using a generalized Madelung transformation, we derive the hydrodynamic representation of the Dirac equation in arbitrary curved space-times coupled to an electromagnetic field. We obtain Dirac-Euler equations for fermions involving a continuity equation and a first integral of the Bernoulli equation. Using the comparison of the Dirac and Klein-Gordon equations we obtain the balance equation for fermion particles. We also use the correspondence between fermions and bosons to derive the hydrodynamic representation of the Weyl equation which is a chiral form of the Dirac equation.

Keywords: Dirac equation; Weyl equation; Fermions; Hydrodynamics

1. Introduction

The Standard Model of elementary particles establishes that there exist two kinds of particles, fermions and bosons. In previous works,[1,2] the energy balance for bosons was derived starting from the general relativistic Klein-Gordon (KG) equation. In the present work, we study a system of fermions described by the Dirac equation in arbitrary curved space-times taking into account electromagnetic effects. We also use the Weyl equation which is a chiral form of the Dirac equation due to the relationship between the Lie algebras of the symmetry groups for both systems of particles. We give the hydrodynamic representation of the Dirac and Weyl equations for fermions using previous results obtained for boson particles.

Many examples of fermion particles in strong gravitational fields can be found in nature. Indeed, the curvature of space-time plays an important role in a neutron star, in the early Universe, or in a fermion cloud (e.g. a dark matter halo) in the vicinity of a black hole. We need to develop a general framework to identify what are the different energy contributions in such systems. In this work we use the geometrical decomposition of the metric in 3+1 slices and the tetrad formalism to study the particle spin in an arbitrary space-time. We define the gamma matrices in curved space-times and derive the generalized Dirac and Weyl equations. Then, using the Madelung transformation, we introduce a hydrodynamic representation of the Dirac and Weyl spinors. This hydrodynamic representation can help us to describe the fermionic system in a general framework.

2. Field Equations

We use the tetrad formalism for the space-time geometry, and the canonical expansion of the space-time in a 3+1 ADM decomposition,[3–8] such that the coordinate t is the parameter of evolution. The 3+1 metric reads

$$\mathrm{d}s^2 = N^2c^2\mathrm{d}t^2 - h_{ij}\left(\mathrm{d}x^i + N^i c\,\mathrm{d}t\right)\left(\mathrm{d}x^j + N^j c\,\mathrm{d}t\right), \tag{1}$$

where N represents the lapse function which measures the proper time of the observers traveling along the world line, N^i is the shift vector that measures the displacement of the observers between the spatial slices and h_{ij} is the 3-dimensional slice-metric. In what follows $i,j,k,l = 1,2,3$; $a,b,c = 0,1,2,3$ are the internal indices and $\mu,\nu,\alpha = 0,1,2,3$ the space-time indices. We write eq. (1) in the tetrad formalism as $\mathrm{d}s^2 = \eta_{ab}e^a_{\ \mu}e^b_{\ \nu}dx^\mu dx^\nu$, where $\eta_{ab} = \mathrm{diag}(1,-1,-1,-1)$. Here $e^a = e^a_{\ \mu}dx^\mu$ is the set of one-forms base of the cotangent space at the space-time manifold given by

$$\begin{aligned} e^0 &= N\mathrm{d}t, \\ e^k &= \hat{e}^k_{\ i}\left(\mathrm{d}x^i + N^i c\,\mathrm{d}t\right), \end{aligned} \tag{2}$$

with inverse

$$\begin{aligned} e_0 &= \frac{1}{N}\left(\frac{\partial}{c\,\partial t} - N^j\frac{\partial}{\partial x^j}\right), \\ e_k &= \hat{e}_k^{\ j}\frac{\partial}{\partial x^j}, \end{aligned} \tag{3}$$

where $\hat{e}^k = \hat{e}^k_{\ i}\mathrm{d}x^i$ are the one-form base to the three-dimensional slice of the cotangent manifold, such that $h_{ij} = \delta_{kl}\hat{e}^k_{\ i}\hat{e}^l_{\ j}$. We can also define the set of vectors base of the tangent-space to the space-time as $e_a = e_a^{\ \mu}\partial_\mu$, such that $e^a e_b = \delta^a_{\ b}$. We will use the tetrad formalism[3,6–10] to describe the space-time geometry where the fermion particles are located.

The action of a fermion system in curved space-time coupled to an electromagnetic field A_μ is given by $S[\psi,\partial_\mu\psi] = \int \mathcal{L}(\psi,\partial_\mu\psi(x^\mu))\,d^4x$, where $\mathcal{L} = \mathcal{L}(\psi,\partial_\mu\psi(x^\mu))$ is the Lagrangian density[11–13]

$$\mathcal{L} = \sqrt{-g}\frac{i\hbar c}{2}\left[\psi^\dagger B\gamma^\mu\left(D_\mu\psi\right) - \left(D_\mu\psi\right)^\dagger B\gamma^\mu\psi + \frac{2imc}{\hbar}\psi^\dagger B\psi\right]. \tag{4}$$

Here $D_\mu = \nabla_\mu + \dfrac{iq}{\hbar c}A_\mu$ is the total covariant derivative accounting for electromagnetic effects. The covariant derivative of a spinor $\psi = (\psi_{\dot{\nu}})$ is given by $\nabla_\mu(\psi_{\dot{\nu}}) = \partial_\mu(\psi_{\dot{\nu}}) + \Gamma^{\dot{\alpha}}_{\mu\dot{\nu}}(\psi_{\dot{\alpha}})$, where $\Gamma^{\dot{\alpha}}_{\mu\dot{\nu}}$ is the spin connection.[3,14] Using the least action principle it is possible to obtain from eq. (4) the corresponding Dirac equation. This equation is given by

$$\left[i\hbar\gamma^\mu\left(\nabla_\mu + iqA_\mu\right) - mc\right]\psi = 0, \tag{5}$$

where $\hbar$, c are the Planck constant and the speed of light respectively, while q,m are the charge and mass of the fermion particle and ψ is its spinor. Besides, the

gamma matrices γ^μ are related to the spin and space-time geometry. They can be written as $\gamma^\mu = e^\mu_{\ a}\tilde{\gamma}^a$, where $\tilde{\gamma}^a$ are the gamma matrices in flat space-time, which are well-know from Quantum Field Theory (QFT).[15–17] Therefore,

$$\begin{aligned}\gamma^0 &= N\tilde{\gamma}^0,\\ \gamma^k &= \hat{e}^k_{\ j}(\tilde{\gamma}^j + N^j\tilde{\gamma}^0).\end{aligned} \tag{6}$$

In general, these matrices fulfill the following anti-commutation relation[3,18]

$$\{\gamma^\mu, \gamma^\nu\} = \gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2g^{\mu\nu}, \tag{7}$$

where $g_{\mu\nu}$ represents the metric that describes the space-time geometry. Furthermore, as we know, the gamma matrices in flat space-time are related to the Pauli matrices, which describe the spin of the fermion particles. In general, the gamma matrices obey the following relation[11–13,19]

$$(\gamma^\mu)^\dagger = B\gamma^\mu B^{-1}, \tag{8}$$

where B is a hermitian matrix, i.e. $B^\dagger = B$, that is uniquely determined by the gamma matrices γ^μ. As usual, we denote by $B^\dagger$ the conjugate (or Hermitian) transpose of B. We note that in QFT the relation (8) is fulfilled when $B = \tilde{\gamma}^0$ and the gamma matrices are in flat space-time. From the action (4) of the fermion system we can find the equation for the transpose conjugated spinor by making an infinitesimal variation of this action with respect to ψ. Another way of getting this equation of motion is to take the transpose conjugate of the Dirac equation (5) and using (8). In this manner we find that the transpose conjugated Dirac equation in curved space-time is given by

$$i\left(\nabla_\mu\bar{\psi}\right)\gamma^\mu - i\psi^\dagger\nabla_\mu\left(B\gamma^\mu\right) + i\bar{\psi}\nabla_\mu\gamma^\mu + \bar{\psi}A_\mu\gamma^\mu + m\bar{\psi} = 0. \tag{9}$$

To simplify the notations, here and in the following we use $mc/\hbar \to m$ in natural units ($c = \hbar = 1$). We consider that $(\nabla_\mu\psi)^\dagger = \nabla_\mu\psi^\dagger$, and we denote the adjoint spinor as $\bar{\psi} = \psi^\dagger B$. Using the gamma matrices in flat space-time and the fact that $B = \tilde{\gamma}^0$ we recover the definition of $\bar{\psi}$ in QFT and the transpose conjugated Dirac equation. However, in an arbitrary space-time $\nabla_\mu\gamma^\mu$ is distinct from zero, since $\gamma^\mu = e^\mu_{\ a}\tilde{\gamma}^a$, so in general $\nabla_\mu e^\mu_{\ a}$ is non-zero.

We can get the conserved charge from the Noether theorem.[20] The Dirac current is

$$J^\mu = \bar{\psi}\gamma^\mu\psi = \psi^\dagger B\gamma^\mu\psi. \tag{10}$$

To obtain the continuity equation

$$\nabla_\mu J^\mu = 0 \tag{11}$$

for the Dirac current, we take the covariant derivative of eq. (10). This gives

$$\nabla_\mu J^\mu = (\nabla_\mu\bar{\psi})\gamma^\mu\psi + \bar{\psi}\left(\nabla_\mu\gamma^\mu\right)\psi + \bar{\psi}\gamma^\mu\nabla_\mu\psi. \tag{12}$$

If we multiply the Dirac equation (5) by $\bar{\psi}$ and its transpose conjugate (9) by ψ and sum both equations, it follows that

$$\nabla_\mu J^\mu = \psi^\dagger \nabla_\mu \left(B\gamma^\mu\right)\psi. \tag{13}$$

If we require that the continuity equation (11) is fulfilled, i.e., that the number of particles is conserved, then we need $\nabla_\mu \left(B\gamma^\mu\right) = 0$, or equivalently

$$(\nabla_\mu B)\gamma^\mu = -B\nabla_\mu\gamma^\mu. \tag{14}$$

At this point, we want to emphasize the consistency conditions for the continuity equation (11). Some authors[21] impose $\nabla_\mu\gamma^\nu = 0$ while others[22] impose $\nabla_\mu B = 0$. These conditions are independent of each other, i.e., in general the condition of Ref.[21] is not fulfilled in Ref.[22] and *vice versa*. In Refs.[12,13] the authors conclude that the condition $\nabla_\mu(B\gamma^\nu) = 0$ is the most convenient because it is implied by $\nabla_\mu\gamma^\nu = 0$ and $\nabla_\mu B = 0$.

In addition, we can note that the matrix B can be obtained for a general metric (1) by solving the differential equation

$$\left(\nabla_0(BN) + \nabla_j(B\hat{e}_i^j N^i)\right)\tilde{\gamma}^0 - \nabla_j(B\hat{e}_i^j)\tilde{\gamma}^i = 0, \tag{15}$$

which follows from eq. (14). Using the condition (14), it is possible to rewrite the transpose conjugated Dirac equation (9) as

$$i\left(\nabla_\mu\bar{\psi}\right)\gamma^\mu + i\bar{\psi}\nabla_\mu\gamma^\mu + \bar{\psi}A_\mu\gamma^\mu + m\bar{\psi} = 0. \tag{16}$$

In order to find the conserved quantity resulting from the continuity equation, we take an arbitrary surface $\mathcal{S}$ enclosing the volume $\mathcal{V}$ which contains the whole system. Let k^j be an orthonormal vector to $\mathcal{S}$ such that

$$\int_{\mathcal{V}} \nabla_\mu J^\mu dV = \int_{\mathcal{V}} \nabla_0 J^0 dV + \int_{\mathcal{S}} k_j J^j dS = 0. \tag{17}$$

We assume that far away from the source, J^μ is negligible. Then, the surface integral in eq. (17) vanishes, and we obtain

$$\frac{dQ}{dt} = \int_{\mathcal{V}} \nabla_0 J^0 dV = 0, \tag{18}$$

where $Q = \int_{\mathcal{V}} J^0 dV$ is the conserved charge and dV is the curved volume element $dV = \sqrt{-g}d^4x$. In QFT this charge is identified with the number of fermions or with the electric charge of the system. In flat space-time we have $B = \tilde{\gamma}^0$, so that $J^0 = \psi^\dagger\psi = n$ represents the number density of fermion particles. In curved space-time J^0 (which is determined by γ^0 and by the generalized gamma matrices) has a different interpretation. The form of B given by eqs. (8) and (14) for each metric is related to the gamma matrices and to the tetrad formalism.

With the Maxwell four-potential we can define the Faraday tensor

$$F_{\mu\nu} = \nabla_\mu A_\nu - \nabla_\nu A_\mu. \tag{19}$$

In the electromagnetic theory, the Faraday tensor $F_{\mu\nu}$ satisfies the Maxwell field equations

$$\nabla_\nu F^{\nu\mu} = J^{E\mu}, \tag{20}$$

where $J^{E\mu}$ is the four-electromagnetic current.

The problem of the Energy Balance for boson particles in a curved space-time is studied in Ref.[1], where the conserved 4-current associated with the KG equation describing the evolution of a complex scalar field $\Phi(x^\mu)$ is defined. We can generalize this idea by defining a new 4-current J_μ^{KG}, changing the scalar field by a spinor and the complex conjugate scalar field by the conjugate transpose of the spinor. Namely, the KG current is redefined as

$$J_\mu^{KG} = i\frac{q}{2m^2}\left[\psi\left(\nabla_\mu - iqA_\mu\right)\psi^\dagger - \psi^\dagger\left(\nabla_\mu + iqA_\mu\right)\psi\right]. \tag{21}$$

3. Dirac Hydrodynamic Representation

Analogously to the hydrodynamic representation of the Schrödinger equation, which was introduced by Madelung,[23] we derive the hydrodynamic representation of the Dirac equation. We carry out the following generalized Madelung transformation for each component of the spinor $\psi = \psi(x^\mu)$ as follows

$$\psi = \exp(i\theta)R, \tag{22}$$

where R is a spinor and θ is a function. For the case where we consider a Dirac electron-like fermion, $\theta = \theta(x^\mu)$, the spinor ψ reads

$$\psi = \begin{pmatrix} R_{\dot{1}} \\ R_{\dot{2}} \\ R_{\dot{3}} \\ R_{\dot{4}} \end{pmatrix} \exp(i\theta) = R\exp(i\theta), \tag{23}$$

where we use the notation $\dot{\mu}$, $\dot{\nu}$, ...$= \dot{1}, \cdots, \dot{4}$ for the spinor indices such that

$$R = \begin{pmatrix} R_{\dot{1}} \\ R_{\dot{2}} \\ R_{\dot{3}} \\ R_{\dot{4}} \end{pmatrix} = \begin{pmatrix} \sqrt{n_{\dot{1}}} \\ \sqrt{n_{\dot{2}}} \\ \sqrt{n_{\dot{3}}} \\ \sqrt{n_{\dot{4}}} \end{pmatrix}. \tag{24}$$

In the appendix we show some exact solutions of the Dirac equation with this ansatz in flat space-time. Here the dot indices represent elements of each component and we do not use the sum convention when the indices are up and down. On the other hand, we assume this notation $R_{\dot{\mu}} = \sqrt{n_{\dot{\mu}}}$ to (24), where $n_{\dot{\mu}}$ is the number density, represents the modulus of $\psi_{\dot{\mu}}$ and θ is its phase (both are real variables). In general, $n_{\dot{\mu}}$ is different for each component of the spinor. Note that the covariant derivative of the spinor ψ in terms of its decomposition (23) is $\nabla_\mu(\psi_{\dot{\nu}}) = \partial_\mu(R_{\dot{\nu}}e^{i\theta}) + \Gamma^{\dot{\alpha}}_{\mu\dot{\nu}}(R_{\dot{\alpha}}e^{i\theta}) = (\partial_\mu R_{\dot{\nu}})e^{i\theta} + i(\partial_\mu\theta)R_{\dot{\nu}}e^{i\theta} + \Gamma^{\dot{\alpha}}_{\mu\dot{\nu}}(R_{\dot{\alpha}}e^{i\theta})$, implying that $\nabla_\mu\theta = \partial_\mu\theta$.

Using the transformation (23) in eq. (5), the Dirac equation in terms of the variables R and θ reads

$$\exp(i\theta)\gamma^{\mu}\left(i\nabla_{\mu}R-(\nabla_{\mu}\theta)R-qA_{\mu}R-\frac{m}{4}\gamma_{\mu}R\right)=0. \tag{25}$$

To get the last term, we used the property of the gamma matrices that $\gamma_{\mu}\gamma^{\mu}=4\mathbb{I}$, where $\mathbb{I}$ is the 4×4 identity matrix. This property results from the anti-commutation relation of the gamma matrices. Similarly, the continuity equation (11) with (10) can be written with these new variables as

$$\left(\nabla_{\mu}R^{T}\right)K^{\mu}R+R^{T}K^{\mu}\left(\nabla_{\mu}R\right)=0, \tag{26}$$

where R^{T} denotes the transpose of R and $K^{\mu}=B\gamma^{\mu}$. Observe that K^{μ} is hermitian ($K^{\mu\dagger}=K^{\mu}$).

In conclusion, we have introduced the hydrodynamic representation of the Dirac equation (25) and its conjugate transpose equation by making the change of variables from eq. (22).

4. Dirac-Euler Equation

As for the Klein-Gordon equation,[1,2] we define the 4-velocity v_{μ} by

$$mv_{\mu\dot{\nu}}=\nabla_{\mu}S_{\dot{\nu}}+qA_{\mu}. \tag{27}$$

Here, $S(x^{\mu})$ is a phase with components $S_{\dot{\alpha}}=\theta_{\dot{\nu}}\delta^{\dot{\nu}}{}_{\dot{\alpha}}-\omega_{\dot{\nu}}\delta^{\dot{\nu}}{}_{\dot{\alpha}}t$ where $\omega_{\dot{\nu}}$ are constants that can be related to the mass of the fermion particle by $\omega_{\dot{\nu}}=mc^{2}/\hbar$ and $\theta_{\dot{\nu}}=\theta$. In this manner we can write

$$\nabla_{\mu}\theta_{\dot{\alpha}}\delta^{\dot{\alpha}}{}_{\dot{\nu}}=(mv_{\mu\dot{\alpha}}-\omega_{\dot{\alpha}}\delta^{0}{}_{\mu})\delta^{\dot{\alpha}}{}_{\dot{\nu}}-qA_{\mu}. \tag{28}$$

We interpret $n_{\dot{\nu}}$ as the density number of fermions and $v_{\mu\dot{\nu}}$ as its velocity. Actually, eq. (25) can be interpreted as the first integral of the Bernoulli equation for fermions in an arbitrary space-time. To see this, we apply the operator $i\gamma^{\mu}D_{\mu}=i\gamma^{\mu}\nabla_{\mu}-q\gamma^{\mu}A_{\mu}$ to the Dirac equation (5) written under the form $i\gamma^{\mu}\nabla_{\mu}\psi=q\gamma^{\mu}A_{\mu}\psi-m\psi$. This yields

$$-\gamma^{\mu}\gamma^{\nu}\left(\nabla_{\mu}\nabla_{\nu}\psi+iq(\nabla_{\mu}A_{\nu})\psi+iqA_{\nu}(\nabla_{\mu}\psi)+iqA_{\mu}(\nabla_{\nu}\psi)-q^{2}A_{\mu}A_{\nu}\psi\right)- m^{2}\psi-\gamma^{\mu}(\nabla_{\mu}\gamma^{\nu})(\nabla_{\nu}\psi+iqA_{\nu}\psi)=0. \tag{29}$$

Using the relation (7) in eq. (29) we obtain

$$\Box_{E}\psi+m^{2}\psi+\frac{i}{2}q\gamma^{\mu}\gamma^{\nu}F_{\mu\nu}\psi+\gamma^{\mu}(\nabla_{\mu}\gamma^{\nu})(D_{\nu}\psi)=0, \tag{30}$$

where we have defined the D'Alambertian operator in the presence of an electromagnetic field by $\Box_{E}=(\nabla_{\mu}+iqA_{\mu})(\nabla^{\mu}+iqA^{\mu})$ and the anti-symmetric Faraday tensor by $F_{\mu\nu}=\nabla_{\mu}A_{\nu}-\nabla_{\nu}A_{\mu}$. Eq. (30) is similar to the Klein-Gordon equation with an electromagnetic source except that here ψ is a spinor instead of a complex SF. The last term of eq. (30) contains the covariant derivative of γ^{μ} which vanishes

in a flat space-time. According to Refs.[1,2] if we apply the transformation (22) to eq. (30), we could expect to obtain the continuity equation for the imaginary part and the Bernoulli equation for the real part. However, in the case of the Dirac equation the four components are mixed by the presence of the four dimensional spinor ψ. Hence, we obtain the following expression

$$i\left[2(mv^\mu-\omega\delta_0^\mu)\nabla_\mu R-qA_\mu+q\nabla_\mu(A^\mu R)+\nabla_\mu(mv^\mu-\omega\delta_0^\mu-qA^\mu)R\right]+\left(m^2v_\mu v^\mu+2m\omega v^0+\frac{\omega^2}{N^2}+m^2\right)R-\Box R+\frac{i}{2}q\gamma^\mu\gamma^\nu F_{\mu\nu}R+\gamma^\mu(\nabla_\mu\gamma^\nu)(i(mv_\nu+\omega\nabla_\nu t)R+D_\nu R)=0. \quad (31)$$

Here, we have defined $\Box=\nabla^\nu\nabla_\nu$ and we have introduced the diagonal matrices $v_\mu=v_{\mu\dot{\nu}}\delta^{\dot{\nu}}_{\dot{\alpha}}$ and $\omega=\omega_{\dot{\nu}}\delta^{\dot{\nu}}_{\dot{\alpha}}$. For bosons, the real and imaginary parts separate into two independent equations, namely, the continuity equation and the Bernoulli equation.[1,2] But in the spinor case, the last line of equation (31) mixes both the imaginary and real parts and there is no natural separation into real and imaginary parts. The system remains coupled.

5. Weyl Representation

The Dirac equation for 1/2-spin particles is associated with the $SO(1,3)$ symmetry group. Nevertheless, we can introduce a new representation as in standard QFT, since there exists a surjective homomorphism between the $SO(1,3)$ and $SU(2)\otimes SU(2)$ Lie groups.

In terms of the Pauli matrices the 4×4 gamma matrices γ^μ can be written as two 2×2 block matrices

$$\gamma^0=N\tilde{\gamma}^0=N\begin{pmatrix}0&\mathbb{I}\\\mathbb{I}&0\end{pmatrix}, \quad (32)$$

$$\gamma^j=\hat{e}^j{}_i(\tilde{\gamma}^i+N^i\tilde{\gamma}^0)=\begin{pmatrix}0&-\hat{e}^j{}_i(\tilde{\sigma}^i-N^i\mathbb{I})\\\hat{e}^j{}_i(\tilde{\sigma}^i+N^i\mathbb{I})&0\end{pmatrix}, \quad (33)$$

where $\tilde{\sigma}^i$ are the 2×2 Pauli matrices in flat space-time and $\mathbb{I}$ is the 2×2 identity matrix. The γ^μ matrices satisfy $\left(\gamma^0\right)^\dagger=\gamma^0$ and $\left(\gamma^j\right)^\dagger=-\gamma^j+2N^j\gamma^0/N$.

As we know, the special unitary group $SU(2)$ is formed by the set of 2×2 complex matrices A, which satisfy $\det(A)=1$. Explicitly, we have

$$A=\begin{pmatrix}a&-\bar{b}\\b&\bar{a}\end{pmatrix}, \quad (34)$$

with $\det(A)=|a|^2+|b|^2=1$, where a and b are complex parameters. Equivalently, we have the identity $A^\dagger=A^{-1}$.

The Lie algebra $\mathfrak{su}(2)$ associated to the $SU(2)$ Lie group is given by the exponential map

$$\exp(\mathfrak{su}(2))\to SU(2). \quad (35)$$

For any element X of the Lie algebra, we have $\exp(X)\exp(X)^\dagger = \mathbb{I}$, implying that $X + X^\dagger = 0$. In what follows, we will indistinctly use $\exp(X)$ and e^X as the exponential map.

In the Weyl representation we can write a Dirac fermion as a four-spinor ψ made of two spinors each of which having two components, for instance

$$\psi = \begin{pmatrix} \psi_R \\ \psi_L \end{pmatrix}, \tag{36}$$

where ψ_R and ψ_L are the right- and the left- handed Weyl spinors, respectively. If we write the adjoint spinor $\bar{\psi}$ and use the Weyl representation, it follows that

$$\bar{\psi} = \psi^\dagger B = \left(\psi_R^\dagger, \psi_L^\dagger\right) B, \tag{37}$$

where B is the matrix from eqs. (8) and (14). If we use the relation (8) it is straightforward to see that the matrix B must have the following form

$$B = \begin{pmatrix} 0 & B_\zeta \\ B_\zeta & 0 \end{pmatrix}, \tag{38}$$

where the 2×2 matrix B_ζ is a diagonal matrix, $B_\zeta = b\mathbb{I}$, with $b = b(x^\mu)$. Therefore, we get $B = b\tilde{\gamma}^0$ and eq. (15) transforms into

$$\nabla_0(Nb) + \nabla_j(\hat{e}_i^j N^i b) = 0, \tag{39}$$

$$\nabla_j(\hat{e}_i^j b)\tilde{\sigma}^i = 0. \tag{40}$$

Using the definition of the spinor and its adjoint we can write the Dirac quadricurrent J^μ from eq. (10) as

$$J^\mu = \left(\psi_R^\dagger, \psi_L^\dagger\right) B\gamma^\mu \begin{pmatrix} \psi_R \\ \psi_L \end{pmatrix}, \tag{41}$$

where the gamma matrices are defined by eqs. (32) and (33) and, in general, B is given by the previously mentioned conditions. This yields

$$J^0 = Nb(\psi_R^\dagger \psi_R + \psi_L^\dagger \psi_L) = Nbn, \tag{42}$$

$$J^j = b\hat{e}^j{}_i(\psi_R^\dagger(\tilde{\sigma}^i + N^i\mathbb{I})\psi_R - \psi_L^\dagger(\tilde{\sigma}^i - N^i\mathbb{I})\psi_L). \tag{43}$$

In order to simplify the notation, we now define the vectors of 2×2 matrices $\mathbb{S}^a = (\mathbb{I}, \tilde{\sigma}^j + N^j\mathbb{I})$ and $\bar{\mathbb{S}}^a = (-\mathbb{I}, \tilde{\sigma}^j - N^j\mathbb{I})$ in terms of the Pauli matrices. $\mathbb{S}^a$ and $\bar{\mathbb{S}}^a$ are the (generalized) Pauli matrices in flat space-time. In terms of these new definitions, the density currents read

$$\begin{aligned} J^j &= b\hat{e}^j{}_i(\psi_R^\dagger \mathbb{S}^i \psi_R - \psi_L^\dagger \bar{\mathbb{S}}^i \psi_L) \\ &= b(\psi_R^\dagger \sigma^i \psi_R - \psi_L^\dagger \bar{\sigma}^i \psi_L), \end{aligned} \tag{44}$$

where we have defined the 2×2 Pauli matrices in a curved space-time by $\sigma^\mu = e^\mu{}_a \mathbb{S}^a$ and $\bar{\sigma}^\mu = e^\mu{}_a \bar{\mathbb{S}}^a$. With this definition, the matrices γ^j read

$$\gamma^j = \begin{pmatrix} 0 & -\bar{\sigma}^j \\ \sigma^j & 0 \end{pmatrix}. \tag{45}$$

Furthermore, observe that the σ^j matrices follow the same commutation relations as the flat space-time Pauli matrices. This means that $[\sigma^i, \bar{\sigma}^j] = -\hat{e}^i_k \hat{e}^j_l [\tilde{\sigma}^k, \tilde{\sigma}^l]$. For the Weyl representation we have to obtain two equations for each Dirac fermion. Thus, we need to redefine the covariant derivative ∇_μ and the spinor affine connection Γ_μ,[14,24] which can be written as $\nabla_\mu = \partial_\mu + \Gamma_\mu$ and $\Gamma_\mu = \frac{1}{4}\bar{\sigma}_\nu \sigma^\nu_{;\mu}$ where $\sigma^\mu_{;\nu} = \partial_\nu \sigma^\mu + \Gamma^\mu_{\alpha\nu}\sigma^\alpha$. Nevertheless, in this representation we need to introduce two other notations due to the presence of $\bar{\sigma}^\mu$. Let $\bar{\nabla}_\mu$ and $\tilde{\Gamma}_\mu$ be the bar covariant derivative and the bar spinor affine connection, respectively, defined by $\bar{\nabla}_\mu = \partial_\mu + \tilde{\Gamma}_\mu$ where $\tilde{\Gamma}_\mu = \frac{1}{4}\sigma_\nu \bar{\sigma}^\nu_{;\mu}$ (we stress that we use the greek indices for denoting the objects in curved space-time as the gamma and Pauli matrices).

We can now apply the Weyl representation to rewrite the Dirac equation (5) for a spinor with four components as

$$\begin{pmatrix} i\sigma^\mu \left(\bar{\nabla}_\mu + iqA_\mu\right)\psi_R - m\psi_L \\ i\bar{\sigma}^\mu \left(\nabla_\mu + iqA_\mu\right)\psi_L - m\psi_R \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \tag{46}$$

These are the Weyl equations for a spinor in a curved space-time coupled to an electromagnetic field. If we apply the Weyl representation to the transpose conjugated Dirac equation (16), it is straightforward to obtain the Weyl equation for the adjoint spinor (37). However, we shall not write the adjoint spinor equation explicitly because the results are analogous to the spinor equation as we have seen in the previous sections.

If we set $B = b\tilde{\gamma}^0$, the current density now reads

$$J^\mu = b\left(\psi^\dagger_R \sigma^\mu \psi_R - \psi^\dagger_L \bar{\sigma}^\mu \psi_L\right). \tag{47}$$

Explicitly, we have

$$J^0 = Nbn, \tag{48}$$

$$J^j = b\hat{e}^j_i \left(\psi^\dagger_R \tilde{\sigma}^i \psi_R - \psi^\dagger_L \tilde{\sigma}^i \psi_L + \frac{N^i}{Nb^2} J^0\right). \tag{49}$$

On the other hand, the last line of eq. (31) can be obtained from the identities

$$\gamma^\mu \gamma^\nu F_{\mu\nu}\psi = \begin{cases} (2NN^k F_{0k} + i\hat{F}_{ij}\epsilon^{ij}{}_k \tilde{\sigma}^k)\psi_R \\ -(2NN^k F_{0k} - i\hat{F}_{ij}\epsilon^{ij}{}_k \tilde{\sigma}^k)\psi_L \end{cases}, \tag{50}$$

and using definition (45), we find that

$$\begin{aligned} \gamma^\mu(\nabla_\mu \gamma^\nu)(D_\nu \psi) &= \begin{cases} -\bar{\mathbb{S}}^a \mathbb{S}^b (\hat{\nabla}_a \hat{e}^\nu_b)(D_\nu \psi_R) \\ -\mathbb{S}^a \bar{\mathbb{S}}^b (\hat{\nabla}_a \hat{e}^\nu_b)(D_\nu \psi_L) \end{cases} \\ &= \begin{cases} (N(\nabla_0 N) - \bar{\sigma}^j(\nabla_j N))(D_0\psi_R) + (N(\nabla_0 \sigma^i) - \bar{\sigma}^j(\nabla_j \sigma^i))(D_i \psi_R) \\ (N(\nabla_0 N) + \sigma^j(\nabla_j N))(D_0\psi_L) - (N(\nabla_0 \bar{\sigma}^i) - \sigma^j(\nabla_j \bar{\sigma}^i))(D_i \psi_L) \end{cases} \\ &= \begin{cases} (\hat{\nabla}_0 N - \bar{\mathbb{S}}^k(\hat{\nabla}_k N))(D_0\psi_R) + (\mathbb{S}^k \hat{\nabla}_0 \hat{e}^i_k - \bar{\mathbb{S}}^k \mathbb{S}^l \hat{\nabla}_k \hat{e}^i_l))(D_i \psi_R) \\ (\hat{\nabla}_0 N + \mathbb{S}^k(\hat{\nabla}_k N))(D_0\psi_L) - (\bar{\mathbb{S}}^k \hat{\nabla}_0 \hat{e}^i_k - \mathbb{S}^k \bar{\mathbb{S}}^l (\hat{\nabla}_k \hat{e}^i_l))(D_i \psi_L), \end{cases} \end{aligned} \tag{51}$$

where $\epsilon^{ij}{}_k$ is the usual Levi-Civita tensor, $\hat{F}_{ij} = \hat{e}_i^l \hat{e}_j^m F_{lm}$ is the directional Maxwell tensor $\hat{F}_{ij} = (\hat{e}_i^l \hat{\nabla}_j - \hat{e}_j^l \hat{\nabla}_i) A_l$, and $\hat{\nabla}_a = \hat{e}_a^\alpha \nabla_\alpha$ is the directional covariant derivative which defines the Cartan connection $\hat{\nabla}_c \hat{e}_b^\nu = \Gamma_{bc}^a \hat{e}_a^\nu$. The Cartan connection $\Gamma_{bc}^a = \hat{e}_\nu^a \hat{\nabla}_c \hat{e}_b^\nu$ determines the Cartan first fundamental form $d\hat{e}^a + \Gamma_b^a \wedge \hat{e}^b$ for the connections $\Gamma_b^a = \Gamma_{bd}^a \hat{e}^d$ with the property that $\Gamma_{ab} + \Gamma_{ba} = 0$, where $\Gamma_{ab} = \eta_{ad} \Gamma_b^d$.

6. Weyl Hydrodynamic Representation

We now have all the ingredients to propose a hydrodynamic representation for the Weyl fermions, following the same procedure as the one developed for the Schrödinger and KG equations in Refs.[1,2].

We start to propose our Madelung transformation in the Weyl spinor, using the exponential map, that is

$$\Psi = \begin{pmatrix} \psi_R \\ \psi_L \end{pmatrix} = \begin{pmatrix} R_R \\ R_L \end{pmatrix} e^{i\theta}. \tag{52}$$

Since ψ_R and ψ_L are two spinors, we observe that R_R and R_L are two two-dimensional vectors. The Weyl representation of the adjoint spinor $\bar{\Psi}$ when $B = b\tilde{\gamma}^0$ is

$$\bar{\Psi} = b \left(\psi_R^\dagger, \psi_L^\dagger \right) \tilde{\gamma}^0 = \left(R_R^\dagger, R_L^\dagger \right) e^{-i\theta}. \tag{53}$$

Since R is a real vector, the transposed conjugate is equal to the transposed, that is $R^\dagger = R^T$.

Using the Madelung transformation (52) in the Weyl equations (46) and applying the Lie algebra and the Lie group, we can get the following expression

$$\begin{pmatrix} -\sigma^\mu \left(\bar{\nabla}_\mu \theta_R \right) R_R + i\sigma^\mu \left(\bar{\nabla}_\mu R_R \right) - q\sigma^\mu A_\mu R_R \\ -\bar{\sigma}^\mu \left(\nabla_\mu \theta_L \right) R_L + i\bar{\sigma}^\mu \left(\nabla_\mu R_L \right) - q\bar{\sigma}^\mu A_\mu R_L \end{pmatrix} = \begin{pmatrix} mR_L \\ mR_R \end{pmatrix}. \tag{54}$$

These are the Weyl equations in curved space-time with the Madelung transformation. We can also apply the Madelung transformation (52) and (53) to the current density (47), thereby obtaining

$$J^\mu = b \left(R_R^T \bar{\sigma}^\mu R_R - R_L^T \sigma^\mu R_L \right). \tag{55}$$

Its components are

$$J^0 = Nb(R_R^T R_R + R_L^T R_L) = Nbn, \tag{56}$$

$$J^j = b \left(\hat{e}_3^j (n_{\dot{1}} - n_{\dot{2}} - n_{\dot{3}} + n_{\dot{4}}) + 2\hat{e}_1^j (\sqrt{n_{\dot{1}} n_{\dot{2}}} - \sqrt{n_{\dot{3}} n_{\dot{4}}}) + \hat{e}_i^j N^i n \right). \tag{57}$$

We note that the zero component, where $n = \sum_{\dot{\nu}=\dot{1}}^{\dot{4}} n_{\dot{\nu}}$ is the density number of fermions in the system, gives the number of both right- and left-handed particles. We can write the following expressions $|\psi_R|^2 = \psi_R^\dagger \psi_R = R_R^T R_R = n_R$ and $|\psi_L|^2 = \psi_L^\dagger \psi_L = R_L^T R_L = n_L$ for the right- and left-handed spinors, as in the Dirac case. Thus, n_R, n_L are the right- and left- handed particle number and $n = n_R + n_L$ is the total density number.

Furthermore, eq. (31) becomes

$$
\begin{aligned}
i\,[2(mv_R^\mu-\omega_R\delta_0^\mu)\nabla_\mu R_R - qA_\mu + q\nabla_\mu(A^\mu R_R) + \nabla_\mu(mv_R^\mu-\omega_R\delta_0^\mu - qA^\mu)R_R] + \\
\left(m^2 v_{R\mu}v_R^\mu + 2m\omega_R v_R^0 + \frac{\omega^2}{N^2} + m^2\right)R_R - \Box R_R + \\
(2NN^k F_{0k} + i\epsilon^{ij}{}_k\hat{F}_{ij}\tilde{\sigma}^k)R_R + \\
(N(\nabla_0 N) - \bar{\sigma}^j(\nabla_j N))((mv_{R0}-\omega_R)R_R + D_0 R_R) + \\
(N(\nabla_0\sigma^i) - \bar{\sigma}^j(\nabla_j\sigma^i))(imv_{Ri}R_R + D_i R_R) = 0.
\end{aligned}
\tag{58}
$$

A similar equation is obtained for the left-handed spinor R_L with the substitution $R \longrightarrow L$ and $\mathbb{S} \longleftrightarrow \bar{\mathbb{S}}$ in eq. (58). Simplifying the first line in this equation for $\dot{\nu} = 1, 2$ corresponding to right-handed components, we get

$$
\begin{aligned}
i\frac{m}{\sqrt{n_{\dot{\nu}}}}\left[-\frac{\omega_{\dot{\nu}}}{m}\nabla_0 n_{\dot{\nu}} + \nabla_\mu(n_{\dot{\nu}}v_{\dot{\nu}}^\mu) + \frac{\omega_{\dot{\nu}}}{m}\Box t\right] + \\
\sqrt{n_{\dot{\nu}}}\left[m^2 v_{\mu R}v_{\dot{\nu}}^\mu + 2m\omega_{\dot{\nu}}v_{\dot{\nu}}^0 + \frac{\omega_R^2}{N^2} + m^2 - \frac{\Box\sqrt{n_{\dot{\nu}}}}{\sqrt{n_{\dot{\nu}}}}\right] + \\
(2NN^k F_{0k} + i\epsilon^{lj}{}_k\hat{F}_{lj}\tilde{\sigma}^k)R_R - \\
(\hat{\nabla}_a\hat{e}_b^\alpha)\bar{\mathbb{S}}^a\mathbb{S}^b((mv_{R\alpha}-\omega_{\dot{\nu}}\delta_\alpha^0)R_R + D_\alpha R_R) = 0.
\end{aligned}
\tag{59}
$$

The equation for the left-handed components $\dot{\nu} = 3, 4$ is obtained by changing $R_R \longrightarrow R_L$ and $\mathbb{S} \longleftrightarrow \bar{\mathbb{S}}$. Here, we have introduced the two-dimensional vectors $v_\mu = (v_{R\mu}, v_{L\mu})$ and $\omega = (\omega_R, \omega_L)$. Explicitly, they are given by

$$
R = \begin{pmatrix} R_R \\ R_L \end{pmatrix} = \begin{pmatrix} R_{\dot{1}} \\ R_{\dot{2}} \\ R_{\dot{3}} \\ R_{\dot{4}} \end{pmatrix} = \begin{pmatrix} \sqrt{n_{\dot{1}}} \\ \sqrt{n_{\dot{2}}} \\ \sqrt{n_{\dot{3}}} \\ \sqrt{n_{\dot{4}}} \end{pmatrix}, \tag{60}
$$

$$
v_\mu = \begin{pmatrix} v_{R\mu} & 0 \\ 0 & v_{L\mu} \end{pmatrix} = \begin{pmatrix} v_{\mu\dot{1}} & 0 & 0 & 0 \\ 0 & v_{\mu\dot{2}} & 0 & 0 \\ 0 & 0 & v_{\mu\dot{3}} & 0 \\ 0 & 0 & 0 & v_{\mu\dot{4}} \end{pmatrix}, \tag{61}
$$

$$
\omega = \begin{pmatrix} \omega_R & 0 \\ 0 & \omega_L \end{pmatrix} = \begin{pmatrix} \omega_{\dot{1}} & 0 & 0 & 0 \\ 0 & \omega_{\dot{2}} & 0 & 0 \\ 0 & 0 & \omega_{\dot{3}} & 0 \\ 0 & 0 & 0 & \omega_{\dot{4}} \end{pmatrix}. \tag{62}
$$

We now write the last two lines of eq. (59) explicitly and separate them into imaginary and real parts, respectively. Using the Pauli representation of the $\tilde{\sigma}^j$ matrices

$$
\tilde{\sigma}^1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \tilde{\sigma}^2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \tilde{\sigma}^3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \tag{63}
$$

we obtain for $\dot{\nu} = \dot{1}$:

$$\frac{m}{\sqrt{n_{\dot{1}}}}\left[-\frac{\omega_{\dot{1}}}{m}\nabla_0 n_{\dot{1}} + \nabla_\mu(n_{\dot{1}}v^\mu_{\dot{1}}) + \frac{\omega_{\dot{1}}}{m}\Box t\right] =$$
$$F_{12}\sqrt{n_{\dot{1}}} + F_{23}\sqrt{n_{\dot{2}}} - 2\Gamma^a_{21}((m\hat{v}_{a\dot{1}} - \omega_{\dot{1}}\hat{\delta}^0_a)\sqrt{n_{\dot{1}}} + \hat{D}_a\sqrt{n_{\dot{1}}}) -$$
$$2(\Gamma^a_{21}N^1 - \Gamma^a_{32}N^3 + \Gamma^a_{20} + \Gamma^a_{32})((m\hat{v}_{a\dot{2}} - \omega_{\dot{2}}\hat{\delta}^0_a)\sqrt{n_{\dot{2}}} + \hat{D}_a\sqrt{n_{\dot{2}}}),$$

where we have used that $\Gamma_{ab}+\Gamma_{ba}=0$ and defined the directional quantities $v_{a\dot{\nu}}=v_{R\alpha\dot{\nu}}\hat{e}^\alpha_a$, $\hat{\delta}^0_a=\delta^0_\alpha\hat{e}^\alpha_a=N\delta^0_a$ and $\hat{D}_a=\hat{e}^\alpha_aD_\alpha$.

The first line of eq. (59) represents the continuity equation of the fermionic fluid. The second line is the Bernoulli equation. In this respect, we note that eq. (25) is the first integral of this equation. Finally, the last three lines of eq. (59) are the source of the fermionic fluid, something that is not present in the case of bosons. This is because the Dirac equation was introduced in Ref.[25] in order to eliminate the negative probability problem of the KG equation. As a result, the Dirac equation involves only first derivatives while the KG equation is a second order equation.

Observe that the structure of equations (64)-(67) is

$$\frac{m}{\sqrt{n_{\dot{\nu}}}}\left[-\frac{\omega_{\dot{\nu}}}{m}\nabla_0 n_{\dot{\nu}}+\nabla_\mu(n_{\dot{\nu}}v^\mu_{\dot{\nu}})+\frac{\omega_{\dot{\nu}}}{m}\Box t\right]=$$
$$e_{1\dot{\nu}}F_{12}\sqrt{n_{\dot{\nu}}}+F_{23}\sqrt{n_{\ddot{\nu}}}-2e_{1\dot{\nu}}\Gamma^a_{21}((m\hat{v}_{a\dot{\nu}}-\omega_{\dot{\nu}}\hat{\delta}^0_a)\sqrt{n_{\dot{\nu}}}+\hat{D}_a\sqrt{n_{\dot{\nu}}})-$$
$$2(\Gamma^a_{21}N^1-\Gamma^a_{32}N^3+\Gamma^a_{20}+e_{2\dot{\nu}}\Gamma^a_{32})((m\hat{v}_{a\ddot{\nu}}-\omega_{\ddot{\nu}}\hat{\delta}^0_a)\sqrt{n_{\ddot{\nu}}}+\hat{D}_a\sqrt{n_{\ddot{\nu}}}),$$
$$\sqrt{n_{\dot{\nu}}}\left[m^2v_{\mu\dot{\nu}}v^\mu_{\dot{\nu}}+2m\omega_{\dot{\nu}}v^0_{\dot{\nu}}+\frac{\omega^2_{\dot{\nu}}}{N^2}+m^2-\frac{\Box\sqrt{n_{\dot{\nu}}}}{\sqrt{n_{\dot{\nu}}}}\right]=$$
$$2N(F_{01}N^1+F_{02}N^2+F_{03}N^3)\sqrt{n_{\dot{\nu}}}-e_{1\dot{\nu}}F_{13}\sqrt{n_{\ddot{\nu}}}+$$
$$\left[\Gamma^a_{11}(1-(N^1)^2)+\Gamma^a_{22}(1-(N^2)^2)+\Gamma^a_{33}(1-(N^3)^2)\right.+$$
$$\left.2e_{2\dot{\nu}}(\Gamma^a_{31}N^1+\Gamma^a_{32}N^2+\Gamma^a_{30})-\Gamma^a_{00}\right]((m\hat{v}_{a\dot{\nu}}-\omega_{\dot{\nu}}\hat{\delta}^0_a)\sqrt{n_{\dot{\nu}}}+\hat{D}_a\sqrt{n_{\dot{\nu}}})+$$
$$(-2e_{3\dot{\nu}}(\Gamma^a_{21}N^2+\Gamma^a_{31}N^3-\Gamma^a_{10})+2e_{1\dot{\nu}}\Gamma^a_{31})((m\hat{v}_{a\ddot{\nu}}-\omega_{\ddot{\nu}}\hat{\delta}^0_a)\sqrt{n_{\ddot{\nu}}}+\hat{D}_a\sqrt{n_{\ddot{\nu}}}),\quad(68)$$

where the coefficients $e_{i\dot{\nu}}$ are ±1 with $e_{1\dot{\nu}}=(+,-,+,-)$, $e_{2\dot{\nu}}=(+,-,+,-)$ and $e_{3\dot{\nu}}=(+,+,-,-)$, and the sub-index $\ddot{\nu}$ is the conjugate of the sub-index $\dot{\nu}$ such that $\ddot{1}=\dot{2}$, $\ddot{2}=\dot{1}$, $\ddot{3}=\dot{4}$ and $\ddot{4}=\dot{3}$.

7. Energy Balance

We can also write equation (30) as a Schrödinger-like equation. If we perform the transformation $\psi = \Psi e^{i\omega_0 t}$, where Ψ is a four spinor that depends on all the variables x^μ, equation (30) becomes

$$i\nabla^0\Psi - \frac{1}{2\omega_0}\Box_E\Psi + \frac{m^2}{2\omega_0}\Psi + \left(-\frac{\omega_0}{N^2} - 2qA^0 + i\Box t\right)\Psi + \frac{1}{2\omega_0}\begin{pmatrix} 2NN^kF_{0k} + i\hat{F}_{ij}\epsilon^{ij}{}_k\tilde{\sigma}^k & 0 \\ 0 & -2NN^kF_{0k} + i\hat{F}_{ij}\epsilon^{ij}{}_k\tilde{\sigma}^k \end{pmatrix}\Psi - \frac{1}{2\omega_0}\begin{pmatrix} \bar{\mathbb{S}}^a\mathbb{S}^b & 0 \\ 0 & \mathbb{S}^a\bar{\mathbb{S}}^b \end{pmatrix}\Gamma^d_{ba}(\hat{D}_d\Psi + i\omega_0 N\delta^0_d\Psi) = 0. \tag{69}$$

Equation (69) is the generalization of the Schrödinger equation for fermions with electromagnetic field interaction in an arbitrary space-time.

Finally, from equation (59) we can identify the different energy contributions to the Fermi gas, and obtain an energy balance equation for fermions analogous to the one obtained for bosons in Refs.[1,2]. In order to simplify the notations, we can re-write equation (59) in terms of the $\dot{\nu}$ coefficients with the understanding that the subindex R refers to each component $R = \dot{1}, \dot{2}$ individually. We get

$$i\left[-\omega_{\dot{\nu}}\nabla_0\ln(n_{\dot{\nu}}) + \frac{m\nabla_\mu(n_{\dot{\nu}}v^\mu_{\dot{\nu}})}{n_{\dot{\nu}}} + \frac{\omega_{\dot{\nu}}}{n_{\dot{\nu}}}\Box t\right] + 2m^2\left(K_{\dot{\nu}} + \frac{1}{m}\omega_{\dot{\nu}}v^0_{\dot{\nu}} + \frac{1}{2}U^N_{\dot{\nu}} + U^Q_{\dot{\nu}}\right) + E_{\dot{\nu}} + U^S_{\dot{\nu}} = 0. \tag{70}$$

This equation is valid for right handed fermions. The result is the same for left handed fermions changing $R_R \longrightarrow R_L$ in the first line, and $\mathbb{S} \longleftrightarrow \bar{\mathbb{S}}$ in the second line.

The first line in eq. (70) describes the free density evolution of the fermions, while the contribution of the different energy terms appears in the second line. The first one is the kinetic energy $K_{\dot{\nu}}$ defined as

$$K_{\dot{\nu}} = \frac{1}{2}v_{\dot{\nu}\mu}v^\mu_{\dot{\nu}}. \tag{71}$$

The lapse potential $U^N_{\dot{\nu}}$ is given by

$$U^N_{\dot{\nu}} = \frac{\omega^2_{\dot{\nu}}}{m^2}\frac{1}{N^2} + 1. \tag{72}$$

It represents the energy contribution due to the chosen lapse function N. The quantum potential $U^Q_{\dot{\nu}}$ is defined as

$$U^Q_{\dot{\nu}} = -\frac{1}{2m^2}\frac{\Box\sqrt{n_{\dot{\nu}}}}{\sqrt{n_{\dot{\nu}}}}. \tag{73}$$

The contribution of the electromagnetic interaction $E_{\dot\nu}$ is given by

$$\begin{aligned} E_{\dot\nu} &= (2NN^k F_{0k} + i\epsilon^{lj}{}_k \hat{F}_{lj}\tilde{\sigma}^k)|_{\dot\nu}, \\ &= 2N(F_{01}N^1 + F_{02}N^2 + F_{03}N^3) - e_{1\dot\nu}F_{13}\sqrt{\frac{n_{\ddot\nu}}{n_{\dot\nu}}} + i\left(e_{1\dot\nu}F_{12} + F_{23}\sqrt{\frac{n_{\ddot\nu}}{n_{\dot\nu}}}\right). \end{aligned} \tag{74}$$

It depends on the Faraday tensor, shift vector and lapse function that are related to the Pauli matrices. This relationship is due to the interaction between the electromagnetic field and the fermionic spin. Finally, the potential $U^S_{\dot\nu}$ describes the interaction between the spin and the geometry of space-time. It is given by

$$\begin{aligned} U^S_{\dot\nu} &= -\left((m\hat{v}_{Rd} - \omega_{\dot\nu}\hat{\delta}^0_d) + \frac{\hat{D}_\alpha\sqrt{n_{\dot\nu}}}{\sqrt{n_{\dot\nu}}}\right)\Gamma^d_{ba}\bar{\mathbb{S}}^a\mathbb{S}^b|_{\dot\nu}, \\ &= \left[\Gamma^a_{11}(1-(N^1)^2) + \Gamma^a_{22}(1-(N^2)^2) + \Gamma^a_{33}(1-(N^3)^2)\right. \\ &\quad \left. + 2e_{2\dot\nu}(\Gamma^a_{31}N^1 + \Gamma^a_{32}N^2 + \Gamma^a_{30}) - \Gamma^a_{00}\right]\left((m\hat{v}_{a\dot\nu} - \omega_{\dot\nu}\hat{\delta}^0_a) + \frac{\hat{D}_a\sqrt{n_{\dot\nu}}}{\sqrt{n_{\dot\nu}}}\right) \\ &\quad + (-2e_{3\dot\nu}(\Gamma^a_{21}N^2 + \Gamma^a_{31}N^3 - \Gamma^a_{10}) + 2e_{1\dot\nu}\Gamma^a_{31})\left((m\hat{v}_{a\ddot\nu} - \omega_{\ddot\nu}\hat{\delta}^0_a)\sqrt{\frac{n_{\ddot\nu}}{n_{\dot\nu}}} + \frac{\hat{D}_a\sqrt{n_{\ddot\nu}}}{\sqrt{n_{\dot\nu}}}\right) \\ &\quad + i\left[-2e_{1\dot\nu}\Gamma^a_{21}\left((m\hat{v}_{a\dot\nu} - \omega_{\dot\nu}\hat{\delta}^0_a) + \frac{\hat{D}_a\sqrt{n_{\dot\nu}}}{\sqrt{n_{\dot\nu}}}\right)\right. \\ &\quad \left. - 2(\Gamma^a_{21}N^1 - \Gamma^a_{32}N^3 + \Gamma^a_{20} + e_{2\dot\nu}\Gamma^a_{32})\left((m\hat{v}_{a\ddot\nu} - \omega_{\ddot\nu}\hat{\delta}^0_a)\sqrt{\frac{n_{\ddot\nu}}{n_{\dot\nu}}} + \frac{\hat{D}_a\sqrt{n_{\ddot\nu}}}{\sqrt{n_{\dot\nu}}}\right)\right] \end{aligned} \tag{75}$$

for $\dot\nu = \dot1, \dot2$, and by making the substitution $\mathbb{S} \longleftrightarrow \bar{\mathbb{S}}$ for $\dot\nu = \dot3, \dot4$. In the foregoing equations, the notation $|_{\dot\nu}$ means that we have to evaluate the quantity at the corresponding $\dot\nu$. Note that $U^S_{\dot\nu}$ disappears if we assume a flat space-time or if we consider particles without spin. Furthermore, $U^S_{\dot\nu}$ is constructed with the generalized gamma matrices (45), which are related to the spin (the Pauli matrices) and to the space-time geometry (tetrads).

8. Conclusions

The main difference between the hydrodynamic representation of bosons[1,2] and fermions concerns the form of the Bernoulli equation. For bosons, after making the Madelung transformation, we can separate the KG equation into real and imaginary parts. By contrast, for fermion particles we have to work with the complete equations of motion because the real and imaginary parts cannot be separated easily. This is related to the fact that the gamma matrices are a representation of the SO(1, 3) group.

The spin is a fundamental outcome of the Dirac equation[25] which combines both elements of special relativity and quantum mechanics and was introduced to solve the problem of negative probability present in the KG equation – first proposed as a relativistic generalization of the Schrödinger equation. Here, we observe that the general relativistic Dirac equation involves an additional contribution due to geometry and spin through the generalized gamma and Pauli matrices. These terms arise from endowing a quantum field with a curvature (geometry) given by a metric in General Relativity. Such a contribution is absent in a flat space-time and in a system without spin as for a scalar field.

With this work we open the possibility of studying in detail the behavior of fermions in different situations (such as massive stars or dark matter halos harboring a central black hole) where general relativity effects may be important. We solved the problem of energy balance for both bosons and fermions. In this manner, we can compare the result of the hydrodynamic representation for classical and quantum fluids in the various geometries mentioned above.

Appendix A. Solutions to the Dirac equation in flat space-time

Equation (5) in flat space-time, using the Pauli matrices (63), reads

$$\begin{bmatrix} \frac{\partial}{\partial t}\psi_y - \frac{\partial}{\partial x}\psi_z + i\frac{\partial}{\partial y}\psi_z - \frac{\partial}{\partial z}\psi_y - m\psi_t \\ \frac{\partial}{\partial t}\psi_z - \frac{\partial}{\partial x}\psi_y - i\frac{\partial}{\partial y}\psi_y + \frac{\partial}{\partial z}\psi_z - m\psi_x \\ \frac{\partial}{\partial t}\psi_t + \frac{\partial}{\partial x}\psi_x - i\frac{\partial}{\partial y}\psi_x + \frac{\partial}{\partial z}\psi_t - m\psi_y \\ \frac{\partial}{\partial t}\psi_x + \frac{\partial}{\partial x}\psi_t + i\frac{\partial}{\partial y}\psi_t - \frac{\partial}{\partial z}\psi_x - m\psi_z \end{bmatrix} = 0, \tag{A.1}$$

where we have defined the spinor as $\psi = (\psi_{\dot{\mu}}) = (\psi_x, \psi_y, \psi_z, \psi_t)^T$. In order to find an exact solution of the previous equation, we use the ansatz $\psi_{\dot{\mu}} = R_{0\dot{\mu}} \exp(i(x_0 x + y_0 y + z_0 z + t_0 t))$, where $x_0 \cdots t_0$ and $R_{0\dot{\mu}}$ are constants. Here we have the simplest solutions of the Dirac equation where the exponential is the same for all components.

We obtain four linear equations

$$\begin{aligned} iR_{0z}\zeta_0^* + iR_{0y}\eta_0 + mR_{0t} &= 0, \\ iR_{0y}\zeta_0 - iR_{0z}\xi_0 + mR_{0x} &= 0, \\ R_{0x}\zeta_0^* + R_{0t}\xi_0 + imR_{0y} &= 0, \\ R_{0t}\zeta_0 - R_{0x}\eta_0 + imR_{0z} &= 0, \end{aligned} \tag{A.2}$$

where $\zeta_0 = x_0 + iy_0$, $\eta_0 = z_0 - t_0$, and $\xi_0 = z_0 + t_0$. The solution of these equations is

$$\begin{aligned} R_{0t} &= -\frac{1}{m}(iR_{0y}\eta_0 + iR_{0z}\zeta_0), \\ R_{0x} &= \frac{1}{m}(iR_{0z}\xi_0 - iR_{0y}\zeta_0^*), \end{aligned} \tag{A.3}$$

where $x_0^2 + y_0^2 + z_0^2 - t_0^2 = m^2$.

Now we use the ansatz $\psi_\mu = R_{0\mu}\exp(i\theta)$, where θ is an arbitrary function of the coordinates. Substituting this ansatz into (A.1) we obtain

$$\begin{aligned} iR_{0z}Z_0^* + iR_{0y}E_0 + mR_{0t} &= 0, \\ iR_{0y}Z_0 - iR_{0z}F_0 + mR_{0x} &= 0, \\ R_{0x}Z_0^* + R_{0t}F_0 + imR_{0y} &= 0, \\ R_{0t}Z_0 - R_{0x}E_0 + imR_{0z} &= 0, \end{aligned} \tag{A.4}$$

where $Z_0 = \theta_{,x} + i\theta_{,y}$, $E_0 = \theta_{,z} - \theta_{,t}$, and $F_0 = \theta_{,z} + \theta_{,t}$. The solution of the previous system of differential equations is

$$\begin{aligned} \theta &= F(X) - it \\ &\quad + \frac{m}{2R_{0t}R_{0z} + 2R_{0x}R_{0y}}\left(i\zeta_0^*(R_{0x}^2 - R_{0z}^2) - i\zeta_0(R_{0y}^2 - R_{0t}^2)\right), \end{aligned} \tag{A.5}$$

where $F(X)$ is an arbitrary function of

$$X = \frac{R_{0t}(-\zeta R_{0y} - \zeta^* R_{0x} + \xi R_{0y} - \eta R_{0z})}{2R_{0t}R_{0z} + 2R_{0x}R_{0y}}. \tag{A.6}$$

We derive the semiclassical Hamiltonian for electron in a hydrogen atom in a weak gravitational field, which takes into account the quantum effects of electron motion in the atom. We show that this Hamiltonian predicts a breakdown of the equivalence between electron passive gravitational mass and its energy in the absence of the gravitational field. More strictly, we demonstrate that quantum measurement of electron mass, which initially is in a ground state and has energy E_1, can give the following quantized values: $m_n = m_e + \frac{E_n}{c^2}$, where E_n is energy of electron orbit nS in a hydrogen atom. We correct some drawbacks of our early pioneering papers and discuss some difficulties in the possible observations of the above mentioned mass quantization phenomenon.

Keywords: Equivalence Principle; Quantum gavity; Equivalence betweem mass and energy

1. Introduction

Einstein's Equivalence Principle (EEP) between gravitational and inertial masses is known to be a keystone of the classical General Relativity. In the current scientific literature, there exists a wide discussion if it can survive in the possible quantum theory of gravity. Since the quantum gravitation theory has not been elaborated yet, the EEP is often studied in framework of the so-called semiclassical approach to quantum gravity, where gravitational field is not quantized, but the matter is quantized.[1–5] Note that gravitational mass of a composite body is not a trivial notion even in classical General Relativity.[6–8] The reason for this is that gravitational field is not directly coupled to the total energy, E, but is coupled to combination, $E + V(\mathbf{r})$, where $V(\mathbf{r})$ is the so-called virial term.[6–8] In quantum case, as shown by us,[1,2,4,5] the existence of the virial term results in breakdown of the equivalence between active and passive gravitational masses and energy of a body with internal degrees of freedom. The goal of our current paper is to suggest new method which demonstrates that the virial term is responsible for inequivalence of passive gravitational mass and energy. Below, we demonstrate the above mentioned inequivalence for a hydrogen atom, which is the simplest quantum object with internal degrees of freedom. Of course our conclusions, obtained in the paper, are applied to any composite quantum body.

2. Quantization of Passive Electron Gravitational Mass

2.1. *Electron wave function with a definite energy in the absence of gravitational field*

Let us consider the case, where at $t < 0$ gravitational field is zero and electron occupies ground state in a hydrogen atom, characterizing by the wave function:

$$\Psi_1(r,t) = \exp\left(\frac{-im_e c^2 t}{\hbar}\right)\exp\left(\frac{-iE_1 t}{\hbar}\right)\Psi_1(r)\ . \tag{1}$$

Note that the wave function (1) corresponds to the $1S$ electron orbit and is known to be a ground state solution of the following Schrödinger equation:

$$i\hbar\frac{\partial\Psi_1(r,t)}{\partial t} = \left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right) - \frac{e^2}{r}\right]\Psi_1(r,t). \tag{2}$$

[Here E_1 is electron ground state energy, r is a distance between the electron with coordinates (x,y,z) and proton; m_e is the bare electron mass, $\hbar$ is the Planck constant, and c is the velocity of light.]

2.2. *Electron wave function in the presence of gravitational field*

Let us consider the following Gedanken experiment: we turn on a weak (e.g., the Earth's) gravitational field at $t = 0$. As known,[9] the interval, characterizing a curved spacetime in the so-called weak field approximation, can be written as

$$ds^2 = -\left(1+2\frac{\phi}{c^2}\right)(cdt)^2 + \left(1-2\frac{\phi}{c^2}\right)(dx^2+dy^2+dz^2),\ \phi = -\frac{GM}{R}, \tag{3}$$

where M is mass of a source of gravity, G is the gravitational constant. Below we use the local Lorentz invariance property of a spacetime in general relativity.[9] To this end, it is convenient to introduce the proper local coordinates,

$$\tilde{t} = \left(1+\frac{\phi}{c^2}\right)t,\ \tilde{x} = \left(1-\frac{\phi}{c^2}\right)x,\ \tilde{y} = \left(1-\frac{\phi}{c^2}\right)y,\ \tilde{z} = \left(1-\frac{\phi}{c^2}\right)z, \tag{4}$$

where the interval (3) has the Minkowski's form,

$$d\tilde{s}^2 = -(cd\tilde{t})^2 + (d\tilde{x}^2+d\tilde{y}^2+d\tilde{z}^2). \tag{5}$$

Due to the local Lorentz invariance, if we disregard the tidal terms (i.e., if we don't differentiate the gravitational potential ϕ), the wave functions, written in the local proper coordinates (4), obeys the same Schrödinger equation at $t, \tilde{t} > 0$:

$$i\hbar\frac{\partial\Psi(\tilde{\mathbf{r}},\tilde{t})}{\partial\tilde{t}} = \left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial\tilde{x}^2}+\frac{\partial^2}{\partial\tilde{y}^2}+\frac{\partial^2}{\partial\tilde{z}^2}\right) - \frac{e^2}{\tilde{r}}\right]\Psi(\tilde{\mathbf{r}},\tilde{t}). \tag{6}$$

Nevertheless, it is important that the wave function (1) is not a solution of the Schrödinger equation (6) and, thus, is not anymore characterized by definite energy and weight in the gravitational field (3). To clarify this point, we rewrite Eq. (6) in

initial, (t, x, y, z), spacetime coordinates:

$$i\hbar\frac{\partial\Psi(\mathbf{r},t)}{\partial t} = \left\{\left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)-\frac{e^2}{r}\right]\right.$$
$$\left.+\left(\frac{\phi}{c^2}\right)\left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)-\frac{e^2}{r}+\hat{V}(\mathbf{r})\right]\right\}\Psi(\mathbf{r},t), \quad (7)$$

where the virial operator[10] is equal to

$$\hat{V}(\mathbf{r}) = -2\frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)-\frac{e^2}{r}. \quad (8)$$

From Eq. (8), it directly follows that the external gravitational field (3) is coupled not only to Hamiltonian (2) but also to the virial operator (8). Note that the Hamiltonian (7),(8) can be also obtained from the results,[11] where some different physical problem is considered, if we disregard all tidal terms.

It is important that the gravitational field (3) can be considered as a sudden perturbation, $\hat{H}_1(\mathbf{r},t)$, to Hamiltonian (2) in the absence of gravitational field:

$$\hat{H}_1(\mathbf{r},t) = \left(\frac{\phi}{c^2}\right)\left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)-\frac{e^2}{r}+\hat{V}(\mathbf{r})\right]\Theta(t), \quad (9)$$

where $\Theta(t)$ is the step-like function. Then, a general solution of Eq. (7) can be written in the following way:

$$\Psi(r,t) = \exp\left(\frac{-i\tilde{m}_e c^2 t}{\hbar}\right)\Psi_1^1(r)\exp\left(\frac{-i\tilde{E}_1 t}{\hbar}\right)$$
$$+\exp\left(\frac{-im_e c^2 t}{\hbar}\right)\sum_{n>1}^{\infty} a_n\Psi_n(r)\exp\left(\frac{-iE_n t}{\hbar}\right), \quad (10)$$

where the wave functions $\Psi_n(r)$ are solutions for the nS orbits in a hydrogen atom and are normalized,

$$\int[\Psi_1^1(r)]^2\, d^3r \simeq 1; \quad \int\Psi_n^2(r)\, d^3r = 1, \quad n>1. \quad (11)$$

[It is easy to show that perturbation (9) can results only in non-zero quantum transitions between $1S$ and nS electron orbits, therefore, we keep in Eq. (10) only $\Psi_n(r)$ wave functions, which are real.]

2.3. *Matrix elements and probabilities*

According with the standard time-dependent perturbation theory,[10] the corrected wave-function of ground state, $\Psi_1^1(r)$, as well as the corrections to mass and energy of ground state in Eq. (10) can be written as:

$$\Psi_1^1(r) = \Psi_1(r) + \left(\frac{\phi}{c^2}\right)\sum_{n>1}^{\infty}\frac{V_{n,1}}{E_1 - E_n}\Psi_n(r),$$
$$\tilde{m}_e = \left(1+\frac{\phi}{c^2}\right)m_e, \quad \tilde{E}_1 = \left(1+\frac{\phi}{c^2}\right)E_1, \quad (12)$$

where $V_{n,1}$ is matrix element of the virial operator (8):

$$V_{n,1} = \int \Psi_n(r)\left[-2\frac{\hbar^2}{2m}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)-\frac{e^2}{r}\right]\Psi_1(r)d^3\mathbf{r}. \tag{13}$$

Note that the very last term in Eq. (12) corresponds to the so-called red shift in gravitational field. It is due to the expected contribution to passive gravitational mass from electron binding energy in the atom. As to the coefficients a_n with $n \neq 1$ in Eq. (10), they can be also written in terms of the virial operator matrix elements,

$$a_n = -\left(\frac{\phi}{c^2}\right)\left(\frac{V_{n,1}}{E_1 - E_n}\right). \tag{14}$$

It is important that the wave function (10)-(14), which corresponds to electron energy levels in the presence of the gravitational field (3) at $t > 0$, is a series of eigenfunctions of electron energy operator, taken in the absence of the field. Therefore, if we measure energy, in electron quantum state (10)-(14), we obtain the following quantized values for electron gravitational mass:

$$m_n = m_e + \frac{E_n}{c^2}, \tag{15}$$

where we omit the red shift effect. From Eqs.(10)-(15), we can state that the expected Einstein's equation, $m_1 = m_e + \frac{E_1}{c^2}$, survives in our case with probability close to 1, whereas with the following small probabilities,

$$P_n = |a_n|^2 = \left(\frac{\phi}{c^2}\right)^2 \frac{V_{n,1}^2}{(E_n - E_1)^2}, \quad n \neq 1, \tag{16}$$

it is broken. The reason for this breakdown is that, the virial term (8) does not commute with the Hamiltonian in the absence of gravitational field (2). As a result, electron wave functions with definite passive gravitational masses are not characterized by definite energies in the absence of gravitational field. Let us calculate probability P_2 near the Earth's surface, where $\frac{\phi^2}{c^4} \approx 0.49 \times 10^{-18}$. From Eq. (16), we obtain the following probability for $n = 2$ in a hydrogen atom:

$$P_2 = |a_2|^2 = 1.5 \times 10^{-19}, \tag{17}$$

where

$$\frac{V_{2,1}}{E_2 - E_1} = 0.56. \tag{18}$$

3. Experimental Aspects

Here, let us describe another Gedanken experiment, where gravitational field is adiabatically switched on. To this end, we consider wave function (1) to be valid at $t \to -\infty$ and apply the following perturbation due to gravitation for the Hamiltonian (2):

$$\hat{H}_2(\mathbf{r},t) = \left(\frac{\phi}{c^2}\right)\left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)-\frac{e^2}{r}+\hat{V}(\mathbf{r})\right]\exp(\lambda t),\ \lambda \to 0. \tag{19}$$

Then, at $t \simeq 0$ (i.e., in the presence of the field), the electron wave function can be written as

$$\Psi(r,t) = \exp\left(\frac{-i\tilde{m}_e c^2 t}{\hbar}\right)\Psi_1^1(r)\exp\left(\frac{-i\tilde{E}_1 t}{\hbar}\right)$$
$$+\exp\left(\frac{-im_e c^2 t}{\hbar}\right)\sum_{n>1}^{\infty}\tilde{a}_n\Psi_n(r)\exp\left(\frac{-iE_n t}{\hbar}\right). \qquad (20)$$

Application of the standard time-dependent perturbation theory[10] in the case of adiabatic switching on gravitational field gives:

$$\Psi_1^1(r) = \Psi_1(r) + \left(\frac{\phi}{c^2}\right)\sum_{n>1}^{\infty}\frac{V_{n,1}}{E_1 - E_n}\Psi_n(r),$$
$$\tilde{m}_e = \left(1+\frac{\phi}{c^2}\right)m_e, \quad \tilde{E}_1 = \left(1+\frac{\phi}{c^2}\right)E_1, \qquad (21)$$

and

$$\tilde{a}_n = 0, \quad \tilde{P}_n = 0. \qquad (22)$$

Thus, in adiabatic limit, the phenomenon of quantization of passive gravitational mass (15),(16) disappears. This means that the possible experimental observations of the above mentioned phenomenon has to be done in quickly changing gravitational field. It is important that step-like function, $\Theta(t)$, which was used to derive Eqs.(15),(16) does not mean motion of an atom or a source of gravity with velocity higher than the speed of light. We can use step-like function if significant change of gravitational field happens quicker that the period of quasiclassical rotation of electron in a hydrogen atom. In the case under consideration, we need the time about $\delta t \leq t_0 = \frac{2\pi\hbar}{E_2 - E_1} \sim 10^{-15}s$. We hope that there exist much more convenient quantum systems with higher values of the parameter t_0, where discussed above phenomenon could be observed. We recall that all excited energy levels are quasistationary and, thus, decay with time by emitting photons. Therefore, it is much more efficient to detect emitted photons than to directly measure a weight. Here, we also stress that we did not calculate the gravitational mass and weight of the atom with an accuracy ϕ^2/c^4 since we did not take in account terms of the order of ϕ^2/c^4 in the metric (3). As to the relatively small probability of the quantization (16), it is not too small and can be compensated by large value of Avogadro number, $N_A \approx 6 \times 10^{23}$. In other words, for macroscopic number of the atoms, we may have large number of emitted photons. For instance, the number of excited electrons (i.e., emitted photons) for 1000 moles of the atoms is estimated as

$$N_n = 2.95 \times 10^8 \times \left(\frac{V_{n,1}}{E_n - E_1}\right)^2, \quad N_2 = 0.9 \times 10^8. \qquad (23)$$

4. Conclusion

In the paper, we have shown that energy is not equivalent to passive gravitational mass of the such simplest composite body as a hydrogen atom. This happens due to the existence in the electron Hamiltonian in gravitational field of the so-called virial term, which does not commute with the Hamiltonian, taken in the absence of the field. It is easy to show that this is a general property of any quantum system with internal degrees of freedom in General Relativity. Therefore, we can conclude that application of the basic quantum laws to General Relativity results in the breakdown of the equivalence between passive gravitational mass and energy. It is important that the non-zero matrix elements (16),(18) of the virial operator (8) are also responsible, as shown by us,[1,2,4] for breakdown of the equivalence between active gravitational mass and energy for a quantum body with internal degrees of freedom. Therefore, formulation of the EEP has to be significantly reinvestigated and changed in semiclassical gravity.

1. Introduction

A standard result of quantum field theory is the existence of divergences when computing observables. This requires the construction of techniques, called regularization and renormalization schemes, to overcome these infinities and produce well defined physical observables. A standard example is the computation of vacuum polarization effects in perturbative Quantum Electrodynamics (QED) which results in the well-known Lamb Shift an the anomalous magnetic momentum of the electron. As a byproduct of these methods, an arbitrary mass scale parameter μ present in the calculations implies a dependence under this scale of the different coupling constants of the theory.[1] Instead of becoming an obstacle it offers a very useful tool, the renormalization group equation,[1,2] to understand the behaviour of the theories at some particular ranges, without knowing the exact details of the theory. The relevant magnitudes that encode the information of this equation are the beta functions, $\beta_O = \mu \frac{dO_R}{d\mu}$, where O_R is any possible renormalized coupling constant of the theory.

At the level of quantum field theory in curved spacetime, similar divergences arise. These appear even when computing observables in the vacuum state since the standard method of regularizing the vacuum divergences in Minkowski, known as *normal ordering*, is not available anymore since it strictly depends on the definition of the vacuum state, which is not unique in this context. Nevertheless, many regularization methods, including Dimensional Regularization and Pauli-Villars have been inherit from the Minkowski spacetime case, and have obtained finite renormalized

*Talk given by A. Ferreiro at the Sixteenth Marcel Grossmann Meeting (2021).

quantities, e.g. the Feynman propagator $G(x,x')$ and the expectation value of the stress energy tensor T_{ab} for scalar, Dirac or gauge fields in curved spacetime.[3–5]

Most methods rely on the convenient expression of the propagator in terms of an integral in the DeWitt-Schwinger proper time

$$G(x,x') = \frac{\Delta^{1/2}(x,x')}{(4\pi)^2}\int_0^\infty \frac{ds}{(is)^2} e^{-im^2 s + \frac{\sigma(x,x')}{2is}} F(x,x',is)\ . \tag{1}$$

The advantage of expression (1) is that it admits an expansion

$$F(x,x',is) = \sum_{j=0}^{\infty} a_j(x,x')(is)^j. \tag{2}$$

Note that the effective action and consequently the stress-energy tensor can be derived from $G(x,x')$ in the limit $x' \to x$ where this expression becomes divergent. In the case of four dimensions $d = 4$, the divergences are encoded and isolated in the first two terms of the expansion (the first three terms in case of the effective action). There are several ways to regulate expression (1). For instance, it can be analytically extended to higher dimension $d > 4$, via dimensional regularization or it can be expanded in terms of point splitting parameter σ. The infinities are recovered in the case of $d \to 4$ and $\sigma \to 0$ respectively. It can be shown[3] that all the divergent pieces of the one loop corrections of a free field can be consistently reabsorbed in the original action

$$S_G = \int d^4x\sqrt{-g}\left(-\Lambda + \frac{1}{2\kappa}R + \alpha_1 C^2 + \alpha_2 R^2 + \alpha_3 E + \alpha_4 \Box R\right), \tag{3}$$

where $\kappa = 8\pi G$. It is in principle possible to use the DeWitt-Schwinger decomposition (1) to compute the exact one-loop contribution.[3,5] In this case, as a byproduct of the DeWitt-Schwinger decomposition we can construct a natural subtraction scheme without invoking any artificial regulator

$$G_{\rm ren}(x,x) = \lim_{x'\to x} G(x,x') - \frac{1}{(4\pi)^2}\sum_{j=0}^{1} a_j(x)\int_0^\infty \frac{ds}{(is)^{(2-j)}} e^{-im^2 s}\ . \tag{4}$$

We can also construct subtraction schemes from dimensional regularization or point splitting. In any case the different regularization and subtraction schemes differ in terms that can always be reabsorbed in the action (3).[4]

Note that the subtracted contribution of (4) needs to include an small imaginary $m^2 - i\epsilon$ to avoid an infrared singularity. In the mass-less case this is an obstacle since the infrared divergence is present in the limit $s \to 0$.[4] In order to overcome this problem we can insert an artificial parameter μ^2 as a mass-scale instead of m^2 in (4) and then take the limit $\mu^2 \to 0$. This has been done for instance to obtain the conformal anomaly.[3] However, another interesting approach is to maintain in all the potential calculations μ^2 different to zero and to modify consistently the coefficients $a_j(x)$ of (4) in order to ensure that no extra divergences appear in the

case of $\mu^2 \neq 0$. In the most general case, without assuming $m^2 = 0$, the extended DeWitt-Schwinger subtraction scheme would be[6]

$$\bar{G}_{\rm ren}(x,x) = \lim_{x' \to x} G(x,x') - \frac{1}{(4\pi)^2} \sum_{j=0}^{1} \bar{a}_j(x) \int_0^\infty \frac{ds}{(is)^{(2-j)}} e^{-i\left(m^2+\mu^2\right)s} \ . \qquad (5)$$

Here the the new coefficients are $\bar{a}_0 = 1$, $\bar{a}_1 = a_1 + \mu^2$ and $\bar{a}_2 = a_1\mu^2 + \frac{1}{2}\mu^4$ [a]. The introduction of this extra parameter is required for the massless limit. However, it also offers a possible running coupling interpretation analogue to the Minimal subtraction scheme in dimensional regularization. We will analyze this in the next section.

An important property of the regularization and renormalization program is that it should not spoil the decoupling of heavy massive fields in the low energy limit. For instance, we should not have to compute the vacuum polarization of the quark top mass when performing a low energy (below the top mass) scattering process in QED. The decoupling of heavy field in renormalizable theories has been well stated by the Appelquist-Carazzone theorem.[8] In the case of QED, Minimal Subtraction is not compatible with decoupling[9] and a different subtraction scheme has to be taken in order to have a physical interpretation of the μ parameter at low energy regime. A possible scheme is known as *Momentum subtraction scheme*,[9] which not only decouples the heavy fields, i.e., $\beta_O \to 0$ when $m^2 \to \infty$ but also recovers the Minimal Subtraction beta functions in the limit of $\mu^2 \to \infty$ or $m^2 \to 0$.

In the case of quantum fields in curved spacetime an analog to the Momentum subtraction scheme has been elusive. A notable result of the subtraction scheme of (5) is that it is consistent with the decoupling of heavy massive fields,[6] as we will show in the next section.

2. Running of the couplings and decoupling of massive fields

In order to compute the running of the couplings with the parameter μ it is useful to use the extended DeWitt-Schwinger subtraction scheme for the effective action, which can be constructed in a similar manner to (5).[7] It is also useful for pedagogical purposes to consider a complex scalar field interacting with an electromagnetic field obeying the Klein-Gordon equation

$$\left(g^{\mu\nu} D^x_\mu D^x_\nu + m^2 + \xi R\right) G(x,x') = -|g(x)|^{-1/2} \delta(x'-x), \qquad (6)$$

where $D_\mu = \nabla_\mu + iqA_\mu$. In this case, the extended DeWitt-Schwinger subtraction scheme takes the form[7]

$$W^{(1)}_{\rm ren} = W^{(1)} - \frac{2i}{2(4\pi)^2} \int d^4x \sqrt{-g} \sum_{j=0}^{2} \bar{a}_j(x) \int_0^\infty \frac{ds}{(is)^{(3-j)}} e^{-i\left(m^2+\mu^2\right)s} \qquad (7)$$

[a] Note here that in terms of adiabatic order, the μ^2 in the exponential of (5) is of adiabatic order zero while the μ^2 of the coefficients are of adiabatic order two. This is equivalent to the methodology taken in[7] for Parker-Fulling adiabatic regularization.

where $W^{(1)}$ is the divergent one-loop effective action constructed from (1) and the coefficients are

$$\bar{a}_0(x) = 1\ , \qquad \bar{a}_1(x) = \left(\frac{1}{6} - \xi\right) R + \mu^2$$
$$\bar{a}_2(x) = \frac{1}{180} R_{\alpha\beta\gamma\delta} R^{\alpha\beta\gamma\delta} - \frac{1}{180} R^{\alpha\beta} R_{\alpha\beta} - \frac{1}{6}\left(\frac{1}{5} - \xi\right) \Box R$$
$$+ \frac{1}{12}\left(\xi - \frac{1}{6}\right)^2 R^2 - \frac{q^2}{12} F_{\mu\nu} F^{\mu\nu} + \left(\frac{1}{6} - \xi\right) R\mu^2 + \frac{1}{2}\mu^4\ . \tag{8}$$

The subtraction terms of (7) can be absorbed into the original action

$$S^c = S_G + \int d^4x \sqrt{-g}\left(-\frac{1}{4} Z_A \tilde{F}_{\mu\nu} \tilde{F}^{\mu\nu} + (\tilde{D}_\mu \phi)^\dagger \tilde{D}^\mu \phi + m^2 |\phi|^2 + \xi R |\phi|^2\right) \tag{9}$$

with $\tilde{D}_\mu = \nabla_\mu + iq Z_A^{1/2} \tilde{A}_\mu$, where we have re-scaled the potential to introduce an extra coupling constant Z_A. The complete effective action would be

$$S^{(1)}_{\rm ren} = W^{(1)}(m, \xi, q Z_A^{1/2}) + S^c(m, \xi, q, Z_A, \Lambda, \kappa, \alpha_i), \tag{10}$$

where we have made visible the explicit dependence of the bare couplings and fields. The complete action in terms of the physical renormalized couplings O_R is

$$S^{(1)}_{\rm ren} = W^{(1)}_{\rm ren}(m_R, \xi_R, q_R Z_R^{1/2}) + S^c_{\rm ren}(Z_R, \Lambda_R, \kappa_R, \alpha_{iR}) \tag{11}$$

where $S^c_{\rm ren}$ is the original S^c upgrading the bare divergent coupling constants to the corresponding renormalized finite ones.In the particular case of a free complex scalar field, it is not difficult to see that expression (7) does not involve any divergent piece that need to be reabsorbed neither in m^2, nor ξ and the combination $qZ^{1/2}$ and therefore we can already write

$$\xi = \xi_R \qquad m = m_R \qquad q Z_A^{1/2} = q_R Z_{AR}^{1/2}. \tag{12}$$

This is of course not a general result and indeed this couplings constants could be divergent in theories including other interactions.[10] We will from now on drop the subscript $_R$ from these terms.

In order to compute the beta functions $\beta_O = \mu \frac{dO_R}{d\mu}$ we will impose the invariance of the renormalized action with respect to the arbitrary parameter μ

$$\mu \frac{d}{d\mu} S^{(1)}_{\rm ren} = 0. \tag{13}$$

From (7), it is easy to check

$$\mu \frac{d}{d\mu} W^{(1)}_{\rm ren} = \int d^4x \sqrt{-g} \frac{1}{16\pi^2 (m^2 + \mu^2)} \left(2\mu^2 a_2(x) - 2\mu^4 a_1(x) - \mu^6\right). \tag{14}$$

Using (12), (13) and (14), we finally obtain the following beta functions

$$\beta_{\alpha 1} = -\frac{1}{960\pi^2}\frac{\mu^2}{m^2+\mu^2} \qquad \beta_{\alpha 2} = -\frac{\left(\xi-\frac{1}{6}\right)^2}{16\pi^2}\frac{\mu^2}{m^2+\mu^2}$$
$$\beta_{\Lambda} = \frac{1}{16\pi^2}\frac{\mu^6}{m^2+\mu^2} \qquad \beta_{\kappa^{-1}} = \frac{\xi-\frac{1}{6}}{4\pi^2}\frac{\mu^4}{m^2+\mu^2} \qquad \beta_{q} = \frac{q_R^3}{48\pi^2}\frac{\mu^2}{m^2+\mu^2} \quad . \tag{15}$$

It can be easily checked that the running of dimensionless coupling constants coincides with the Minimal Subtraction beta functions,[11] but with the advantage that the structure $\frac{\mu^2}{m^2+\mu^2}$, similar to the cutoff Wilsonian scheme[12] makes a vanishing contribution when $m^2 \to \infty$ thus making this renormalization scheme compatible with decoupling of heavy massive fields. The remarkable result is that also the running of both the Newton constant and the cosmological constant also decouple in this limit, thus enforcing the fact that higher massive fields do not contribute to the low energy regime, even when the gravitational field is present.

We consider the renormalization of the one-loop effective action for the Yukawa interaction. We compute the beta functions in the generalized DeWitt-Schwinger subtraction scheme. For the quantized scalar field we obtain that all the beta functions exhibit decoupling for heavy fields as stated by the Appelquist-Carazzone theorem including also the gravitational couplings. For the quantized Dirac field, decoupling appears for almost all of them. We obtain the atypical result that the mass parameter of the background scalar field, does not decouple.[a]

Keywords: Decoupling, renormalization, running couplings, beta functions, one-loop effective Lagrangian, DeWitt-Schwinger expansion

1. Introduction

Regularization and renormalization of infinities of quantum fields in curved spacetime is a subtle subject. Infinite quantities emerge at the vacuum level and can not be erased due to the non-trivial structure of the classical gravitational background field. There are well established covariant and pragmatic methods to evaluate the vacuum expectation value of the stress-energy tensor in physically reasonable states.[2–7] For a general spacetime, the DeWitt-Schwinger technique[8–10] allows us to evaluate and renormalize the stress-energy tensor as well as the one-loop effective action which constitute a practical tool that encodes all the relevant information about the quantum effects of fields.

The regularization machinery usually incorporates an arbitrary, non physical, mass-scale parameter. Studying how the coupling constants depend on this scale, i.e., the running of the couplings, is very useful in physical situations where more formal computations are very involved. This is done by requiring that physical quantities should not depend on spurious parameters.[11–13] As a representative case, in dimensional regularization an arbitrary mass scale μ is introduced to compensate the fictitious dimensions. In the case of the DeWitt-Schwinger proper-time expansion a mass scale μ is usually introduced in the short distance logarithmic term $\log \mu^2\sigma/2$ to overcome an infrared divergence for massless fields. Changing the

[a]Expanded version of the talk given by S. Nadal-Gisbert in the Sixteenth Marcel Grossmann Meeting (2021).

mass scale μ to μ' allows to obtain an effective running for the parameters of the Lagrangian.

Another important feature of effective field theories is that massive fields should decouple at low energies[14,15] as stated by the Appelquist-Carazzone theorem[16b]. This idea which lies at the heart of the effective field theories states that a field of mass m can not influence the physics at scales larger than m^{-1}. In a physical renormalization scheme this idea should be manifested in the beta functions of the theory if they want to describe both infrared and ultraviolet regimes. Moreover, in gravitational physics decoupling is crucial to get a proper physical interpretation in the cosmic infrared regime. This can be particularly relevant for the cosmological constant problem and for the running of the Newton's gravitational constant.[19–22] A partial list of works dealing with this issue in a curved space are.[23–28]

Recently, an arbitrary scale parameter μ has been introduced in the DeWitt-Schwinger subtraction scheme in order to consistently construct the subtraction terms avoiding the infrared divergences[29] (see also[30–32]). This was done for the free complex scalar field in the Einstein-Maxwell theory. This approach has the benefit of producing the decoupling of heavy fields. In this work we further extend this approach by including Yukawa interactions with spinor fields and scalars also coupled to gravity. This model has been broadly studied in dimensional regularization[24,33–35] also by including gauge fields.[36,37] We will concentrate in the simplest case of a scalar background coupled to a quantized dirac field and also to a scalar field. The aim of this work is to compute the beta functions in the generalized DeWitt-Schwinger renormalization approach and observe whether decoupling explicitly appears.

2. Interaction with a quantized scalar field and renormalization

Consider a quantized real scalar field φ coupled to a real scalar background ϕ via the Yukawa interaction $\frac{h^2}{2}\phi^2\varphi^2$

$$S = \int d^4x\sqrt{-g}\left\{-\Lambda + \frac{R}{16\pi G} + \frac{1}{2}\nabla^\mu\varphi\nabla_\mu\varphi - \frac{1}{2}\left(m^2+\xi R\right)\varphi^2 \right.$$
$$\left. -\frac{h^2}{2}\phi^2\varphi^2 + \frac{1}{2}\nabla^\mu\phi\nabla_\mu\phi - V(\phi)\right\}\ , \tag{1}$$

where m^2 is the mass parameter for the quantized scalar, ξ is the coupling of φ^2 to the Ricci scalar, and $V(\phi)$ is a general potential that can contain interactions between the background field and the curvature but is independent of the quantized scalar field φ. The Feynman propagator G_F for φ satisfies

$$\left(\Box_x + m^2 + \xi R + h^2\phi^2\right) G_{\rm F}(x,x') = -|g(x)|^{-1/2}\delta(x-x'). \tag{2}$$

[b]There are some situations were decoupling is violated. This typically happens on theories with spontaneously broken gauge symmetries.[17,18]

The effective action can be generated from this propagator by $S_{\rm eff} = -i\frac{1}{2}\,{\rm Tr}\log(-G_{\rm F})$. The ultraviolet divergences of the one-loop effective Lagrangian can be explicitly manifested if one expresses the Feynman propagator as an integral in the proper time s,

$$G_{\rm F}(x,x') = -i\int_0^\infty ds\; e^{-im^2 s}\langle x,s|x',0\rangle\;, \tag{3}$$

where m^2 is understood to have an infinitesimal negative imaginary part ($m^2 \equiv m^2 - i\epsilon$). The heat kernel $\langle x,s|x',0\rangle$ can be expanded in powers of the proper time as follows

$$\langle x,s|x',0\rangle = i\frac{\Delta^{1/2}(x,x')}{(4\pi)^2(is)^2}\exp\frac{\sigma(x,x')}{2is}\sum_{j=0}^\infty a_j(x,x')(is)^j\;, \tag{4}$$

where $\Delta(x,x')$ is the Van Vleck-Morette determinant and $\sigma(x,x')$ is the proper distance along the geodesic from x' to x. Therefore, the effective Lagrangian, defined as $S_{\rm eff} = \int d^4x\sqrt{-g}L_{\rm eff}$, has the following asymptotic expansion

$$L_{\rm eff} = \frac{i}{2(4\pi)^2}\sum_{j=0}^\infty a_j(x)\int_0^\infty e^{-ism^2}(is)^{j-3}ds\;. \tag{5}$$

The first coefficients $a_n(x,x')$ are given, in the coincidence limit $x\to x'$, by[5]

$$\begin{aligned} a_0(x) =& 1\;, \qquad a_1(x) = \frac{1}{6}R - Q \\ a_2(x) =& \frac{1}{180}R_{\alpha\beta\gamma\delta}R^{\alpha\beta\gamma\delta} - \frac{1}{180}R^{\alpha\beta}R_{\alpha\beta} - \frac{1}{30}\Box R + \frac{1}{72}\;R^2 \\ &+ \frac{1}{2}Q^2 - \frac{1}{6}RQ + \frac{1}{6}\Box Q + \frac{1}{12}W_{\mu\nu}W^{\mu\nu}\;, \end{aligned} \tag{6}$$

where for the case of a scalar field we have $W_{\mu\nu} \equiv [\nabla_\mu,\nabla_\nu] = 0$ and $Q = \xi R + h^2\phi^2$. Expansion (5) shows that the ultraviolet divergent terms of the effective Lagrangian are localized in the first three terms of the DeWitt-Schwinger expansion in the limit $s\to 0$ of the integral. The renormalization procedure can be performed by directly subtracting these divergent terms to the total one-loop contribution.

$$L_{\rm ren} = \int_0^\infty ds\left[\frac{e^{-im^2 s}}{is}\langle x,s|x,0\rangle - \frac{i}{2(4\pi)^2}\sum_{j=0}^2 a_j(x)\frac{e^{-ism^2}}{(is)^{-j+3}}\right], \tag{7}$$

where the notation of $L_{\rm ren}$ has to be understood as the finite one-loop correction to the background Lagrangian. One can notice that the massless case inherits an infrared divergence ($s\to\infty$ limit). We avoid it by introducing a mass scale μ^2 in the exponential term of the DeWitt-Schwinger expansion by writing $\sum_j a_j(x)e^{-ism^2} \to \sum_j \bar{a}_j(x)e^{-is(m^2+\mu^2)}$ in (5). As mentioned in,[29] this is the unique way of introducing the μ parameter if we want the exponential form to remain. The main point of the introduction of the arbitrary parameter μ at the same level of the mass, is to obtain decoupling in the infrared behaviour of the beta functions, as we will see.

The DeWitt coefficients a_j are redefined by consistency with the adiabatic orders, $\bar{a}_0(x) = 1, \bar{a}_1(x) = a_1(x) + \mu^2, \bar{a}_2(x) = a_2(x) + a_1(x)\mu^2 + \frac{1}{2}\mu^4$, and renormalization is now performed by taking the difference $L_{\rm ren}(\mu) = L_{\rm eff} - L_{\rm div}(\mu)$, as for the standard situation with $\mu = 0$, (7)

$$L_{\rm ren}(\mu) = \int_0^\infty ds \left[\frac{e^{-im^2 s}}{is} \langle x, s | x, 0 \rangle - \frac{i}{2(4\pi)^2} \sum_{j=0}^{2} \bar{a}_j(x) \frac{e^{-is(m^2+\mu^2)}}{(is)^{-j+3}} \right] . \qquad (8)$$

We note that the renormalized one-loop Lagrangian depends now on μ. This dependece in the arbitrary parameter μ has to be compensated by a running of the couplings of the background Lagrangian, thus the physical one-loop renormalized Lagrangian $L_{\rm phys} = L_{\rm B}(\mu) + L_{\rm ren}(\mu)$ is μ-independent, where $L_{\rm B}(\mu)$ refers to the background Lagrangian.

2.1. *Running of the coupling constants and decoupling*

The background Lagrangian required for renormalization is given by

$$L_{\rm B} = L_{\rm grav} + \frac{1}{2} Z \nabla^\mu \phi \nabla_\mu \phi - \frac{M^2}{2} Z \phi^2 - \frac{\xi_\phi}{2} R Z \phi^2 - \frac{\lambda}{4!} Z^2 \phi^4 + \gamma_1 \Box Z \phi^2 , \qquad (9)$$

where

$$L_{\rm grav} = -\Lambda + \frac{1}{2}\kappa R + \alpha_1 R^2 + \alpha_2 R_{\mu\nu} R^{\mu\nu} + \alpha_3 R_{\mu\nu\alpha\beta} R^{\mu\nu\alpha\beta} + \alpha_4 \Box R . \qquad (10)$$

We have defined $\kappa = 1/8\pi G$. The new terms are required to absorb the divergences of the one-loop correction. The coupling Z will not receive any contribution from the scalar quantum fluctuations, therefore we can canonically normalize it to 1. The remaining couplings $\lambda(\mu), \kappa(\mu), \alpha_i(\mu), M(\mu)$, etc will inherit a dependence on the mass scale μ.

The beta functions and the running couplings are built from the renormalization process, therefore they get only contributions from the divergent terms. For this reason, it is enough to approximate (8) with the first three terms of the asymptotic expansion for the heat kernel.

$$L_{\rm ren}(\mu) \approx \frac{i}{2(4\pi)^2} \int_0^\infty \frac{ds}{s^3} \Big\{ e^{-im^2 s} \left[1 + (is) a_1(x) + (is)^2 a_2(x) \right] - e^{-is(m^2+\mu^2)} \left[1 + (is)\bar{a}_1(x) + (is)^2 \bar{a}_2(x) \right] \Big\} . \qquad (11)$$

This is a finite integral that can now be computed. Its result depends on the DeWitt coeficients $a_0(x)$, $a_1(x)$ and $a_2(x)$ and also with the arbitrary μ parameter. Requiring that the physical one-loop renormalized Lagrangian $L_{\rm phys} = L_{\rm B}(\mu) + L_{\rm ren}(\mu)$ has to be μ-independent, leads to the running of the couplings and the beta functions.

$$\frac{dL_{\rm phys}}{d\mu} = 0 \quad \rightarrow \quad \beta_i \frac{\partial L_B}{\partial q_i} = -\mu \frac{\partial L_{\rm ren}}{\partial \mu} , \qquad (12)$$

where q_i refers to all the parameters of the Lagrangian and $\beta_i = \mu \frac{\partial q_i}{\partial \mu}$. A representative of the beta functions that we obtain are

$$\beta_\lambda = \frac{3h^4}{4\pi^2}\frac{\mu^2}{m^2+\mu^2} \qquad \beta_\Lambda = \frac{1}{32\pi^2}\frac{\mu^6}{m^2+\mu^2}$$
$$\beta_\kappa = \frac{\bar{\xi}}{8\pi^2}\frac{\mu^4}{m^2+\mu^2} \qquad \beta_{M^2} = -\frac{h^2}{8\pi^2}\frac{\mu^4}{m^2+\mu^2}\ , \tag{13}$$

where we have defined $\bar{\xi} = \left(\xi - \frac{1}{6}\right)$. The rest of beta functions can be found in Appendix A. Several remarks are worth of mention in these results. For the dimensionless parameters, like $\lambda(\mu)$, we obtain a factor of the form $\mu^2/(m^2+\mu^2)$, this factor also arises in the hierarchy of beta functions in the Wilsonian renormalization approach for a scalar field theory.[38] Analyzing this factor it is easy to see that for $m^2 \gg \mu^2$ the dimensionless beta functions decouple as expected in the infrared regime. Moreover for $\mu^2 \gg m^2$ the ultraviolet regime is recovered as expected from dimensional regularization with MS (minimal subtraction).[33] Another important feature concerns the dimensional couplings. For the Newton and cosmological constants we recover the same result as in the free field theory. Furthermore, all the dimensional couplings also decouple when $m^2 \gg \mu^2$.

3. Renormalization for Dirac fields

In this section we consider a quantized Dirac field ψ coupled via Yukawa interaction $g_Y \phi \bar{\psi}\psi$ with a classical scalar background ϕ. The action is given by

$$S = \int d^4x\sqrt{-g}\left(-\Lambda + \frac{R}{16\pi G} + \bar{\psi}\left(i\gamma^\mu\nabla_\mu - m\right)\psi - g_Y\phi\bar{\psi}\psi + \frac{1}{2}\nabla^\mu\phi\nabla_\mu\phi - V(\phi)\right), \tag{14}$$

where the covariant derivative ∇_μ acting on the Dirac field is defined as the ordinary derivative plus the spin connection term. $\gamma^\mu(x)$ are the curved space Dirac matrices $\gamma^\mu(x) = e_a{}^\mu\gamma^a$, defined in terms of the usual Dirac matrices in Minkowski space γ^a and the vierbein $e_a{}^\mu$.

In order to build the DeWitt-Schwinger expansion one needs the Klein-Gordon equation for the Dirac field

$$(\Box_x + m^2 + Q)G_{\rm F}(x,x') = -|g(x)|^{-1/2}\delta(x-x')\ . \tag{15}$$

Consequently, the one-loop effective action takes the form $S^{(1)}_{\rm eff} = \frac{1}{2}i\,{\rm Tr}\log(-G_F)$. One can expand the heat kernel in the proper time asymptotic series as for the scalar field (4) and make use of the same coefficients (6). In this case Q is given by

$$Q(x) = \frac{1}{4}R(x) + ig_Y\gamma^\mu\nabla_\mu\phi(x) + g_Y^2\phi^2(x) + 2g_Y m\phi(x)\ . \tag{16}$$

It is important to stress the appearance of the last term in the above expression which is proportional to m. This contrast with the obtained expression for Q in the scalar case ($Q = \xi R + h^2\phi^2$). Generically, all DeWitt coefficients a_n (or $\bar{a}_n$) are local geometrical quantities independent of the mass of the field. The Yukawa interaction for Dirac fermions introduces a mass-dependent term in the expression for $Q(x)$. This term will be the responsible of the violation of the decoupling characteristic for the background scalar mass parameter.

As in the previous section one gets the expression for the subtraction terms with the asymptotic expansion

$$L_{\rm div}(\mu) = \frac{-i}{2(4\pi)^2}\sum_{j=0}^{2}\operatorname{tr}\bar{a}_j(x)\int_0^\infty e^{-is(m^2+\mu^2)}(is)^{j-3}ds\ . \tag{17}$$

The main difference with the scalar case is that one needs to take into account the trace of the spinor indices acting on the coefficients $\operatorname{tr}\bar{a}_j(x)$. We still have the modified DeWitt coefficients $\bar{a}_0(x) = 1$, $\bar{a}_1(x) = a_1(x) + \mu^2$, and $\bar{a}_2(x) = a_2(x) + \left(\frac{1}{6}R - Q\right)\mu^2 + \frac{1}{2}\mu^4$ related to the DeWitt coefficients (6) but now with Q given by (16) and $W_{\mu\nu} = [\nabla_\mu, \nabla_\nu] = -\frac{1}{8}R_{\mu\nu ab}\left[\gamma^a, \gamma^b\right]$.

3.1. *Running of the coupling constant and decoupling*

The background Lagrangian terms are required by renormalization in order to absorb the divergent terms coming from the one-loop correction (17)

$$\begin{aligned} L_{\rm B} = {} & L_{\rm grav} + \frac{1}{2}Z\nabla^\mu\phi\nabla_\mu\phi - \frac{M^2}{2}Z\phi^2 - \frac{\xi}{2}RZ\phi^2 - \tau Z^{1/2}\phi - \frac{\eta}{3!}Z^{3/2}\phi^3 \\ & - \frac{\lambda}{4!}Z^2\phi^4 - \xi_1 RZ^{1/2}\phi + \gamma_1\Box Z\phi^2 + \gamma_2\Box Z^{1/2}\phi\ , \end{aligned} \tag{18}$$

where $L_{\rm grav}$ was given in (10). In the Dirac case, Z gets a contribution from the quantum fluctuations of the Dirac field. Therefore, it has a running that can be related to a running of the field ϕ by a reparametrization. We write $Z = 1 + \delta Z$ as usual, to take into account canonical normalization and the one-loop correction. For simplicity, we introduce new primed couplings to absorb Z, except for the kinetic term, where we leave Z explicitly

$$\frac{1}{2}Z\nabla^\mu\phi\nabla_\mu\phi - \frac{M'^2}{2}\phi^2 - \frac{\xi'}{2}R\phi^2 - \tau'\phi - \frac{\eta'}{3!}\phi^3 - \frac{\lambda'}{4!}\phi^4 - \xi_1' R\phi + \gamma_1'\Box\phi^2 + \gamma_2'\Box\phi\ . \tag{19}$$

As for the scalars, we just need to consider the divergent part of the one-loop effective action (11) to compute the running of the parameters. Again, we impose that the physical one-loop renormalized Lagrangian $L_{\rm phys} = L_{\rm B}(\mu) + L_{\rm ren}(\mu)$ must be independent of the value of μ. Therefore considering (12) for this background Lagrangian we can obtain the beta functions for the primed parameters. By direct differentiation and keeping one-loop order $\mathcal{O}(\hbar)$, it is straightforward to obtain the

beta functions of the unprimed original couplings

$$\begin{aligned}
\beta_{M^2} &= \beta_{M'^2} - M^2\beta_Z & \beta_\xi &= \beta_{\xi'} - \xi\beta_Z \\
\beta_{\xi_1} &= \beta_{\xi_1'} - \frac{1}{2}\xi_1\beta_Z & \beta_\tau &= \beta_{\tau'} - \frac{\tau}{2}\beta_Z \\
\beta_\eta &= \beta_{\eta'} - \frac{3}{2}\eta\beta_Z & \beta_\lambda &= \beta_{\lambda'} - 2\lambda\beta_Z \\
\beta_{\gamma_1} &= \beta_{\gamma_1'} - \gamma_1\beta_Z & \beta_{\gamma_2} &= \beta_{\gamma_2'} - \frac{1}{2}\gamma_2\beta_Z \ .
\end{aligned}$$

The result for all the beta functions can be seen in Appendix A. Let us analyze the different regimes of the scalar wave function Z as a representative of the dimensionless parameters.

$$\beta_Z = -\frac{g_Y^2}{4\pi^2}\frac{\mu^2}{m^2+\mu^2} \ . \tag{20}$$

In the ultraviolet regime, $\mu \gg m$ we recover the result from dimensional regularization with MS.[33,34]

$$\beta_Z = -\frac{g_Y^2}{4\pi^2}\frac{\mu^2}{m^2+\mu^2} \to_{\mu\gg m} -\frac{g_Y^2}{4\pi^2} \ , \tag{21}$$

while for the infrared regime, $\mu \ll m$, we find decoupling

$$\beta_Z = -\frac{g_Y^2}{4\pi^2}\frac{\mu^2}{m^2+\mu^2} \to_{\mu\ll m} -\frac{g_Y^2}{4\pi^2}\frac{\mu^2}{m^2} \ . \tag{22}$$

The other beta functions for the dimensionless parameters exhibit the same behaviour. Decoupling of massive fields is manifested in the infrared regime and the ultraviolet regime agrees with the results of dimensional regularization with MS.[33,34]

Things are more involved for the dimensional constants. We observe different behaviours with the parameter μ. For example for the couplings $\Lambda(\mu)$, $\kappa(\mu)$ and $M'^2(\mu)$ we get

$$\begin{aligned}
\beta_\Lambda &= -\frac{1}{8\pi^2}\frac{\mu^6}{m^2+\mu^2} & \beta_\kappa &= -\frac{1}{24\pi^2}\frac{\mu^4}{m^2+\mu^2} \\
\beta_{M^2} &= \frac{g_Y^2}{8\pi^2}\frac{\mu^2}{m^2+\mu^2}\left(+4\mu^2 - 8m^2 + 2M^2\right) \ .
\end{aligned} \tag{23}$$

A common feature is that decoupling appears when $m^2 \gg \mu^2$ for all the dimensional couplings except for the background mass parameter M^2. In this case the beta function essentially reproduces the value obtained via dimensional regularization with MS times a factor of order μ^2/m^2. The origin of the term proportional to $-8m^2$ can be retrieved from the term $2g_Y m\phi$ in Q. This can be linked to the fact that when building the DeWitt-Schwinger expansion all the mass dependence is assumed to be encoded in the exponential term[39] in the form m^2 and this expansion does not work properly if Q inherits a mass dependence. The latter result shows that finding decoupling for all the coupling constants, of a given theory, although it is

crucial to define a cosmic infrared regime, it is indeed a nontrivial task, as already emphasized in.[25]

Finally it is worth showing the finite expression for the running of the Newton gravitational constant G, the cosmological constant Λ and the scalar mass term M'^2 coming from the Dirac field at two different scales μ and μ_0.

$$\Lambda(\mu) = \Lambda_0 - \frac{1}{32\pi^2}\left((\mu^4-\mu_0^4) - 2m^2(\mu^2-\mu_0^2) + 2m^4\log\left(\frac{m^2+\mu^2}{m^2+\mu_0^2}\right)\right), \tag{24}$$

$$G(\mu) = \frac{G_0}{1-\frac{G_0}{6\pi}\left(\mu^2-\mu_0^2 - m^2\log\left(\frac{m^2+\mu^2}{m^2+\mu_0^2}\right)\right)}\ , \tag{25}$$

$$M'^2(\mu) = M_0'^2 + \frac{g_Y^2}{4\pi^2}\left((\mu^2-\mu_0^2) - 3m^2\log\left(\frac{m^2+\mu^2}{m^2+\mu_0^2}\right)\right), \tag{26}$$

where G_0, Λ_0 and $M_0'^2$ are the parameters at the scale μ_0. Note the appearance of μ^4 and μ^2 terms. In more conventional approaches only the logarithmic terms are present. However these non-logarithmic terms can be traced to the non trivial quartic and quadratic divergences and are indeed responsible of the appearance of decoupling. Expanding $\Lambda(\mu)$ and $G(\mu)$ for $\mu^2 \gg m^2$ one can check that the runnings are suppressed by a factor μ^6/m^2 and μ^4/m^2. However for $M'^2(\mu)$ we still get a non suppressed term proportional to μ^2.

4. Conclusions and final comments

We have considered the one-loop effective action for a quantized scalar field and Dirac field coupled to a background scalar field and gravity. Using the upgraded DeWitt-Schwinger subtraction scheme we have renormalized the theory and computed the beta functions for all the parameters. As a remarkable result, for the dimensionless couplings we obtain the beta functions that satisfy both ultraviolet and infrared regimes. In the ultraviolet regime we recover the beta function from MS scheme. In the infrared regime the beta functions explicitly exhibit the decoupling property. For the dimensional parameters new μ^4 and μ^2 terms appear in the runnings. These terms signal the presence of quadratic and quartic divergences and are indeed the responsible for the decoupling in the running couplings. Therefore, the obtained beta functions of the dimensional parameters exhibit the property of decoupling in the low energy regime, including the Newton's and cosmological constant. The exception is for the contribution of the Dirac field to the scalar mass parameter. As stress before the reason is localized in the linear term $2g_y m\phi$ in Q.

Appendix A

The obtained beta functions for the scalar one-loop correction are

$$\begin{aligned}
\beta_{\xi_\phi} &= \frac{h^2\bar{\xi}}{8\pi^2}\frac{\mu^2}{m^2+\mu^2} & \beta_{\alpha_1} &= -\frac{\bar{\xi}^2}{32\pi^2}\frac{\mu^2}{m^2+\mu^2}\\
\beta_{\alpha_4} &= -\frac{\xi-\frac{1}{5}}{96\pi^2}\frac{\mu^2}{m^2+\mu^2} & \beta_{\alpha_2} &= \frac{1}{2880\pi^2}\frac{\mu^2}{m^2+\mu^2}\\
\beta_{\alpha_3} &= -\frac{1}{2880\pi^2}\frac{\mu^2}{m^2+\mu^2} & \beta\gamma_1 &= -\frac{h^2}{96\pi^2}\frac{\mu^2}{m^2+\mu^2}\\
\beta_\lambda &= \frac{3h^4}{4\pi^2}\frac{\mu^2}{m^2+\mu^2} & \beta_\Lambda &= \frac{1}{32\pi^2}\frac{\mu^6}{m^2+\mu^2}\\
\beta_\kappa &= \frac{\bar{\xi}}{8\pi^2}\frac{\mu^4}{m^2+\mu^2} & \beta_{M^2} &= -\frac{h^2}{8\pi^2}\frac{\mu^4}{m^2+\mu^2}\ .
\end{aligned} \tag{A.1}$$

Dimensionless beta functions for the Dirac field are:

$$\begin{aligned}
\beta_Z &= -\frac{g_Y^2}{4\pi^2}\frac{\mu^2}{m^2+\mu^2}\\
\beta_\xi &= -\frac{g_Y^2}{24\pi^2}\frac{\mu^2}{m^2+\mu^2}(1-6\xi) & \beta_\lambda &= -\frac{g_Y^2}{8\pi^2}\frac{\mu^2}{m^2+\mu^2}\left(24g_Y^2-4\lambda\right)\\
\beta_{\alpha_1} &= \frac{1}{1152\pi^2}\frac{\mu^2}{m^2+\mu^2} & \beta_{\alpha_2} &= -\frac{1}{720\pi^2}\frac{\mu^2}{m^2+\mu^2}\\
\beta_{\alpha_3} &= -\frac{7}{5760\pi^2}\frac{\mu^2}{m^2+\mu^2} & \beta_{\alpha_4} &= \frac{1}{480\pi^2}\frac{\mu^2}{m^2+\mu^2}\\
\beta_{\gamma_1} &= \frac{g_Y^2}{4\pi^2}\frac{\mu^2}{m^2+\mu^2}\left(\frac{1}{6}+\gamma_1\right) & \beta_{\gamma_2} &= \frac{g_Y}{8\pi^2}\frac{\mu^2}{m^2+\mu^2}\left(\frac{2}{3}m+\gamma_2\right)\ .
\end{aligned} \tag{A.2}$$

Dimensional beta functions for the Dirac field:

$$\begin{aligned}
\beta_\Lambda &= -\frac{1}{8\pi^2}\frac{\mu^6}{m^2+\mu^2} & \beta_{\xi_1} &= \frac{g_Y}{8\pi^2}\frac{\mu^2}{m^2+\mu^2}\left(-\frac{m}{3}+g_Y\xi_1\right)\\
\beta_\kappa &= -\frac{1}{24\pi^2}\frac{\mu^4}{m^2+\mu^2} & \beta_\tau &= -\frac{g_Y}{8\pi^2}\frac{\mu^2}{m^2+\mu^2}\left(4m\mu^2-\tau g_Y\right)\\
\beta_{M^2} &= \frac{g_Y^2}{8\pi^2}\frac{\mu^2}{m^2+\mu^2}\left(+4\mu^2-8m^2+2M^2\right) & \beta_\eta &= -\frac{g_Y^3}{8\pi^2}\frac{\mu^2}{m^2+\mu^2}\left(24g_Y m-3\eta\right)\ .
\end{aligned} \tag{A.3}$$

The evaporation of four-dimensional spherically symmetric black holes is presented in the framework of quantum field theory in curved spacetimes and semiclassical gravity. It is discussed how the evaporation process can be sourced by the presence of the trace anomaly of a massless, conformally coupled scalar field outside the apparent horizon of the black hole.

Keywords: Evaporation; black hole; trace anomaly; semiclassical gravity; Vaidya spacetime

1. Quantum fields in curved spacetimes

From the time of the discovery made by Hawking that black holes can emit radiation,[1,2] black hole evaporation has become of great interest in analyzing the interplay between matter and gravity. A theoretical framework where modelling black hole evaporation is represented by quantum field theory in curved spacetimes,[3] which consists of describing the propagation of a quantum field over a classical curved background. On one side, the background is assumed to be a four-dimensional globally hyperbolic spacetime $(\mathcal{M}, g)$, where $\mathcal{M}$ is a smooth manifold and g a Lorentzian metric with signature $(-,+,+,+)$. On the other side, the quantum field is the fundamental observable, which is viewed as an operator-valued distribution living in a $*$-algebra $\mathcal{A}(\mathcal{M})$. For a real, free Klein-Gordon field ϕ the $*$-algebra is generated by the set of linear smeared fields $\{\phi(f), f \in \mathcal{D}(\mathcal{M})\}$ satisfying the following relations:

$$\phi(Pf) = 0, \qquad \phi(f)^* = \phi(\bar{f}), \qquad [\phi(f), \phi(h)] = \mathrm{i}\Delta(f,h).$$

Here, $P = -\Box_g + m^2 + \xi R$ is the Klein-Gordon operator constructed from the d'Alambertian operator $\Box_g = g^{\mu\nu}\nabla_\mu\nabla_\nu$ on $(\mathcal{M}, g)$, and $\Delta = \Delta_R - \Delta_A$ is the causal propagator of the spacetime, which is defined as the difference between the unique retarded and advanced fundamental solutions of P. A generic quantum state ω is a linear, positive, normalized functional over $\mathcal{A}(\mathcal{M})$, and it is determined by the n-point functions

$$\omega_n(f_1, \dots, f_n) = \langle \phi(f_1) \dots \phi(f_n) \rangle_\omega \in \mathcal{D}'(\mathcal{M}^n).$$

Actually, for Gaussian pure states it is sufficient to known the kernel of the two-point function $\omega_2(x', x) = \langle \phi(x')\phi(x) \rangle_\omega$.

Different from the flat case, where the Poincaré invariance selects a vacuum state uniquely as preferred reference state, in a curved spacetime there is not in principle a preferred notion of "vacuum" dictated by the symmetries of the spacetime. However, a guiding principle to select physically reasonable states in curved spacetimes is that Wick normal-ordered fields like $:\phi^2:$ and $:T_{\mu\nu}:$ should acquire finite expectation values when evaluated on ω. In globally hyperbolic spacetimes, the set of Hadamard states represents the right class where computing normal-ordered fields, because they share the same ultraviolet singular structure of the Minkowski vacuum two-point function $\langle 0|\phi(x')\phi(x)|0\rangle$. Given $\sigma(x', x)$ the one half of the signed geodesic distance between x' and x, the two-point function of a Hadamard state is always locally of the form

$$\omega_2(x', x) = \frac{1}{8\pi^2}\left(\mathscr{H}_{0^+}(x', x) + w(x', x)\right).$$

Here,

$$\mathscr{H}_{0^+}(x', x) = \lim_{\varepsilon\to 0^+} \frac{u(x', x)}{\sigma_\varepsilon} + \sum_{n\geq 0} v_n(x', x)\sigma(x', x)^n \log\left(\frac{\sigma_\varepsilon}{\mu^2}\right) \tag{1}$$

is the universal singularity called Hadamard parametrix viewed in the distributional sense, where $\sigma_\varepsilon(x', x) = \sigma(x', x) + \mathrm{i}\epsilon(t(x') - t(x))$, t is any time function and $\mu > 0$ is a length scale. The coefficients $u(x', x)$, $v_n(x', x)$ are real-valued bi-scalars fixed by the geometry and the equation of motion, while $w(x', x)$ characterizes the state and must be chosen in such a way that ω_2 is a bi-solution of the Klein-Gordon equation. The Hadamard point-splitting regularization consists of subtracting the divergences contained in $\mathscr{H}_{0^+}(x', x)$ before computing the coinciding point limits: it generalizes the normal-ordering prescription in the flat spacetime, and it is also local and covariant, because only local geometry enters in the subtraction. This procedure, and more generally any prescription to obtain Wick observables, is always unique up to a fixed combination of local terms depending on the mass and on the curvature, whose coefficients represent the renormalization freedom of the quantum theory.[4,5]

1.1. *Semiclassical gravity, the quantum stress-energy tensor, and the trace anomaly*

Strictly related to a formulation of quantum fields propagating in curved backgrounds is the semiclassical theory of gravity, which aims to analyze the back-reaction of quantum fields on the spacetime geometry using the semiclassical Einstein equations

$$G_{\mu\nu} = 8\pi \langle :T_{\mu\nu}: \rangle_\omega \tag{2}$$

in units convention $G = c = \hbar = 1$. In this equations, the classical Einstein tensor is equated to the renormalized quantum stress-energy tensor evaluated in a certain quantum state ω. Any pair formed by a spacetime and a quantum state satisfying

these equations constitutes a solution in semiclassical gravity: such a solution models a curved spacetime which incorporates quantum effects due to the propagation of the matter field, and it is expected to describe physical phenomena where the interplay between quantum matter and curvature becomes significant, like in the early Universe or in the vicinity of black holes. On the other hand, any semiclassical model represents an approximation of a more fundamental theory of quantum gravity, and thus it should be only valid in a regime where quantum gravity effects are negligible, and when fluctuations of the stress-energy tensor $:T_{\mu\nu}:$ are small.

A conserved quantum stress-energy tensor which can enter Eqs. (2) can be constructed in perturbative interacting quantum field theory in curved spacetimes according to the Hadamard point-splitting procedure.[5–7] For the stress-energy tensor of a free Klein-Gordon field

$$T_{\mu\nu} = \nabla_\mu\phi\nabla_\mu\phi - \frac{1}{2}g_{\mu\nu}\left(\nabla_\rho\phi\nabla^\rho\phi + m^2\phi^2\right) + \xi\left(G_{\mu\nu}\phi^2 - \nabla_\mu\nabla_\nu\phi^2 + g_{\mu\nu}\nabla_\rho\nabla^\rho\phi^2\right),$$

the Hadamard renormalization procedure yields the following expectation value:

$$\langle :T_{\mu\nu}: \rangle_\omega (x) = \lim_{x'\to x} D_{\mu\nu} w(x', x),$$

where

$$\begin{aligned} D_{\mu\nu} =& (1-2\xi) g_\mu^{\mu'} \nabla_{\mu'}\nabla_\nu - 2\xi\nabla_\mu\nabla_\nu + \xi G_{\mu\nu} + \\ & g_{\mu\nu}\left\{2\xi\Box_g + \left(2\xi - \frac{1}{2}\right) g_\rho^{\rho'}\nabla_{\rho'}\nabla^\rho - \frac{1}{2}m^2\right\} + \frac{1}{3}g_{\mu\nu}P \end{aligned}$$

is the bi-differential operator which realizes the point-splitting of $T_{\mu\nu}$, and $w(x', x)$ is the smooth part of the Hadamard state ω. In this expression, unprimed and primed indices denote covariant derivatives in the points x and x', respectively, while $g_\nu^{\nu'}$ is the bitensor of parallel transport. The last term proportional to $g_{\mu\nu}$, which vanishes in the classical case, must be added to obtain $\nabla^\mu \langle :T_{\mu\nu}: \rangle_\omega (x) = 0$. However, any construction of a covariantly conserved expectation value of $:T_{\mu\nu}:$ leads to the violation of the classical conformal invariance of $T_{\mu\nu}$, and it gives rise to the so-called trace anomaly; namely, the trace of the quantum stress-energy tensor does not vanish for a massless, conformally coupled field, i.e., when $m = 0$ and $\xi = 1/6$, different from its classical counterpart. This anomalous trace does not depend on the choice of the quantum state, but it is a local contribution depending on the geometry and on the linear equation of motion of the matter field. In the Hadamard point-splitting regularization scheme and for a free scalar field ϕ, it is proportional to the Hadamard coefficient v_1 evaluated in the coinciding limit, and it reads in four dimensions as

$$\langle :T_\rho{}^\rho: \rangle_\omega = \lambda\left(C_{\alpha\beta\gamma\delta}C^{\alpha\beta\gamma\delta} + R_{\mu\nu}R^{\mu\nu} - \frac{1}{3}R^2\right), \qquad \lambda = \frac{1}{2880\pi^2}, \tag{3}$$

where $C_{\alpha\beta\gamma\delta}$ is the Weyl tensor, $R_{\mu\nu}$ is the Ricci tensor and R is the Ricci scalar. The $\Box_g R$ usually appearing in $\langle :T_\rho{}^\rho: \rangle_\omega$ was removed by a judicious choice of the

renormalization constants, according to the previous discussion about local and covariant Wick observables in curved spacetimes. In the case of $\langle{:}T_\rho{}^\rho{:}\rangle_\omega$, the renormalization scalar freedom is[5]

$$Q = \tilde{\beta}_1 m^4 + \tilde{\beta}_2 m^2 R + \tilde{\beta}_3 R^2 + \tilde{\beta}_4 \Box_g R,$$

where $\tilde{\beta}_i \in \mathbb{R}$ are renormalization constants. Hence, in some special cases like the massless, conformally coupled field, the higher-order derivative term proportional to $\Box_g R$ can be always cancelled by choosing properly $\tilde{\beta}_4$, thus meeting the requirement that curvature terms do not contain non-classical higher order derivatives of the metric.[8]

2. Evaporation of spherically symmetric black holes

A model of evaporation of black holes which incorporates the back-reaction of the matter fields on the geometry can be fully developed in the framework of four-dimensional spherically symmetric spacetimes. In this class of geometries, invariants like the mass of the black hole and the area of the horizon can be provided thanks to the spherical symmetry[9]: the area of each two-sphere is $\mathcal{A} = 4\pi r^2$, where r is the radius, while the mass

$$m = \frac{r}{2}\left(1 - \nabla^\rho r \nabla_\rho r\right)$$

represents the Misner-Sharp energy enclosed inside the sphere. The metric of every spherically symmetric spacetime can be always represented in double-null coordinates with respect to the null normal directions ∂_V and ∂_U as

$$\mathrm{d}s^2 = -2A(V,U)\mathrm{d}V\mathrm{d}U + r^2(V,U)\mathrm{d}\Omega, \tag{4}$$

where $\mathrm{d}\Omega = \mathrm{d}\theta^2 + \sin^2\theta \mathrm{d}\varphi^2$ denotes the line-element of the two-sphere of unit radius $\mathbb{S}^2$. The orientation of the spacetime can be fixed in such a way that $A(V,U) > 0$ and at spatial infinity $\partial_V r > 0$, $\partial_U r < 0$. To study evaporation, another convenient choice of parametrization is the Bardeen-Vaidya metric[10]

$$\mathrm{d}s^2 = -\mathrm{e}^{2\Psi(v,r)}\left(1 - \frac{2m(v,r)}{r}\right)\mathrm{d}v^2 + 2\mathrm{e}^{\Psi(v,r)}\mathrm{d}v\mathrm{d}r + r^2\mathrm{d}\Omega, \tag{5}$$

where v denotes the advanced time coordinate and parametrizes any ingoing radial null geodesic.

The notion of horizon in spherically symmetric black holes is encoded in the idea that no light rays can escape from this hypersurface, whereas they can fall inside. Namely, it is a future outer local trapping horizon.[11] To formulate this idea on mathematical grounds, one introduces a pair of null radial geodesic congruences with respect to the outgoing and ingoing directions ∂_V and ∂_U, respectively, and the relative expansion parameters

$$\theta_+ = \frac{2}{Ar}\partial_V r, \qquad \theta_- = \frac{2}{Ar}\partial_U r.$$

Each expansion parameter measures the rate of variation of the cross-sectional area of the geodesic congruence: $\theta_{\pm} = A^{-1}\partial_{V,U}\log(\mathcal{A})$, and it determines if the congruence is expanding or focusing along that null direction. Thus, the apparent horizon of a spherically symmetric black hole is defined as a three-manifold $\mathcal{H}$ foliated by closed surfaces such that

$$\theta_+ \overset{\mathcal{H}}{=} 0, \qquad \theta_- \overset{\mathcal{H}}{<} 0, \qquad \partial_U\theta_+ \overset{\mathcal{H}}{<} 0, \tag{6}$$

and it is located in $\mathcal{H} : r - 2m = 0$ (the subscript $\mathcal{H}$ labels the evaluation on the apparent horizon). The third condition captures the property that this trapping horizon is outer and it is referred to a black hole. In coordinates (v, r), the hypersurface $\mathcal{H}$ is a one-dimensional line $r_{\mathcal{H}}(v)$ in the plane (v, r), and hence the mass of an evaporating black hole is defined by the relation

$$M(v) = m\left(v, r_{\mathcal{H}}(v)\right) = \frac{r_{\mathcal{H}}(v)}{2}. \tag{7}$$

On spherically symmetric black holes, the mechanism of evaporation can be described in terms of the variation of the mass

$$\Delta M = \int_{\delta\mathcal{H}} \mathrm{d}m, \tag{8}$$

along a small portion $\delta\mathcal{H}$ of the apparent horizon. In coordinates (v, r), $\delta\mathcal{H}$ corresponds to the line enclosed between two points $P = (v_P, r_{\mathcal{H}}(v_P))$ and $Q = (v_Q, r_{\mathcal{H}}(v_Q))$ in the (v, r) plane, and the dynamics of $M(v)$ is fully determined by the rate of evaporation $\dot{M}(v) = \partial_v M(v)$. If one considers a generic stress-energy tensor $T_{\mu\nu}$, then the evolution of $M(v)$ is governed by the vv-component of the (semiclassical) Einstein equations evaluated on $\mathcal{H}$, which reads

$$\dot{M}(v) = \mathcal{A}_{\mathcal{H}}(v)T_{vv}(v, r_{\mathcal{H}}(v)), \tag{9}$$

where $\dot{M}(v)$ and $\mathcal{A}_{\mathcal{H}} = 4\pi r_{\mathcal{H}}^2$ denote the rate of evaporation and the area of the horizon, respectively. Thus,

$$\Delta M = 4\pi \int_{v_P}^{v_Q} \frac{M}{\kappa} T_{vv}(r_{\mathcal{H}})\mathrm{d}v. \tag{10}$$

As $T_{vv} \overset{\mathcal{H}}{=} T_{VV}$, both $\dot{M}(v)$ and ΔM depend on the ingoing flux of matter which is falling inside the black hole from the horizon. Whenever quantum matter is involved in the back-reaction process, it may happen that the quantum stress-energy tensor $\langle{:}T_{\mu\nu}{:}\rangle_\omega$ violates the classical null energy condition on the horizon, and hence the ingoing quantum component $\langle{:}T_{VV}{:}\rangle_\omega$ may be negative on $\delta\mathcal{H}$. In the end, the presence of a negative ingoing flux on the horizon makes the black hole mass to evaporate with a negative rate $\dot{M}(v) < 0$.

2.1. *The static black hole*

The vacuum spherically symmetric spacetime is the Schwarzschild solution of the Einstein equations according to Birkhoff's theorem, and it describes a static spherical black hole of constant mass M.[12] A double-null parametrization for arbitrary $U, V > 0$ is the maximally extension of the Schwarzschild eternal black hole in the so-called Kruskal-Szekeres coordinates

$$\mathrm{d}s^2 = -\frac{32M^3}{r}\mathrm{e}^{-r/2M}\mathrm{d}V\mathrm{d}U + r^2(V,U)\mathrm{d}\Omega,$$

where $r(V,U)$ is implicitly defined by

$$UV = \left(1 - \frac{r}{2M}\right)\mathrm{e}^{r/2M}.$$

On the other hand, the Bardeen-Vaidya metric corresponds to the advanced Eddington-Finkelstein coordinates, with $\Psi(v,r) = 0$ and $m(v,r) = M$.

The static symmetry of the Schwarzschild spacetime reflects the existence of a Killing vector field $\xi = \frac{1}{4M}(V\partial_V - U\partial_U)$, which is unit timelike at infinity and it is hypersurface orthogonal. Due to the static symmetry, the apparent horizon coincides with the null event horizon of the black hole, which is located in the Schwarzschild radius $r = 2M$ (see Figure 1[a]). The surface gravity of the black hole is defined by the equation $\nabla^\mu\xi^2 = -2\kappa\xi^\mu$ and it constant along each null generator of ξ. Physically, the surface gravity represents the gravitational acceleration detected along the black hole horizon, and it is strictly positive on the event horizon.

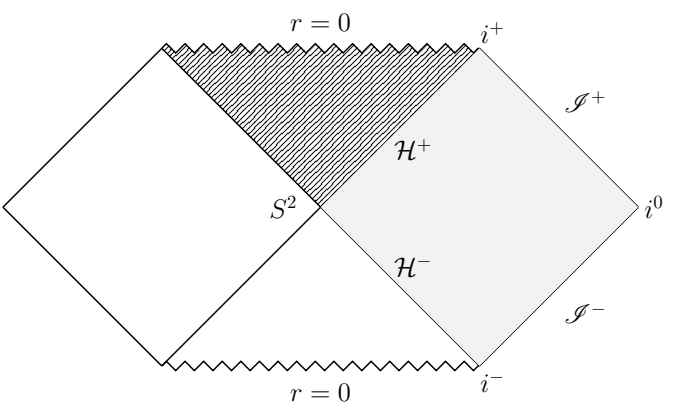

Fig. 1. Penrose diagram of the maximally extended Schwarzschild spacetime. The bifurcated Killing horizon $\mathcal{H} = \mathcal{H}^+ \cup \mathcal{H}^-$ associated to ξ is composed by two null surfaces $\mathcal{H}^\pm$ located in $U = 0$ and $V = 0$, respectively. The event horizon $\mathcal{H}^+$ corresponds to the future branch of $\mathcal{H}$, and it separates the outer region (grey region) from the black hole region (dashed region); the null surfaces intersects each other in the sphere of bifurcation S^2 located in $U = 0$, $V = 0$.

[a]Penrose diagrams were made in TikZ and are based on the Latex code posted in StackExchange.[13]

According to Hawking's works, a static black hole can emits thermal radiation at infinity in form of a flux of quantum particles, if the back-reaction is not taken into account and after assuming a vacuum state in the asymptotic past. The temperature of the radiation is the so-called Hawking temperature and it is proportional to the surface gravity of the black hole: in the units convention adopted in this paper it reads

$$T_H = \frac{\kappa}{2\pi} = \frac{1}{8\pi k_B M},$$

with k_B being the Boltzmann constant. The correspondence between the temperature of the radiation and the surface gravity lets to interpret the first law of black hole mechanics

$$\mathrm{d}M = \frac{\kappa}{8\pi}\mathrm{d}\mathcal{A} + \Omega \mathrm{d}J$$

from a thermodynamic point of view, with M and $\mathcal{A}/4$ playing the role of energy and entropy of the black hole, respectively. More recently,[14] it was shown that in case of a static black hole formed in a gravitational collapse, the Hawking radiation with temperature T_H always appears at future infinity whenever the state ω is a Hadamard state approaching the ground state near spatial infinity; for instance, in the case of the Unruh state,[15,16] which is regular on the horizon and respects the spherical symmetries of the spacetime.

Thus, the power of the radiation emitted from the black hole at future infinity is regarded as describing the evaporation of the black hole, because it can be instantaneously equated to the rate of loss of mass in the adiabatic approximation, namely neglecting how the spacetime is dynamically changing during the evaporation. Starting from this assumption, the negative ingoing flux on the horizon, that is, $\langle{:}T_{vv}{:}\rangle_\omega \overset{\mathcal{H}}{=} \langle{:}T_{VV}{:}\rangle_\omega$, can be related to the positive outgoing flux $\langle{:}T_{uu}{:}\rangle_\omega$ detected at infinity, where u denotes the retarded Eddington-Finkelstein coordinate parametrizing outgoing null geodesics. In the Unruh state, it holds that

$$\frac{\dot{M}(v)}{4\pi} = \lim_{r\to r_{\mathcal{H}}} \left(\langle{:}T_{VV}{:}\rangle_\omega\, r^2\right) = -\lim_{r\to\infty} \left(\langle{:}T_{uu}{:}\rangle_\omega\, r^2\right) = -\frac{L_{\mathcal{H}}}{4\pi}, \tag{11}$$

where $L_{\mathcal{H}} > 0$ denotes the luminosity of the black hole, namely the radial flux of particles measured by a static observer at large distance from the black hole.[17] Indeed, Eq. (11) loses meaning outside the adiabatic approximation, since the rate $\dot{M}(v)$ always vanishes in case of constant mass. It turns out, in fact, that the Schwarzschild spacetime is never a solution of the semiclassical Einstein equations, and hence an eternal black hole cannot be in equilibrium with the back-reaction of any quantum matter field in the semiclassical approach.

2.2. *Dynamical black holes*

The direct correspondence given in Eq. (11) between the ingoing negative flux and the positive outgoing flux holds in Schwarzschild spacetime thanks to the existence

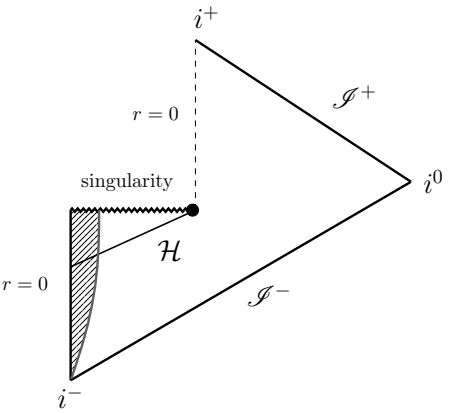

Fig. 2. Penrose diagram of a Schwarzschild gravitational collapse followed by evaporation and leaving an empty space at the end of the evolution. The black dot represents the end of the evaporation, and the dashed line denotes the new regular centre of the spacetime after the evaporation.[2]

of a global Killing field which is timelike outside the event horizon, but it is missing in arbitrary dynamical backgrounds. In this case, the mechanism of evaporation and the following emission of power radiated should be dealt separately as causally related processes: from one hand, evaporation is a local effect induced by the negative ingoing flux and affecting the horizon; on the other hand, the expected Hawking radiation is associated to the positive outgoing flux emitted to infinity, and it depends globally on the entire history of spacetime.

Moreover, the adiabatic approximation is unable to describe evaporations when the spacetime is treated with its full dynamics, since it does not give informations about the evolution of the apparent horizon. In this respect, the Penrose diagram shown in Figure 2 should be modified in case of dynamical backgrounds outside that approximation, because the dynamics of $\mathcal{H}$ depends sharply on the negative flux $\langle{:}T_{VV}{:}\rangle_\omega$, and the causal structure of the spacetime may be significantly modified in the back-reaction process. Conversely, a semiclassical model of evaporation should necessarily rely on the semiclassical Einstein equations (2) to study the variation of the mass $M(v)$ induced by the back-reaction of the quantum matter content, without further assumptions.

Contrary to Schwarzschild spacetimes modelling static black holes and event horizons, a general spherically symmetric spacetime describes a dynamical black hole, whose evolution is dictated by the dynamics of the apparent horizon (6). To define properties of spherically symmetric black holes like the surface gravity, there is a preferred choice of a vector field, which replaces the standard Killing vector field in stationary spacetimes. It is the Kodama vector[18] $K = g^{-1}(*_n \mathrm{d}r)$, where $*_n$ denotes the Hodge operator in the two-dimensional spacetime normal to the two-sphere. This vector is timelike in the region outside the horizon, it becomes lightlike on $\mathcal{H}$, and eventually it is spacelike in the interior of the black hole. It also reduces

to the Killing vector ξ in stationary spacetimes. Furthermore, it is divergenceless: $\nabla_\mu K^\mu = 0$, and it can be used to define conserved currents $T_{\mu\nu}K^\nu$ given any symmetric tensor $T_{\mu\nu}$ which respects the spherical symmetry. Finally, from the definition of K it holds that

$$\mathscr{L}_K K_\mu = K^\nu \left(\nabla_\nu K_\mu - \nabla_\mu K_\nu\right) \overset{\mathcal{H}}{=} \pm\kappa K_\mu, \tag{12}$$

where $\mathscr{L}_K$ denotes the Lie derivative along K, and

$$\kappa \doteq \frac{1}{2}\Box_n r, \tag{13}$$

where the d'Alambertian operator is evaluated in the two-dimensional normal spacetime. Namely, this quantity corresponds to the definition of the surface gravity for a dynamical black hole and it reduces to the standard one in the case of a Killing vector field. In particular, $\partial_U \theta_+ < 0$ implies that $\kappa > 0$ on $\mathcal{H}$.

In analogy with the static case, Hayward showed[9] that the four laws of black hole mechanics can be generalized in presence of spherical symmetry to apparent horizons using the properties of the Kodama vector and the definition of the surface gravity given in Eq. (13). In this class of spacetimes, the first law reads

$$m' = \frac{\kappa}{8\pi}\mathcal{A}' + wV', \tag{14}$$

where the prime denotes the derivative along the horizon, i.e., $f' = \ell \cdot \nabla f$, and ℓ is any tangent vector to $\mathcal{H}$. Here, the second contribution in the right-hand side represents the variation of the work done by the matter on the horizon, where $V = \frac{4}{3}\pi r^3$ and $w = A^{-1}T_{UV}$. Furthermore, the same thermodynamic interpretation already seen in the static case can be given in terms of the Kodama surface gravity, with $\kappa/2\pi$ playing the role of dynamical local temperature of the apparent horizon with respect to the time parameter defined of the Kodama vector. This correspondence was shown in the dynamical case by studying the tunnelling probability of quantum matter across apparent horizons using the Hamilton-Jacobi method,[19,20] and by analyzing the scaling limit of the Hadamard two-point function on such horizons.[21]

According the previous section, *cf.* Eqs. (9) and (10), evaporation of spherically symmetric black holes is fully determined by the ingoing flux located on the horizon. However, in the absence of further symmetries it is very challenging to evaluate the component $\langle{:}T_{VV}{:}\rangle_\omega$, and, more generally, the renormalized quantum stress-energy tensor $\langle{:}T_{\mu\nu}{:}\rangle_\omega$, in a state ω which was a vacuum state in the past. On the other hand, the variation of the mass of the black hole can be constrained by the matter-geometry content in the causal past and outside the black hole horizon.[22] This is accomplished by applying the divergence theorem (Stokes' theorem) to the currents J_r and J_k obtained by contracting the stress-energy tensor with the gradient ∇r and with the Kodama vector K, respectively. The domain over which the divergence theorem is spherically symmetric and it has the form $\mathrm{D} \times \mathbb{S}^2$, where D is a suitable region in the two-dimensional normal spacetime intersecting a portion of

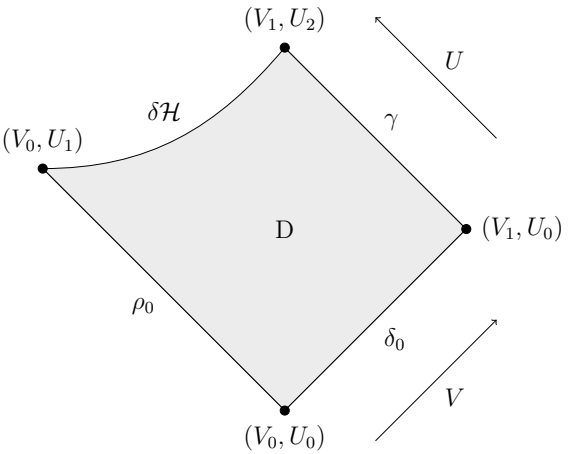

Fig. 3. Picture of the domain D. For spacelike $\delta\mathcal{H}$, $\mathrm{D} \times \mathbb{S}^2 = J^+((V_0, U_0) \times \mathbb{S}^2) \cap J^-(\delta\mathcal{H} \times \mathbb{S}^2)$, with $U_2 < U_1$. The points $P = (V_0, U_1)$ and $Q = (V_1, U_2)$ denote the extreme values of $\delta\mathcal{H}$ in the (V, U) plane. In describing evaporation, the initial conditions are posed on $S_0 = \{(V, U, \theta, \varphi) \in \mathcal{M} \mid V = V_0,\ U = U_0\}$ and on the curves ρ_0 and δ_0 of the boundary $\partial\mathrm{D}$.[22]

the apparent horizon. A representation of D for a spacelike portion of the horizon is pictured in Figure 3.

If one considers a stress-energy tensor $T_{\mu\nu}$ which respects the spherical symmetry and which satisfies vacuum-like initial condition at the boundary of $J^+(S_0)$, namely

$$T_{\mu\nu}(p) = 0, \qquad p \in \partial J^+(S_0), \tag{15}$$

then applying the divergence theorem to J_r yields

$$\Delta M = -\left(\mathcal{S} + \mathcal{W}\right), \tag{16}$$

where

$$\mathcal{S} = 2\pi \int_{\mathrm{D}} \nabla \cdot J_r \mathrm{d}V_{\mathrm{D}}, \tag{17}$$

$$\mathcal{W} = 4\pi \int_{\gamma} \frac{T_{UV} r^2}{A} (-\partial_U r) \mathrm{d}U. \tag{18}$$

Here, $\mathrm{d}V_{\mathrm{D}} \doteq A r^2 \mathrm{d}V \wedge \mathrm{d}U$ is the volume form on D in the (V, U) plane. Eq. (17) denotes the matter source inside the domain D which influences the variation of the mass, while Eq. (18) is related to the work done by the matter when evaluated on $\mathcal{H}$, in view of Hayward's first law (14). Moreover, applying the divergence theorem to J_K in spacetimes where $\mathcal{W} = 0$ yields

$$\left.\frac{\Delta M}{4\pi}\right|_{\mathcal{W}=0} = -\int_{\gamma} \frac{T_{UU} r^2}{A} \partial_V r \mathrm{d}U. \tag{19}$$

Namely, in the quantum case the variation of the mass is related to the outgoing flux $\langle{:}T_{UU}{:}\rangle_\omega$ across γ, which can interpreted as Hawking radiation sourced by $\mathcal{S}$ and emitted from the evaporating black hole to infinity. In this view, the relation (19) generalizes Eq. (11) to more general non-static, spherically symmetric black holes outside the adiabatic approximation.

2.3. *The trace anomaly as source of evaporation*

It is well known that the evaporation of a black hole, viewed as emission of Hawking radiation at infinity, can be ascribed to the presence of an anomalous trace in the stress-energy tensor of a quantum matter field in the vicinity of the horizon.[23–26] However, such analysis are often provided after making some approximations on the spacetime, like the adiabatic one. On the contrary, a full semiclassical approach to study the evaporation sourced by the trace anomaly should only rely on the semiclassical Einstein equations in four dimensions, without making further assumptions or referring to asymptotic effects which need global informations about the spacetime.

Based on the results presented in the previous section, the variation of the black hole mass can be related to the source term $\mathcal{S}$ given in Eq. (17), and to the boundary term $\mathcal{W}$ given in Eq. (18). Thus, it was proved[22] that the evaporation of a four-dimensional dynamical black hole can be induced by the trace anomaly (3) of a massless, conformally coupled scalar field affecting the horizon from the outside of the black hole, provided a weighted version of Eq. (16). This result is obtained using only the semiclassical Einstein equations (2), once the initial condition (15) is assumed on the state ω and a quantum averaged energy condition on $\langle{:}T_{UV}{:}\rangle_\omega$ is posed. Such a condition is of the form

$$\int_\gamma \frac{\langle{:}T_{UV}{:}\rangle_\omega\, r^2}{A} f(V,U) A \mathrm{d}U \geq 0, \tag{20}$$

where γ is one of the boundary hypersurface of the domain $\mathrm{D} \times \mathbb{S}^2$ (see Figure 3), and $f(V,U)$ is a certain strictly positive exponential function constructed from the geometry of the spacetime, whose role is to tame the contributions inside $\langle{:}T_\rho{}^\rho{:}\rangle_\omega$ which do not contribute to a negative variation of the mass. The form of the function f is similar to the ones entering usual quantum averaged weak energy conditions, which were shown to be valid both in flat and curved spacetimes for several values of the coupling-to-curvature parameter.[27]

In principle, it is difficult to verify if such an energy condition can be fulfilled by the quantum collapsing matter during the evaporation process, because the lack of a quantum state in spherically symmetric spacetimes which was a vacuum in the past prevents to evaluate $\langle{:}T_{\mu\nu}{:}\rangle_\omega$ on and outside the horizon. However, one can expect that this condition is satisfied in an approximate way by a background geometry which is not too different from the one obtained in a classical model of gravitational collapse. Indeed, classical solutions are approximately valid in semiclassical gravity,

because quantum corrections are usually small outside the horizon, and thus one can assume that solutions of the full semiclassical equations maintain their classical form outside the horizon. To provide a simple application, consider the Vaidya spacetime

$$\mathrm{d}s^2 = -\left(1 - \frac{2M(v)}{r}\right)\mathrm{d}v^2 + 2\mathrm{d}v\mathrm{d}r + r^2\mathrm{d}\Omega,$$

which describes a null radiating spherically symmetric star with time-dependent mass $M(v)$. If one supposes that the quantum state fulfils $\langle{:}T_{UV}{:}\rangle_\omega = 0$, namely it makes the above metric a solution of Eqs. (2), then the negative ingoing flux on the horizon induced by the anomalous trace (3) can be evaluated explicitly, and it reads

$$\langle{:}T_{VV}{:}\rangle_\omega \, r^2 \overset{\mathcal{H}}{=} -\frac{3\lambda}{40M(v)^2}.$$

Hence,

$$\dot{M}(v) = -\frac{3\pi\lambda}{10M(v)^2}, \qquad \frac{\mathrm{d}S_{\mathcal{H}}(v)}{\mathrm{d}v} = -\frac{12\pi^2\lambda}{5M(v)},$$

where $S_{\mathcal{H}} = \mathcal{A}_{\mathcal{H}}/4$ denotes the Wald-Kodama entropy.

3. Conclusions

The evaporation of four-dimensional spherically symmetric black holes in semiclassical gravity can be fully ascribed to the presence of a negative ingoing flux on the horizon, which determines the global behaviour of the decreasing mass of the black hole. Whereas the evaporation of any static black hole can be described directly in terms of Hawking radiation and black hole luminosity, for dynamical black holes the variation of the mass can be constrained by the quantum matter content outside and in the causal past of the black hole, without directly referring to any expected radiation detected at infinity. When conformally coupled quantum scalar fields are involved, the evaporation can be sourced by the trace anomaly of the quantum stress-energy tensor, assuming vacuum-like initial conditions in the past, and an auxiliary quantum energy condition outside the horizon. It is, however, very challenging to extend these results to more generic quantum matter contents, due to the difficulties in evaluating the renormalized stress-energy tensor in a quantum state. In order to overcome this issue, a semiclassical analysis which takes advantage of some quantum energy conditions similar to the one presented in Eq. (20) might be viable in the future.

On decay of the false Unruh vacuum

A. Shkerin

William I. Fine Theoretical Physics Institute, School of Physics and Astronomy, University of Minnesota, Minneapolis, MN 55455, USA
E-mail: ashkerin@umn.edu

We provide a method to calculate the rate of false vacuum decay induced by a black hole. The method uses complex tunneling solutions and consistently takes into account the structure of quantum vacuum in the black hole metric via boundary conditions. We illustrate the technique by computing the rate of decay of the Unruh vacuum in a toy two-dimensional model of a scalar field with inverted Liouville potential in a background of a dilaton black hole.

Keywords: Black holes; false vacuum decay; Unruh vacuum; quantum fields and gravity

1. Introduction and motivation

There has been significant interest recently in the problem of black hole catalysis of vacuum decay.[1–15] A part of the motivation driving these studies comes from the fact that the Standard Model electroweak vacuum may not be absolutely stable.[16–22] Requiring the lifetime of the vacuum exceed the age of the Universe puts constraints on the parameters of the Standard Model, of its possible extensions, and of systems and environments which catalyze vacuum decay, including black holes.[23]

The catalyzing effect of a black hole (BH) is two-fold. First, it is a local spacetime inhomogeneity. Hence, as for any impurity, one expects for the BH to facilitate nucleation of bubbles of true vacuum in its vicinity. Second, associated with BHs is the quantum vacuum effect manifesting itself as Hawking radiation. As any field excitation, this radiation is expected to increase the decay rate. For small enough BHs, the catalyzing effects due to curved geometry and quantum vacuum may be equally important.

In the semiclassical regime, the vacuum decay is described by a (complex) classical solution of field equations. The solution — bounce — saturates the amplitude of transition from the false to the true vacuum regions. It is important to note that the vacuum is defined not only by classical field expectation values but also by the state of quantum fluctuations around these values. Different false vacuum states reveal themselves through different boundary conditions imposed on the bounce.

It is well-known how to look for the bounce solution in equilibrium systems.[24–27] Realistic BHs, however, are not in thermal equilibrium with their environment. In particular, this is true for hypothetical small primordial BHs that could exist in the early Universe but are completely evaporated by now.[28] It is desirable to have an approach to vacuum decay that can handle such non-equilibrium systems as a hot isolated BH in a comparatively low energy background. This system is described

by the Unruh state.[29] In the Unruh vacuum, the BH emits Hawking radiation but does not receive anything from asymptotic infinity.

In this report, based on Ref. 30, we outline the recent progress made in the study of BH catalysis of false vacuum decay. In Sec. 2 we provide a general method to calculate the decay probability of a false vacuum state characterized by an arbitrary (Gaussian) density matrix. The method employs complex tunneling solutions and, when applied to a BH, allows one to discriminate between different vacuum states associated with the BH. In particular, it allows one to compute the rate of decay of the Unruh vacuum for which equilibrium methods are not applicable. In Sec. 3 we discuss the application of the method to a toy two-dimensional model of vacuum decay in the presence of a BH. Sec. 4 is dedicated to conclusions and outlook.

2. The method

To illustrate the method, we consider a real scalar field in the background of a dilaton BH in two dimensions.[31] The only region that is relevant for vacuum decay is the external (physical) patch of the BH spacetime.[30] It is convenient to introduce tortoise coordinates (t, x) covering this patch. Then the metric is read off from the line element

$$ds^2 = \Omega(x)(-dt^2 + dx^2) \,, \tag{1}$$

where the conformal factor takes the form

$$\Omega(x) = \frac{1}{1 + e^{-2\lambda x}} \,. \tag{2}$$

The parameter λ is related to the BH temperature $T_{\rm BH}$ as $\lambda = 2\pi T_{\rm BH}$. For the sake of brevity, we will refer to λ itself as temperature. The horizon is located at $x \to -\infty$. Near the horizon, the conformal factor behaves as $\Omega(x) \approx e^{2\lambda x}$ and the metric (1) is approximately the Rindler one.[32] The physical size of the near-horizon region is

$$l_h \sim \int_{-\infty}^{0} dx \sqrt{\Omega} \sim \frac{1}{\lambda} \,. \tag{3}$$

In the opposite limit, $x \to \infty$, the metric is asymptotically flat. The vacuum boundary conditions are imposed in the remote past, $t \to -\infty$, on both sides of the physical patch, $x \to \pm\infty$.

Next, we take the following scalar field action

$$S = \frac{1}{\mathrm{g}^2} \int d^2x \sqrt{-g} \left(-\frac{1}{2} g^{\mu\nu} \partial_\mu \varphi \partial_\nu \varphi - \frac{m^2 \varphi^2}{2} - V_{\rm int}(\varphi) \right) \,. \tag{4}$$

Here $V_{\rm int}(\varphi)$ is the interaction part of the tunneling potential chosen such that the false vacuum is located at $\varphi = 0$, and $V_{\rm int}(0) = 0$. For convenience, we factored out the small coupling constant g that controls the semiclassical expansion. In the

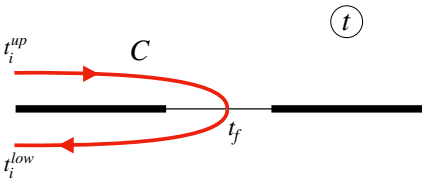

Fig. 1. Contour C in the complex time plane for the calculation of the vacuum decay probability. Black lines denote the branch-point singularities of the bounce in a theory with scalar potential unbounded from below.

background specified by eqs. (1) and (2), the action (4) becomes

$$S = \frac{1}{\mathrm{g}^2} \int dt dx \left(-\frac{1}{2} \eta^{\mu\nu} \partial_\mu \varphi \partial_\nu \varphi - \frac{1}{2} \Omega m^2 \varphi^2 - \Omega V_{\mathrm{int}}(\varphi) \right) , \tag{5}$$

where $\eta^{\mu\nu} = \mathrm{diag}(-1, 1)$ is the Minkowski metric. We see that the dependence on the background is contained entirely in the (position-dependent) potential of the field φ.

Let us study linear perturbations around the false vacuum $\varphi = 0$. To this end, we neglect the self-interaction part of the potential V_{int}, and decompose φ using a complete set of positive- and negative-frequency modes:

$$\varphi_\omega^+(t, x) = f_\omega(x) e^{-i\omega t} , \quad \varphi_\omega^-(t, x) = f_\omega^*(x) e^{i\omega t} , \quad \omega > 0 . \tag{6}$$

The equation for f_ω follows from the linearized field equation for φ and reads

$$-f_\omega'' + U_{\mathrm{eff}}(x) f_\omega = \omega^2 f_\omega , \tag{7}$$

where prime denotes derivative with respect to x. This is the Schrödinger equation with the potential

$$U_{\mathrm{eff}}(x) = m^2 \Omega . \tag{8}$$

Next, we turn to the construction of the bounce solution. Bounce φ_{b} is a regular solution of fields equations that saturates the transition amplitude from the false vacuum initial state to the basin of attraction of true vacuum. In our case, the field equation of motion is

$$\Box \varphi - U_{\mathrm{eff}}(x) \varphi - \Omega V_{\mathrm{int}}'(\varphi) = 0 . \tag{9}$$

The bounce lives on a contour C in the complex time plane. The contour runs from the initial moment of time in the asymptotic past, $t = t_i^{up}$, as shown in Fig. 1, to the final moment $t = t_f$ and back to the asymptotic past, $t = t_i^{low}$. The contour must bypass singularities of the bounce. Assuming that the bounce is unique, its values on the upper and lower sides of the contour are complex conjugated, hence at $t = t_f$ it is real and can be analytically continued along the real time axis where it describes the evolution of the field after tunneling.

In the limits $t \to t_i^{up}$ and $t \to t_i^{low}$ the bounce must satisfy boundary conditions imposed by the false vacuum state. These boundary conditions turn out to be the

same as for the time-ordered Green's function in the corresponding vacuum X.[30] The latter is defined as a time-ordered average of the field operators $\hat{\varphi}$ in the state X,

$$\mathcal{G}_{\rm X}(t,x;t',x') = {}_X\langle T(\hat{\varphi}(t,x)\hat{\varphi}(t',x'))\rangle_X \ . \tag{10}$$

In turn, the field operator is composed out of the complete set of modes (6) in the standard way.[33]

A Green's function $\mathcal{G}$ satisfies the equation

$$(\Box - U_{\rm eff}(x))\,\mathcal{G}(t,x;t',x') = i\delta(t-t')\delta(x-x') \ . \tag{11}$$

Using eq. (11), the field equation (9) can be recast into the integral form. To select a particular solution—bounce—of the integral equation, one should, first, adopt the time-integration contour C in the complex time plane and, second, choose a particular Green's function $\mathcal{G}_{\rm X}$. Thus, we arrive at

$$\varphi_{\rm b}(t,x) = -i\int_C dt' \int_{-\infty}^{\infty} dx' \mathcal{G}_{\rm X}(t,x;t',x')\Omega(x')V'_{\rm int}(\varphi_{\rm b}(t',x')) \ . \tag{12}$$

This form of the bounce equation will be useful in what follows.

Finally, let us discuss the tunneling rate Γ. The latter is defined as the probability of tunneling per unit time. We are interested in the main exponential dependence and write

$$\Gamma \sim e^{-B} \ . \tag{13}$$

Up to boundary terms, the coefficient B equals the imaginary part of the bounce action computed along the contour C. One can show that[30]

$$B = -\frac{i}{\mathrm{g}^2}\int_C dt \int_{-\infty}^{\infty} dx \left(\frac{1}{2}\varphi_{\rm b}V'_{\rm int}(\varphi_{\rm b}) - V_{\rm int}(\varphi_{\rm b})\right) \ . \tag{14}$$

3. The toy model

3.1. *Tunneling in flat spacetime*

In general, solving eq. (12) (or eq. (9) on the contour C with the vacuum boundary conditions) requires a numerical procedure. A big simplification of the problem happens in theories where the nonlinear core of the bounce, where it probes the true vacuum region, is much smaller in size than the Compton wavelength of the free field $\propto m^{-1}$. Then the source in the integral (12) is essentially point-like, and the solution outside the core is simply proportional to the Green's function $\mathcal{G}_{\rm X}$. On the other hand, the core itself can be found in neglecting the mass term in the field equation (9). The full solution is constructed by matching the long-distance asymptotics of the core with the short-distance asymptotics of the Green's function.

To meet the above requirements, we consider the following interaction potential[30]

$$V_{\rm int}(\varphi) = -2\kappa\,(e^{\varphi} - 1) \tag{15}$$

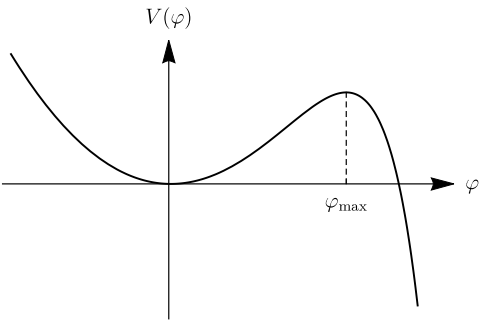

Fig. 2. The scalar field potential.

with $\kappa > 0$. In flat spacetime, the full scalar field potential $V(\varphi) = \frac{1}{2}m^2\varphi^2 + V_{\rm int}(\varphi)$ is shown in Fig. 2. To ensure the applicability of the split-and-match procedure, the following relation between the parameters is adopted

$$\ln \frac{m}{\sqrt{\kappa}} \gg 1 \, . \tag{16}$$

Thanks to this hierarchy, the theory possesses two intrinsic energy scales: the mass scale m and the scale associated with the potential barrier $m \ln \frac{m}{\sqrt{\kappa}}$. Generally speaking, the first controls the width of the linear tail of the bounce, while the second determines the size of its core. The barrier separating the regions of false and true vacua has its maximum at

$$\varphi_{\max} \approx 2 \ln \frac{m}{\sqrt{\kappa}} \, , \tag{17}$$

where only the leading logarithmic term is taken into account.

To illustrate the matching procedure outlined above, let us discuss bounce in the flat-space Minkowski vacuum. Assume that the only singularities of the bounce are located on the real-time axis. Then, the contour C can be deformed into the contour C' that runs along the Euclidean time axis, see Fig. 3(a) for illustration. The vacuum boundary condition at C, which is provided by the Feynman Green's function, becomes the vanishing boundary condition at C'. Hence, the standard Euclidean approach is reproduced.[24,25]

To find the core of the bounce, we neglect the mass term in eq. (9) and, using eq. (15), obtain

$$\Box \, \varphi_{\rm b}\big|_{\rm core} + 2\kappa e^{\,\varphi_{\rm b}|_{\rm core}} = 0 \, . \tag{18}$$

This is the Liouville equation, and its general solution is known. Next, the linear tail of the bounce is proportional to the (massive scalar) Feynman Green's function

$$\mathcal{G}_{\rm F}(-i\tau, x; 0, 0) = \frac{1}{2\pi} K_0 \left(m\sqrt{\tau^2 + x^2 + i\epsilon} \right) \, , \tag{19}$$

where $\tau = it$ is the Euclidean time coordinate and K_0 is the modified Bessel function of the second kind. The core and the tail are matched in the region where, on the

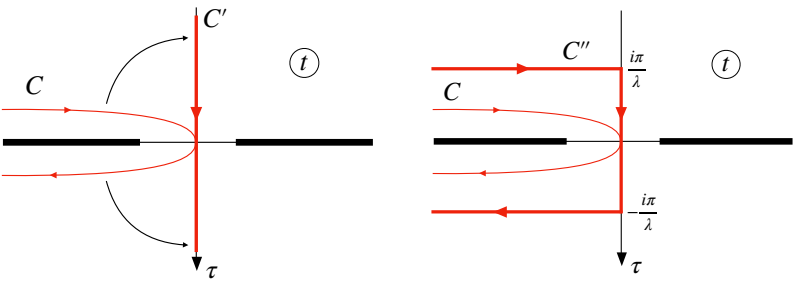

Fig. 3. (a) Deformation of the contour C into the Euclidean time contour C' used for the calculation of the flat-space Minkowski bounce. Black lines denote singularities of the bounce. (b) Deformation of C into C'' containing the Euclidean time segment which is used for the calculation of the Unruh bounce.

one hand, the solution to the Liouville equation is linearized and, on the other hand, the Green's function is approximated by its short-distance asymptotics. We obtain

$$\varphi_{\rm b}|_{\rm core} = \ln\left[\frac{4C_M^2}{(1+\kappa C_M^2(\tau^2+x^2))^2}\right] \tag{20}$$

$$\varphi_{\rm b}|_{\rm tail} = 8\pi\mathcal{G}_{\rm F}(-i\tau,x;0,0)\ , \tag{21}$$

where $C_M = m^2 e^{2\gamma_E}/(2\kappa)$ and γ_E is the Euler constant. The matching region is defined by $(C_M\sqrt{\kappa})^{-1} \ll \sqrt{\tau^2+x^2} \ll m^{-1}$. Its existence is ensured by eq. (16). We see that the bounce is real for real τ, vanishes at infinity and has zero time derivative at $\tau = 0$. Hence, it is a valid tunneling solution. Moreover, it has no singularities apart from the ones on the real-time axis, which justifies the deformation of the contour C into C'.

The tunneling suppression is given by eq. (14) where one should substitute the core of the bounce (20). To the leading-log approximation, this gives

$$B_M = \frac{16\pi}{\mathrm{g}^2}\ln\frac{m}{\sqrt{\kappa}}\ . \tag{22}$$

We observe that the suppression is enhanced by the large logarithm.

In the BH background (2), the linearized field equation (7) is still exactly solvable, and this allows us to compute explicitly the Green's functions of interest. The solvability of the equation for the core of the bounce is lost, but can be recovered in the two regions: near the horizon where the metric is approximately the Rindler one, and far away from the BH where the spacetime is asymptotically flat. From eq. (2) we see that the two regions are defined by $x < 0$, $|x| \gg \lambda^{-1}$ and $x > 0$, $|x| \gg \lambda^{-1}$, respectively. Although we do not have the explicit bounce solution in the transition region $|x| \lesssim \lambda^{-1}$, we will still be able to draw a qualitative picture of the evolution of the bounce across this region.

3.2. *Decay of the Unruh vacuum near horizon*

As discussed in introduction, the Unruh vacuum corresponds to a flux of thermal radiation propagating from the BH, whose spectrum is regularized by the m^2-asymptotics of the mode potential (8). In the absence of area growth in one spatial dimension, the flux enhances the vacuum decay rate at any distance from the BH. In the near-horizon region, the decay rate is additionally enhanced due to the accumulation of field excitations and curved geometry. Let us discuss the near-horizon case first.

To find the Unruh bounce in the BH vicinity, we have to integrate eq. (9) with $\Omega = e^{2\lambda x}$ along the contour C shown in Fig. 1 and satisfy the boundary condition imposed by the Unruh vacuum. The contour, in fact, can be deformed partially to the Euclidean time domain, as shown in Fig. 3(b). In the core region of the bounce the field equation reduces to

$$\Box\, \varphi_{\rm b}\big|_{\rm core} + 2\kappa e^{2\lambda x + \varphi_{\rm b}|_{\rm core}} = 0\,. \tag{23}$$

This again admits a general solution. The tail of the bounce is determined by the time-ordered Unruh Green's function $\mathcal{G}_U$ computed in the BH vicinity. Overall, we write

$$\varphi_{\rm b}\big|_{\rm core} = \ln\left[\frac{4\lambda^2 b_{U1}}{\kappa\left(-2\lambda(v-v_1)\sinh\left(\frac{\lambda}{2}(u-u_1)\right) + b_{U1}e^{\frac{\lambda}{2}(u-u_1)}\right)^2}\right] - 2\lambda x \tag{24}$$

$$\varphi_{\rm b}\big|_{\rm tail} = 8\pi\mathcal{G}_U(t,x;0,x_1)\,. \tag{25}$$

Here we defined $u = t - x$, $v = t + x$, and $u_1 = t - x_1$, $v_1 = t + x_1$. The parameter x_1 determines the position of the center of the bounce[a] and b_{U1} is found from matching the core and the tail. The expression for the Unruh Green's function at $m|x - x_1| \ll 1$ is given by eq. (A.2) from the appendix. Using it, we get

$$b_{U1} = \bar{b}_{U1}e^{-2\lambda x_1}\,, \qquad \bar{b}_{U1} = \frac{\kappa}{m^2}e^{\frac{32\lambda}{3\pi m} - 2\gamma_E - \frac{3}{2}}\,, \tag{26}$$

where we additionally assumed $\lambda \gg m$. We obtain a one-parameter family of solutions parametrized by x_1. This is an artefact of our approximation of the near-horizon geometry by the Rindler spacetime. Upon taking into account BH corrections to the Rindler metric, a unique tunneling solution is selected.

The bounce (24), (25) is real on the real-time axis and describes the tun-away toward the true vacuum $\varphi \to +\infty$ at positive time. Hence, it is a valid tunneling solution.

Investigating the applicability of the matching procedure, one arrives at the following condition[30]

$$\bar{b}_{U1} \lesssim 1\,. \tag{27}$$

[a]We used the time translational invariance of the theory to put the center of the bounce at $t = 0$.

This inequality translates into the upper bound on the BH temperature, $\lambda \lesssim \lambda_{U1}$, where to the leading-log accuracy

$$\lambda_{U1} = \frac{3\pi m}{16} \ln \frac{m}{\sqrt{\kappa}} \,. \tag{28}$$

At $\lambda > \lambda_{U1}$, the bound (27) is violated and the matching procedure breaks down. This can be given a physical interpretation: at $\lambda \simeq \lambda_{U1}$ the nonlinear core of the bounce stops fitting the near-horizon region, as its physical size exceeds l_h, see eq. (3). The subsequent evolution of the bounce happens outside the BH vicinity, and we will discuss it below.

To compute the exponential suppression of the decay rate, we use the general expression (14) with the contour C'' depicted in Fig. 3(b). The result is[30]

$$B_{U1} = \frac{16\pi}{\mathrm{g}^2} \left(\ln \sqrt{\frac{\lambda m}{\kappa}} - \frac{8\lambda}{3\pi m} \right) \,, \quad \lambda \lesssim \lambda_{U1} \,, \tag{29}$$

where for the sake of simplicity we omitted the order-one terms in the parentheses. We see that the suppression decreases with the BH temperature and becomes approximately half of the vacuum suppression at $\lambda \approx \lambda_{U1}$.

3.3. *Decay of the Unruh vacuum away from the black hole*

Far from the BH, the vacuum decay proceeds in the flat spacetime, and the only difference between the Unruh and Minkowski vacua is the presence of out-of-equilibrium field excitations. The question of how such excitations catalyze vacuum decay is interesting by itself.

Solving eq. (18) on the contour C'' and matching with the Unruh Green's function in the corresponding region, we arrive at the following solution

$$\varphi_{\mathrm{b}}\big|_{\mathrm{core}} = \ln \left[\frac{4\lambda^2 b_{U2}}{\kappa \left(-2\lambda (v - v_2) \sinh \left(\frac{\lambda}{2} (u - u_2) \right) + b_{U1} e^{\frac{\lambda}{2}(u-u_2)} \right)^2} \right] \tag{30}$$

$$\varphi_{\mathrm{b}}\big|_{\mathrm{tail}} = 8\pi \mathcal{G}_U(t, x; 0, x_2) \,, \tag{31}$$

where we denoted $u_2 = t - x_2$, $v_2 = t + x_2$, and the expression for $\mathcal{G}_U$ in the limit $|x - x_2| \ll m^{-1}$ and $\lambda \gg m$ is given in eq. (A.3) from the appendix. The parameter b_{U2} is found upon matching the core and the tail of the bounce and equals

$$b_{U2} = \frac{\kappa}{m^2} e^{\frac{8\lambda}{3\pi m} - 2\gamma_E + \frac{1}{2}} \,. \tag{32}$$

Similarly to the case studied above, one can take

$$b_{U2} \lesssim 1 \tag{33}$$

as a conservative condition for the validity of the bounce solution (30), (31). The bound (33) translates into the condition $\lambda \lesssim \lambda_{U2}$, where, to the leading-log accuracy,

$$\lambda_{U2} = \frac{3\pi m}{4} \ln \frac{m}{\sqrt{\kappa}} \,. \tag{34}$$

Finally, for the exponential suppression of the decay rate we get

$$B_{U2} = \frac{16\pi}{\mathrm{g}^2}\left(\ln\sqrt{\frac{\lambda m}{\kappa}} - \frac{2\lambda}{3\pi m}\right), \qquad \lambda \lesssim \lambda_{U2}\ . \tag{35}$$

We see that the coefficient in the linear in λ term is smaller than in eq. (29). Thus, the tunneling far from the horizon is more suppressed, as expected. Again, the suppression becomes half of the flat space one when the critical temperature is reached.

What happens with the decay rate at $\lambda > \lambda_{U2}$? We could not find the relevant tunneling solution in this regime. Therefore, let us proceed with a different method. At $\lambda \gg m$, the dominant contribution to the Unruh Green's function comes from the modes with $\omega \sim m$. The occupation number of modes of the dominant frequency is large, being enhanced by λ/m. Hence, the flux of particles in the Unruh state is essentially classical. It is these modes that are relevant for vacuum decay. Therefore, the vacuum decay probability can be estimated as the probability of the classical field fluctuation to reach beyond the maximum of the potential barrier at $\varphi = \varphi_{\max}$, see eq. (17) and Fig. 2. To find the variance of classical fluctuations $(\delta\varphi)^2_U$, we take the Unruh Green's function at coincident points, upon renormalizing it by subtraction of the Green's function in empty space,

$$(\delta\varphi)^2_U = \mathrm{g}^2 \lim_{t,x\to 0}\left[\mathcal{G}_U(t,x;0,0) - \mathcal{G}_F(t,x;0,0)\right]\ . \tag{36}$$

Since the interaction quickly dies out at $\varphi < \varphi_{\max}$, one can take the field fluctuations to be Gaussian. Then we obtain the following estimation of the decay rate due to classical field fluctuations

$$\Gamma_{U2,\mathrm{high}-\lambda} \sim \exp\left(-\frac{\varphi^2_{\max}}{2(\delta\varphi)^2_U}\right) \sim \exp\left(-\frac{6\pi^2 m}{\mathrm{g}^2\lambda}\left(\ln\frac{m}{\sqrt{\kappa}}\right)^2\right)\ . \tag{37}$$

As a consistency check, at $\lambda \approx \lambda_{U2}$ the stochastic estimate coincides with the bounce suppression (35) in the leading-log approximation.

Finally, let us go back to the near-horizon tunneling channel and see what happens with the decay rate after the critical temperature (28) is reached. At this point we can use again the stochastic estimate. We use the expression for the Unruh Green's function (A.3) to the right side from the barrier but not far from it and obtain

$$\Gamma_{U1,\mathrm{high}-\lambda} \sim \exp\left(-\frac{3\pi^2 m}{2\mathrm{g}^2\lambda}\left(\ln\frac{m}{\sqrt{\kappa}}\right)^2\right)\ . \tag{38}$$

We observe that in the leading-log approximation the suppression is continuous across the transition from the low- to high-temperature regime.

4. Conclusions and outlook

In this report we discussed the method to compute the rate of decay of the false Unruh vacuum. We applied the method to a toy model of a real scalar field in

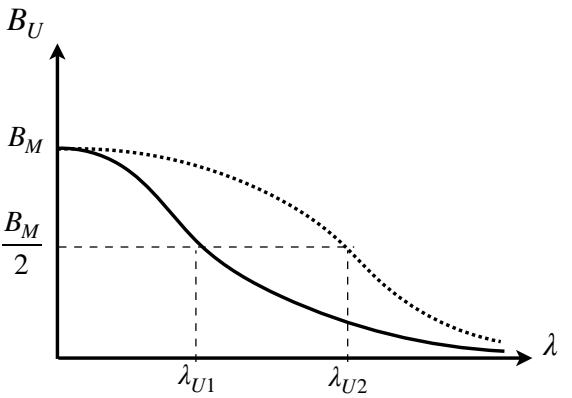

Fig. 4. Suppression of the Unruh vacuum decay as a function of BH temperature. The solid line represents the decay channel in the BH vicinity, and the dotted line shows the decay channel far from the BH. B_M, λ_{U1} and λ_{U2} are given in eqs. (22), (28) and (34), respectively.

the background of a dilaton BH in two dimensions. The results are summarized in Fig. 4. We see, in particular, that the decay channel far from the BH is suppressed as compared to the one close to the BH. This is in agreement with expectations. We also see that at high BH temperature the decay becomes unsuppressed.

Let us discuss to what extent our results are generalized to a realistic case such as a Schwarzschild BH in four dimensions. One should understand which features of the four-dimensional geometry are captured by the toy model in two dimensions, and which are not. For this, we can limit our discussion to the linear part of the theory. This is reasonable, since, as discussed above, properties of linear modes (or, more precisely, of Green's functions) are crucial for finding vacuum boundary conditions and, eventually, the decay rate. Then, one can readily compare the linear sector of the toy model with that of the spherical reduction of the free four-dimensional theory. More precisely, we can compare the greybody factors for linear perturbations. The four-dimensional greybody factor includes the barrier whose height depends on the size of the BH (and on its temperature). There is no such barrier in two dimensions. Its presence in four dimensions can change the results concerning the Unruh vacuum decay at high temperatures. Indeed, the barrier reduces the flux of Hawking radiation far from the BH and promotes the accumulation of Hawking quanta in the near-horizon region. In principle, our method allows us to take this effect into account, and we leave this study for future work.

Next, we found that the Unruh bounce does not exist above the certain temperature, both in the BH vicinity and in the asymptotically-flat region. Here, the situation is similar to the decay from a state in thermal equilibrium. It is known that a finite-temperature periodic instanton, which describes tunneling from such a state, yields to a static configuration—sphaleron—once the temperature exceeds a critical value.[34] The sphaleron corresponds to classical thermal jumps of the field

over the barrier separating the false and true vacua. One can expect that in the case of Unruh vacuum a similar transition happens. We could not find the analog of sphaleron in the Unruh state analytically. However, thanks to the properties of our model, we were able to use the simple stochastic estimate and compute the decay rate above the critical temperature. Let us reiterate that the validity of the estimate relies on the two facts. First, (almost) any relevant for decay field fluctuation is Gaussian, as it follows from the scalar field potential. Second, the field excitations of relevant frequency, $\omega \sim m$, have large occupation numbers and, hence, can be treated as classical. In more general situations, the stochastic approach to vacuum decay can still be applicable, but would require a full-fledged numerical simulation. We also leave this for future work.

Appendix A. Unruh Green's function

Here we quote the expressions for the (massive scalar) Unruh Green's function in two dimensions. We focus on the two regions: the near-horizon one ("left"), defined by the condition $x, x' < 0$, $|x|, |x'| \gg \lambda^{-1}$, and the asymptotically-flat one ("right"), determined by $x, x' > 0$, $|x|, |x'| \gg \lambda^{-1}$. Given that the metric (1) is static, we can set $t' = 0$ in the Green's function. Next, we consider the limit

$$|x - x'| \ll m^{-1} , \qquad |t| \ll m^{-1} . \tag{A.1}$$

Under these assumptions, the Unruh Green's function reads as follows[30]

$$\begin{aligned} \mathcal{G}_U(t, x; 0, x')\big|_{\text{left}} = &-\frac{1}{4\pi} \ln \left[2 \sinh \left(\frac{\lambda}{2} (x - x' - t) \right) m(x - x' + t) + i\epsilon \right] \\ &- \frac{\lambda(x + x')}{4\pi} + \frac{4\lambda}{3\pi^2 m} + \frac{\ln 2 - \gamma_E}{4\pi} - \frac{3}{16\pi} \end{aligned} \tag{A.2}$$

and

$$\begin{aligned} \mathcal{G}_U(t, x; 0, x')\big|_{\text{right}} = &-\frac{1}{4\pi} \ln \left[2 \sinh \left(\frac{\lambda}{2} (x - x' - t) \right) m(x - x' + t) + i\epsilon \right] \\ &+ \begin{cases} -\frac{\lambda}{4\pi}(x + x') + \frac{4\lambda}{3\pi^2 m} + \frac{\ln 2 - \gamma_E}{4\pi} - \frac{3}{16\pi} , & x + x' \ll m^{-1} \\ \frac{\lambda}{3\pi^2 m} + \frac{\ln 2 - \gamma_E}{4\pi} + \frac{1}{16\pi} , & x + x' \gg m^{-1} \end{cases} \end{aligned} \tag{A.3}$$

Behaviour of noise kernel in de Sitter and FRW space-times

Validity of the results of semiclassical analysis relies upon the assumption that the 2nd order or higher order corrections are negligible compared to 1st order semiclassical results which are based only on expectation values of operators. However, if the quantum fluctuations are large, then one may need to supplement semiclassical analysis with corrections coming from second order calculations. In the stochastic gravity paradigm, these fluctuations are quantified by noise kernel which are then supposed to act as a source of geometric fluctuations. In this work, we study the behaviour of noise kernel for a scalar field in de Sitter spacetime. We also carry out a similar analysis for some other FRW spacetimes invoking an equivalence that exists between scalar fields in de Sitter and FRW spacetimes.

Keywords: Stochastic gravity, Noise kernel etc.

1. Introduction

In semiclassical approach, we take matter fields to be quantum fields evolving over the classical geometry of a spacetime.[1] However, in this approach, we consider only the 1st order effects, for example, we replace classical stress energy tensor in Einstein's equations by the expectation value of the corresponding operator w.r.t. some quantum state in which the matter field is supposed to be. Now, conclusions drawn on the basis of such an analysis always rely on the implicit assumption that the 2nd or higher order quantum effects are relatively small and will not significantly affect the 1st order results. Though, in situations where higher order effects are appreciable, one may need to revisit the conclusions made on the basis of these 1st order calculations and may have to supplement them with 2nd or higher order calculations. For these considerations, one may resort to stochastic gravity[2,3] paradigm where one tries to incorporate the effects of quantum fluctuations, inherent in quantum matter fields, on the dynamics of classical background. These quantum fluctuations are quantified by what is called noise kernel which is given as follows:

$$N_{abcd} = \frac{1}{8}\{\hat{t}_{ab}, \hat{t}_{cd}\}, = \frac{1}{8}(\langle \hat{t}_{abcd}(x,x')\rangle + \langle \hat{t}_{cdab}(x,x')\rangle) \tag{1}$$

where $\hat{t}_{ab} = \hat{T}_{ab} - \langle \hat{T}_{ab} \rangle$, and

$$\begin{aligned} \langle \hat{t}_{abcd}(x, x') \rangle &\equiv \langle \hat{t}_{ab}(x) \hat{t}_{cd}(x') \rangle \\ &= \langle 0 | \hat{T}_{ab}(x) \hat{T}_{cd}(x') | 0 \rangle - \langle 0 | \hat{T}_{ab}(x) | 0 \rangle \langle 0 | \hat{T}_{cd}(x') | 0 \rangle \,. \end{aligned} \tag{2}$$

Stress energy quantum operator, $\hat{T}_{ab}$, is obtained by replacing classical fields by their quantum counterparts and the classical expression for stress energy tensor is obtained by taking the metric variation of the matter action, more precisely, $T_{ab}(x) = -\frac{2}{\sqrt{-g}} \frac{\delta S_M}{\delta g^{ab}(x)}$.

In this work, we are interested in studying the behaviour of noise kernel for scalar fields in a wide class of FRW spacetimes.[4,5] The line element for a general FRW spacetime is given by

$$ds^2 = a^2(\eta)(-d\eta^2 + d\vec{x}^2) \,, \tag{3}$$

where the scale factor, $a(\eta)$, characterizes that spacetime. In particular, we are interested in de Sitter spacetime, with $a(\eta) = \frac{-1}{H\eta}$. de Sitter spacetime is a maximally symmetric spacetime and present day observations[6] suggest that the early universe went through a period of nearly de Sitter phase. Similarly, universe is also believed to have undergone through other FRW type periods/epochs. Therefore, studying these second order quantum effects in FRW settings is an important cosmological task and may be helpful in better understand the cosmological data. We make use of an equivalence that exists between scalar fields in de Sitter and FRW spacetimes, to study the noise kernel in FRW spacetimes in terms of the noise kernel in de Sitter spacetime. Equally important is the study of backreaction of the noise kernel on the classical geometry of spacetime, though in the present work, we largely ignore this aspect of the analysis.

2. Point-Splitting technique and Bunch Davies vacuum

Let's consider a minimally coupled massive scalar field in general space-time metric i.e.,

$$S[g_{\alpha\beta}, \phi] = -\frac{1}{2} \int d\eta d^3\vec{x} \sqrt{-g} \left(g^{\alpha\beta} \nabla_\alpha \phi \nabla_\beta \phi + m^2 \phi^2 \right) . \tag{4}$$

We find that its stress energy operator is given by:

$$T_{\alpha\beta}(x) = \nabla_\alpha \phi \nabla_\beta \phi - \frac{1}{2} g_{\alpha\beta} (g^{\gamma\delta} \nabla_\gamma \phi \nabla_\delta \phi + m^2 \phi^2) \,. \tag{5}$$

One can write the above stress energy expression in the following point-split form[7]

$$T_{ab}(x) = \lim_{y\to x} P_{ab}(x,y)\phi(x)\phi(y)\,, \tag{6}$$

where

$$P_{ab}(x,y) = \left(\delta^c_{(a}\delta^d_{b)} - \frac{1}{2}\left(\frac{g_{ab}(x)+g_{ab}(y)}{2}\right)\left(\frac{g^{cd}(x)+g^{cd}(y)}{2}\right)\right)\nabla^x_c\nabla^y_d$$
$$- \frac{1}{2}\left(\frac{g_{ab}(x)+g_{ab}(y)}{2}\right)m^2\,. \tag{7}$$

Now substituting the above point split form in the formula for stress-energy two point correlator w.r.t the vacuum of the field, we find that

$$\langle t_{abcd}(x,x')\rangle = \lim_{\substack{y\to x\\ y'\to x'}} P_{ab}(x,y)P_{cd}(x',y')\langle 0|\phi(x)\phi(y)\phi(x')\phi(y')|0\rangle$$
$$- \lim_{\substack{y\to x\\ y'\to x'}} P_{ab}(x,y)P_{cd}(x',y')\langle 0|\phi(x)\phi(y)|0\rangle\langle 0|\phi(x')\phi(y')|0\rangle\,. \tag{8}$$

After some manipulations, this becomes

$$\langle t_{abcd}(x,x')\rangle = 2\lim_{\substack{y\to x\\ y'\to x'}} P_{ab}(x,y)P_{cd}(x',y')G(x,x')G(y,y')\,, \tag{9}$$

where $G(x,x')$ is the Wightman function for the scalar field in the considered vacuum,

$$G(x,x') = \langle 0|\,\phi(x)\phi(x')\,|0\rangle\ . \tag{10}$$

For de Sitter spacetime, we determine the behaviour of noise kernel for Bunch Davies vacuum[8,9] which is given by

$$G(Z) = (H^2/16\pi^2)\Gamma(a)\Gamma(b)_2F_1\left(a,b,2,\frac{1+Z}{2}\right), \tag{11}$$

where $Z(x,x') = 1+\frac{(\eta-\eta')^2-(\vec{x}-\vec{x}')^2}{2\eta\eta'}$ and $a,b = \frac{3}{2}\pm\sqrt{\frac{9}{4}-\frac{m^2}{H^2}}$. We see that the Bunch Davies vacuum depends on the coordinates only through the invariant distance $Z(x,x')$ between them.

3. Noise Kernel in de Sitter universe

Since for de Sitter spacetime, $g_{ab} = \frac{1}{(H\eta)^2}\eta_{ab}$, we find that

$$\begin{aligned}\langle t_{abcd}(x,x')\rangle_{dS} = \Bigg(& \nabla_b\nabla'_c G(x,x')\nabla_a\nabla'_d G(x,x') + \nabla_b\nabla'_d G(x,x')\nabla_a\nabla'_c G(x,x') \\ & - \eta_{cd}\eta^{\rho\sigma}\nabla_a\nabla'_\rho G(x,x')\nabla_b\nabla'_\sigma G(x,x') \\ & - \frac{1}{H^2\eta'^2}m^2\eta_{cd}\nabla_a G(x,x')\nabla_b G(x,x') \\ & - \eta_{ab}\eta^{\gamma\delta}\nabla_\gamma\nabla'_c G(x,x')\nabla_\delta\nabla'_d G(x,x') \\ & + \frac{1}{2}\eta_{ab}\eta^{\gamma\delta}\eta_{cd}\eta^{\rho\sigma}\nabla_\gamma\nabla'_\rho G(x,x')\nabla_\delta\nabla'_\sigma G(x,x') \\ & + \frac{1}{2H^2\eta'^2}m^2\eta_{ab}\eta^{\gamma\delta}\eta_{cd}\nabla_\gamma G(x,x')\nabla_\delta G(x,x') \\ & - \frac{1}{H^2\eta^2}m^2\eta_{ab}\nabla'_c G(x,x')\nabla'_d G(x,x') \\ & + \frac{1}{2H^2\eta^2}m^2\eta_{ab}\eta_{cd}\eta^{\rho\sigma}\nabla'_\rho G(x,x')\nabla'_\sigma G(x,x') \\ & + \frac{1}{2H^4\eta^2\eta'^2}m^4\eta_{ab}\eta_{cd}G(x,x')G(x,x')\Bigg). \end{aligned} \tag{12}$$

In order to see whether the primordial fluctuations are significant or not in an expanding universe, we consider constant time sheets i.e., we take $\eta = \eta'$ and look at the behaviour of noise kernel in the limit in which $a(\eta) \to \infty$ i.e., $\eta \to 0$ limit. Therefore, for Bunch Davies vacuum, the $(a = b = c = d = 0)$ component of the stress energy correlator behaves in the following manner[10]:

$$\langle t_{00}(\eta,\vec{x})t_{00}(\eta,\vec{x}')\rangle_{dS}\big|_{\text{late time}} = \frac{H^4\Gamma^2(\nu)\Gamma^2(\frac{5}{2}-\nu)}{\pi^5}\left[\frac{9\eta^{2-4\nu}}{32(\Delta\vec{x})^{6-4\nu}} + O(\eta^{4-4\nu})\right], \tag{13}$$

where $\nu = \sqrt{\frac{9}{4} - \frac{m^2}{H^2}}$.

From the above expression, we see that the above considered component of stress energy correlator vanishes in the $\eta \to 0$ limit when ν lies between $[0, \frac{1}{2})$ while it diverges in the same limit for ν lying between $(\frac{1}{2}, \frac{3}{2}]$. At $\nu = \frac{1}{2}$, it becomes independent of ν and is given by $\frac{9H^4}{32\pi^4(\Delta\vec{x})^4}$. The range for ν is decided by the requirement that the mass of the field, m, cannot take imaginary values. Since energy density at any spacetime point, x, is given by $T_{ab}(x)t^a t^b$, where t^a is tangent vector to a comoving observer at that point, we find that the energy-energy density is given by:

$$\frac{< \hat{T}_{00}(\eta,\vec{x})\hat{T}_{00}(\eta',\vec{x}') >_{dS}}{(a(\eta)a(\eta'))^2}. \tag{14}$$

Using the above formula and the fact that $a(\eta) = -\frac{1}{H\eta}$, we find that the energy-energy correlator vanishes for all values of ν lying between $[0, \frac{3}{2}]$ except at $\frac{3}{2}$ for

which it attains a constant value equal to $\frac{9H^4}{128\pi^4}$. One can also extend the above results to include all other components of the stress energy correlator as well as the non-minimal coupling.[10]

4. Noise Kernel for Friedmann spaces

As has already been stated, in order to study the behaviour of noise kernel in FRW spacetimes we make use of an equivalence between scalar fields in de Sitter and FRW spacetimes. So the idea is as follows[11]:

We consider a massless scalar field in a generic FRW universe i.e., $g_{\alpha\beta} = a^2(\eta)\eta_{\alpha\beta}$ with $a(\eta) = (H\eta)^{-q}$, with the action given by

$$S = -\frac{1}{2}\int d^4x\, a^4\big(a^{-2}\,\eta^{\alpha\beta}\partial_\alpha\phi\,\partial_\beta\phi\big)\,. \tag{15}$$

Under the transformation, $\phi(x) = (H\eta)^{-1+q}\,\psi(x)$, the action becomes

$$S = -\frac{1}{2}\int d^4x\, b^4\big(b^{-2}\,\eta^{\alpha\beta}\partial_\alpha\psi\,\partial_\beta\psi - m_{eff}^2\psi^2\big)\,, \tag{16}$$

where $b(\eta) = (H\eta)^{-1}$ and $m_{eff}^2 = H^2(1-q)(2+q)$. Therefore, with the above transformation, one can map a massless scalar field in a Friedmann universe with scaling factor, $a(\eta) = (H\eta)^{-q}$, to a massive scalar field in a de Sitter universe. From the relation, $m_{eff}^2 = H^2(1-q)(2+q)$, we conclude that the range $[0, \frac{3}{2}]$ of $\frac{m^2}{H^2}$ gets mapped to q between the range $[-2, 1]$. And since we are interested in the limit of η for which $a(\eta) \to \infty$, we find that, for $q \to [-2, 0]$, the late time limit corresponds to $\eta \to \infty$ while for $q \to [0, 1]$, the late time limit corresponds to $\eta \to 0$. From the above transformation between fields, we see that the Wightman functions in FRW spacetime and de Sitter spacetime are related by $G^{F.R.W.}(x, x') = (H\eta)^{q-1}(H\eta')^{q-1}G^{d.S.}(x, x')$. Using this relation between Wightman functions, we find that the stress energy correlator is given by:

$$\begin{aligned}
&\langle t_{00}(\eta,\vec{x})t_{00}(\eta,\vec{x'})\rangle_{F.R.W.}\\
&= (H\eta)^{4(q-1)}\Bigg[\frac{G^2}{2\eta^4}(q-1)^4 \;+ GG'\Big[\frac{(2q^3-7q^2+8q-3)(\Delta x)^2}{2\eta^6} - \frac{(q-1)^2}{\eta^4}\Big]\\
&+ GG''\frac{(q-1)^2(\Delta\vec{x})^4}{4\eta^8} + G'G''\Big[\frac{(q-\frac{3}{2})(\Delta\vec{x})^6}{4\eta^{10}} + \frac{(q-\frac{9}{4})(\Delta\vec{x})^4}{\eta^8} - \frac{(\Delta\vec{x})^2}{\eta^6}\Big]\\
&+ (G')^2\Big[\frac{2}{\eta^4} + \frac{(q^2-5q+\frac{11}{2})(\Delta\vec{x})^2}{\eta^6} + \frac{(2q^2-6q+\frac{9}{2})(\Delta\vec{x})^4}{4\eta^8}\Big]\\
&+ (G'')^2\Big[\frac{(\Delta\vec{x})^6}{4\eta^{10}} + \frac{(\Delta\vec{x})^8}{32\eta^{12}} + \frac{(\Delta\vec{x})^4}{2\eta^8}\Big]\Bigg]\,,
\end{aligned} \tag{17}$$

where $G(\eta, \vec{x}, \vec{x}')$ is the Wightman function in de Sitter universe[a]. Again taking the Wightman function to be the one corresponding to Bunch Davies vacuum, the

[a]We have suppressed the superscript d.S. in this expression.

behaviour of noise kernel for different cases can be summarized as follows[10]:

- $q = 1$: This is just massless scalar field case in de Sitter spacetime for which results are already given in the last section.
- $q \in (0, 1)$: In this case, the late time universe correspond to $\eta \to 0$ limit. And we find that, in this limit, $\langle t_{00}(\eta, \vec{x}) t_{00}(\eta, \vec{x'})\rangle_{P.L.}\big|_{\eta\to 0} = \frac{H^{4q}(\Delta\vec{x})^{4q-8}}{8\pi^5}\Big((11 - 12q{+}4q^2)(\Gamma(2{-}q))^2(\Gamma(0.5{+}q))^2\Big)$ i.e., it is time independent and it decreases with spatial distance.
- $q \in (-2, 0)$: In this case, the late time universe corresponds to $\eta \to \infty$. For this case, we have $\langle t_{00}(\eta, \vec{x}) t_{00}(\eta, \vec{x'})\rangle_{F.R.W.}\big|_{\text{late time}} = \lim_{\eta\to\infty}(H\eta)^{4q-4}\left[\frac{3H^4\eta^4}{2\pi^4(\Delta\vec{x})^8} + lower\ powers\ of\ \eta\right]$. This implies that there are no late time correlations in this case.
- $q = -2$: This is a slightly interesting case as in this case massless field in FRW spacetime goes to a massless scalar field in de Sitter spacetime. And because of this the stress energy correlator shows the infrared divergence as is present in Wightman function for a massless scalar in de Sitter spacetime.

Using the relation between the exponent, q, of the scale factor for a given FRW universe and the equation of state parameter, w, for the corresponding ideal fluid, i.e, $q = -2/(1 + 3w)$, we see that, for Friedmann universes with $q \in (0, 1]$, the equation of state parameter $w \in (-\infty, -1]$ whereas $w \in [0, \infty)$ for $q \in [-2, 0)$. Therefore, the results of the previous section with corresponding fluids can be summarized by the following diagram:

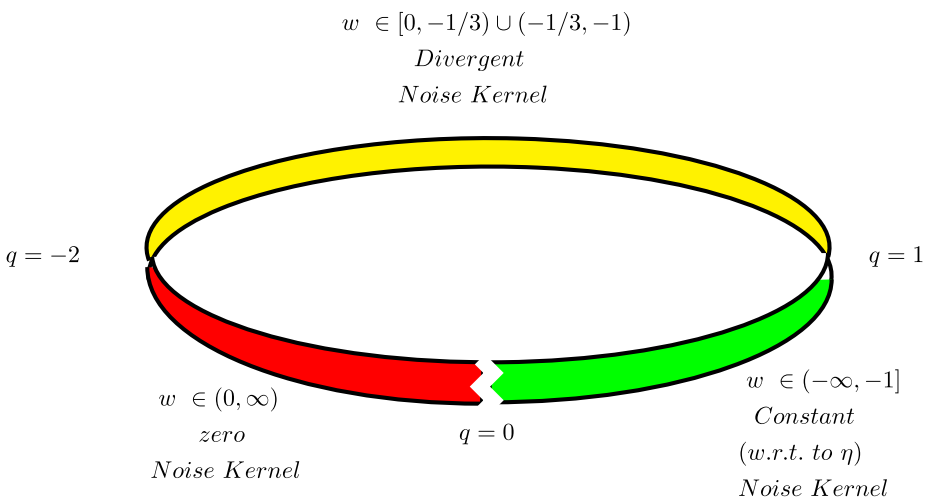

Fig. 1. Relation between different types of fluid (and the corresponding Friedmann space-times) and the behaviour of stress energy correlator in these regions.

Results for different epochs of the universe can be summarized in the following table[10]:

Table 1. Behaviour of the $(a = 0, b = 0, c = 0, d = 0)$ component of the stress-energy correlator and energy-energy correlator in the late time universe.[10]

	Radiation dominated $q = -1$	Dust dominated $q = -2$	de Sitter $q = 1$ & $\nu \in [0, \frac{1}{2})$	de Sitter $q = 1$ & $\nu \in (\frac{1}{2}, \frac{3}{2})$
$< t_{00}(\eta, \vec{x}) t_{00}(\eta, \vec{x'}) >$	0	∞	0	∞
$\frac{< t_{00}(\eta, \vec{x}) t_{00}(\eta, \vec{x'}) >}{(a(\eta))^4}$	0	∞	0	0

In the light of above results, we conclude that the semiclassical analyses alone may not be sufficient to draw any robust predictions about physical observables and questions related to the stability of the spacetimes. For example, for universe with positive equation of state parameter, the semiclassical analysis can still be trusted, at least in this stochastic approach, however, one may need to seriously relook at first order results for fluids with negative equation of state parameter and need to supplement them with, at least, 2nd order calculations. Similarly, for very light scalar fields, stochastic calculations may render the semiclasical conclusions invalid.[1,12]

The semiclassical approximation takes into account the gravitational contribution of zero-point energies. We model this contribution via the renormalized stress-energy tensor (RSET) of a massless scalar field, which we compute in a cutoff-regularized version of the Polyakov approximation. When the field is in the Boulware vacuum state (the natural vacuum for stellar geometries), the RSET works in favor of violating the Buchdahl compactness limit. We review the family of classical constant-density stellar solutions, paying particular attention to the notion of criticality—the presence of offsets in the mass function—and use it as a warm up for the analysis of the semiclassical set of solutions. For stars that surpass Buchdahl limit by far, the critical solution has an irregular pressure. This divergence in pressure moves inward by introducing a negative offset in the mass. In the semiclassical theory we find something rather different, namely that the critical configuration already displays a pressure that diverges exactly at the center of the structure. This drastic difference between the classical and semiclassical space of solutions suggests that semiclassical gravity could potentially allow for the existence of ultracompact stellar objects.

Keywords: Quantum fields in curved spacetimes, relativistic stars, semiclassical gravity

1. Introduction

In recent times, new windows have opened towards probing the nature of astrophysical black holes through both gravitational wave[1] and electromagnetic[2] observations. As observations aspire to unveiling the nature of these dark and compact objects, the issue of guessing what lurks behind their event horizons, assuming these long-lived surfaces exist in the first place, becomes more pressing than ever[a]. Among all

[a]Expanded version of the contributed talk by J.A. for the Sixteenth Marcel Grossmann Meeting (2021).

the different theories that, in principle, manage to change our notion of theoretical (Schwarzschild) black holes, semiclassical gravity stands out, mainly because it exhibits a conceptually well-stablished framework that has led to the discovery of effects such as cosmological particle creation[3] and Hawking evaporation.[4]

The main idea behind semiclassical gravity is that an effective geometrical description of the spacetime is retained, while the sources of this classical spacetime are of quantum origin. Therefore, this approximate scheme could be regarded as a conservative approach towards a theory of quantum gravity, in the sense that it captures the first corrections to classical general relativity originated by the zero-point energies of quantum matter fields. The presence of spacetime curvature modifies these zero-point energies in a way that cannot be renormalized away, the subsequent contribution from these zero-point energies to spacetime curvature being captured by the semiclassical field equations

$$G_{\mu\nu} = 8\pi \left(T_{\mu\nu} + \hbar \langle \hat{T}_{\mu\nu} \rangle \right), \tag{1}$$

where $\langle \hat{T}_{\mu\nu} \rangle$ is the vacuum expectation value of the renormalized stress-energy tensor (RSET) of quantized fields. Obtaining analytical expressions for the RSET is an arduous task,[5] so it is typical to resort to highly symmetrical or dimensionally reduced models where the RSET can be computed explicitly.[6,7]

2. The Polyakov RSET: Boulware vs Buchdahl

For simplicity, we restrict our analysis to static and spherically symmetric spacetimes with line element

$$ds^2 = -e^{2\phi(r)} dt^2 + \left[1 - C(r)\right]^{-1} dr^2 + r^2 d\Omega^2, \tag{2}$$

where $d\Omega^2$ is the line element of 2-spheres and ϕ, C are the redshift and compactness functions, respectively. The former measures the amount of redshift suffered by outgoing null rays and the latter is a measure of the amount of mass contained within concentrical spheres, namely $C(r) = 2m(r)/r$, with $m(r)$ the Misner-Sharp mass.[8]

An appealing method for obtaining a particularly simple RSET is via the s-wave Polyakov approximation.[9] This approximation models the RSET as that of a massless scalar field propagating in a $1+1$ dimensional spacetime [the t, r sector of (2)]. The resulting RSET is a function of the components of the metric[10] and has the form

$$\begin{aligned} \langle \hat{T}_{rr} \rangle^{(2)} &= -\frac{l_{\mathrm{P}}^2 \psi^2}{2} + \langle \mathrm{SDT} \rangle, \quad \langle \hat{\mathrm{T}}_{\mathrm{rt}} \rangle^{(2)} = \langle \hat{\mathrm{T}}_{\mathrm{tr}} \rangle^{(2)} = 0, \\ \langle \hat{T}_{tt} \rangle^{(2)} &= \frac{l_{\mathrm{P}}^2 e^{2\phi}}{2} \left[2\psi' \left(1 - C\right) + \psi^2 \left(1 - C\right) - \psi C' \right] + \langle \mathrm{SDT} \rangle, \end{aligned} \tag{3}$$

where $\langle \mathrm{SDT} \rangle$ stands for state dependent terms, $l_{\mathrm{P}} = 1/\sqrt{12\pi}$, $\psi = \phi'$ and the $'$ denotes derivatives with respect to the r coordinate. These components are then

identified with those of a $3+1$ dimensional tensor

$$\langle \hat{T}_{\mu\nu} \rangle^{(\mathrm{P})} = F(r) \delta^a_\mu \delta^b_\nu \langle \hat{T}_{ab} \rangle^{(2)}, \tag{4}$$

where Latin indices take $0, 1$ values and Greek indices take $0, 3$ values.

The Polyakov RSET provides an appropriate balance between simplicity and accuracy (see[11] for an extended discussion). There is an ambiguity in the $3+1$-dimensional Polyakov RSET given by the radial function $F(r)$. Typically, this function is fixed to be $F(r) = 1/r^2$ to yield a covariantly conserved RSET with vanishing angular pressures. In turn, the resulting RSET is singular at $r = 0$, even computed over entirely regular stellar spacetimes. This poses a problem when backreaction is taken into account and it is the main motivation behind exploring other choices of regulator function. Following a conservative logic, we supplied the regulator with a cut-off of the form $F_{\mathrm{CP}}(r) = 1/(r^2 + \alpha l_{\mathrm{P}}^2)$, with $\alpha > 1$. This distortion of the regulator function induces a non-conservation of the RSET, which can be compensated by the introduction of angular pressures.[12]

In previous works[12,13] we explored the sets of semiclassical vacuum and electrovacuum solutions using the cut-off regulator Polyakov RSET. In what follows we will consider the Boulware vacuum state, obtained by taking $\langle \mathrm{SDT} \rangle = 0$, as it is the sole state compatible with staticity (absence of stationary fluxes) and asymptotic flatness. The Boulware state is singular at the Schwarzschild event horizon, hence backreaction will affect it in a non-perturbative manner. The semiclassical counterpart of the Schwarzschild black hole has its horizon replaced by the throat of an asymmetric wormhole. At finite affine distance inside this throat lives an undressed singularity. This result motivates the introduction of a classical matter fluid as the only semiclassically-consistent possibility of obtaining geometries devoid from singularities. We will explore whether these geometries are potentially able to mimic astrophysical black holes.

This potentiality comes from realizing that semiclassical physics provides several ways of surpassing the Buchdahl compactness bound[14] that applies to relativistic stars in hydrostatic equilibrium. The conditions for deriving this limit involve that (i) the star has a Schwarzschild exterior, (ii) pressures in the angular directions that do not surpass the pressure in the radial direction, and (iii) a density profile that is non-increasing outwards. Semiclassical corrections modify the exterior (vacuum) geometry so that it is no longer Schwarzschild but an asymmetric wormhole. The RSETs are anisotropic by construction, although this anisotropy is underestimated in regularized Polyakov-like approximations. Lastly, the violations of energy conditions provided by the RSET generate regions inside the star where the energy density decreases inwards.

In this contribution, we report on several results concerning the self-consistent solutions to (1). We will point out the remarkable differences that exist between constant-density stellar solutions in the classical and semiclassical theories. We will elaborate on the notion of criticality—a criteria for identifying stellar geometries that exhibit deficit or excess of mass that come from singular sources—and use

it to obtain a family of *quasi-regular* semiclassical geometries. These quasi-regular geometries are characterized by a central (singular) core such that at its boundary the mass function is not trans-Planckian and pressures are finite.

3. Criticality in classical stars

First we give a brief summary of classical stellar equilibrium applied to the constant-density perfect fluid. In this simplified setting, the concept of criticality can be introduced in a clear fashion, paving the path toward the more involved analysis involving semiclassical corrections. The stress-energy tensor (SET) of the isotropic perfect fluid is

$$T_{\mu\nu} = (\rho + p)\, u_\mu u_\nu + p g_{\mu\nu}, \tag{5}$$

with p and ρ denoting the pressure and energy density measured by an observer comoving with the fluid with 4-velocity u^μ. In the following we will consider that the fluid obeys an equation of state of the form

$$\rho = \text{const.} \tag{6}$$

There are several reasons behind considering a constant-density fluid. First, this equation of state leaves the pressure of the fluid free to arrange itself in whichever form necessary to attain equilibrium. Second, the classical field equations admit (in some cases) analytical solutions. This characteristic is lost once we introduce semiclassical corrections. Finally, the constant-density assumption saturates one of the conditions necessary for the Buchdahl limit to hold.[15]

Covariant conservation of the classical SET yields

$$p' = -(\rho + p)\, \psi. \tag{7}$$

The rr and tt components of the classical field equations (1) take the form

$$C = \frac{-8\pi r^2 p + 2r\psi}{1 + 2r\psi}, \quad C' = 8\pi r\rho - \frac{C}{r}. \tag{8}$$

Expressions (6, 7, 8) form a closed system. The differential equation for C can be directly integrated, yielding

$$C = \frac{8}{3}\pi r^2 \rho + \frac{2m_0}{r}. \tag{9}$$

Here, m_0 is an arbitrary integration constant that accounts for a constant shift in the Misner-Sharp mass $m(r)$. The following relation

$$M_{\text{ADM}} = \int_0^R 4\pi r^2 \rho \, \mathrm{d}r + m_0, \tag{10}$$

calls for interpreting m_0 as a term that compensates the disagreement between the mass generated by the whole fluid sphere and the ADM mass M_{ADM}. Therefore, regularity in the compactness of a classical star enforces $\rho = \rho_{\text{crit}} = 3C(R)/8\pi R^2$, where ρ_{crit} stands for the critical density. We use this value to distinguish three

families of solutions

- Sub-critical regime ($\rho < \rho_{\rm crit}$): These solutions are characterized by a positive m_0 and can be interpreted as a fluid sphere with a mass excess whose gravitational pull cannot be withstood by finite pressures. Sub-critical solutions have infinite pressure singularities at some $r > 0$. For a fixed $C(R)$, the radius where this singularity appears nears the surface as ρ decreases.
- Critical regime ($\rho = \rho_{\rm crit}$): These solutions have a vanishing mass at $r = 0$ ($m_0 = 0$) and can be regular or irregular depending on whether the Buchdahl compactness bound is being surpassed. Critical solutions that surpass Buchdahl limit ($C(R) = 8/9$) display a pressure divergence at

$$R_{\rm div} = 3R\sqrt{1 - \frac{8}{9C(R)}}. \tag{11}$$

- Super-critical regime ($\rho > \rho_{\rm crit}$): Stellar geometries characterized by a negative m_0. The gravitational repulsion exherted by this negative mass tames the growing of the pressure of the fluid but at the cost of producing a curvature singularity at $r = 0$. As m_0 becomes more negative, the pressure at the core decreases, eventually becoming finite at $r = 0$ for some separatrix density.

Despite its apparent simplicity, this space of solutions reveals an important characteristic: for stars that surpass the Buchdahl limit, $C(R) = 8/9$, the respective separatrices for the pressure and mass functions do not overlap in any region. Fig. 1 shows integrations surrounding the critical solution, the only one with a regular compactness function[b]. The associated pressure profiles all develop singularities significantly far from $r = 0$. On the other hand, Fig. 2 shows integrations surrounding the solution separatrix in pressure, that is, the solution which is super-critical enough as to have a pressure that diverges exactly at $r = 0$. However, the price to pay for generating finite-pressure configurations is that the mass goes highly super-critical. At this point, enforcing the mass function to vanish at $r = 0$ would require introducing an additional positive mass contribution inside a small core. This sort of regularization cannot come without additional pathologies as the density of such sphere would necessarily be trans-Planckian. In what follows we will show that semiclassical corrections naturally provide this regularization mechanism for the mass, although they fail in achieving a strictly regular behavior at $r = 0$.

4. Semiclassical corrections in stellar spacetimes

The classical equations (8) guarantee the behavior of the compactness is independent from that of the pressure, although the converse is not true. The addition

[b]Recall that $C = 2m/r$, so only a Misner-Sharp mass that vanishes at the origin returns a non-singular compactness.

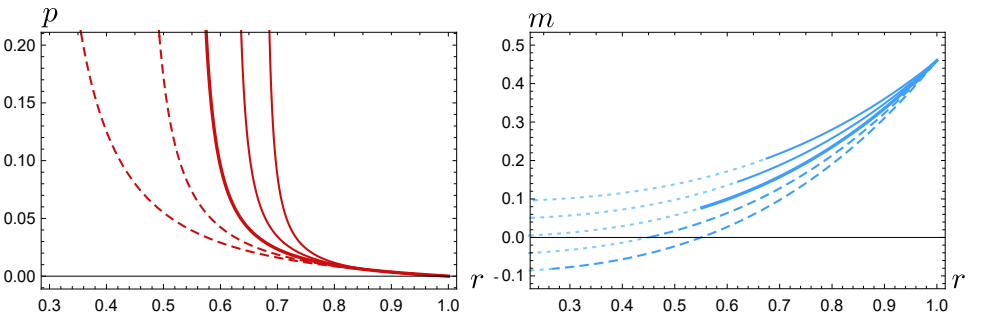

Fig. 1. Pressure (left panel) and Misner-Sharp mass (right panel) profiles surrounding the critical solution of a star with $C(R) = 0.92$ and $R = 1$. The thick, continuous line denotes the critical solution, while thin lines are sub-critical and dashed lines are super-critical stars. The only solution regular in the mass (critical) has a highly irregular pressure. The mass curves have been analytically extended for pictorical purposes, but the associated pressure profiles are singular. From right to left (top to bottom) $\rho/\rho_{\rm crit} = \{0.8, 0.9, 1.0, 1.1, 1.2\}$.

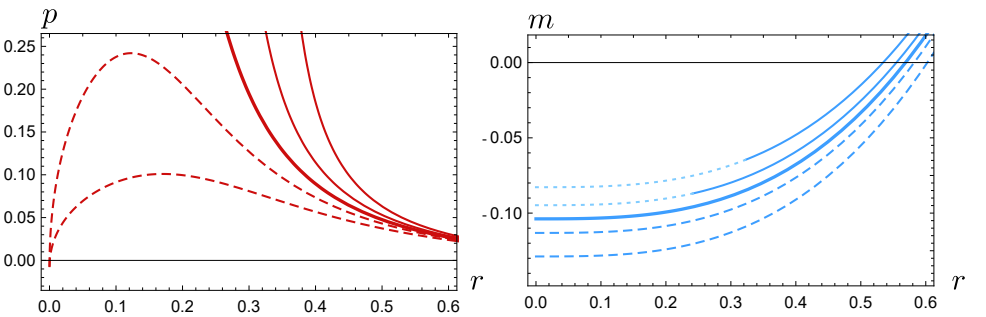

Fig. 2. Pressure (left panel) and Misner-Sharp mass (right panel) profiles surrounding the pressure-separatrix solution of a star with $C(R) = 0.92$ and $R = 1$. The thick, continuous line denotes the separatrix solution, while thin lines are infinite-pressure solutions and dashed lines are finite-pressure ones. Note that making the pressure everywhere finite enforces a negative central mass. All integrations are super-critical because $m_0 < 0$. From right to left (top to bottom) $\rho/\rho_{\rm crit} \simeq \{1.18, 1.21, 1.23, 1.25, 1.28\}$.

of semiclassical corrections intertwines the behavior of both functions. As a consequence, when we analyze the semiclassical equations, the notion of criticality becomes more involved. This is because the differential equation for the compactness cannot be integrated analytically, so we lack an explicit expression that informs about the value of $\rho_{\rm crit}$. The most relevant departure of semiclassical stars with respect to their classical counterparts is that, in the semiclassical theory, the separatrix solutions in mass and pressure overlap in a narrow region of the parameter space. In the following we will catalogue the space of semiclassical constant-density solutions and elaborate on this aspect.

Introducing the cut-off regularized Polyakov RSET (4) as a curvature source in the field equations (1), they result in

$$C = \frac{-8\pi r^2 p + 2r\psi + l_{\rm P}^2 r^2\psi^2/\left(r^2+\alpha l_{\rm P}^2\right)}{1 + 2r\psi + l_{\rm P}^2 r^2\psi^2/\left(r^2+\alpha l_{\rm P}^2\right)}, \tag{12}$$

$$C' = \frac{8\pi r^2\rho - C + l_{\rm P}^2 r^2\left(\psi^2 + 2\psi'\right)(1-C)/\left(r^2+\alpha l_{\rm P}^2\right)}{r + l_{\rm P}^2 r^2\psi/\left(r^2+\alpha l_{\rm P}^2\right)}. \tag{13}$$

Semiclassical corrections to stellar spacetimes are typically negligible (they are proportional to $\hbar$) unless the geometries under consideration are able to explore and stimulate the energetic contributions of the Boulware state as to compensate their suppression of order $\hbar$. The scale that can potentially compensate this screening of semiclassical effects is the compactness of the star. In the following, we will be considering spheres of fluid whose surface is located very close and above the throat of the vacuum wormhole geometry [$C(R) \to 1$]. Such a configuration is defined by the following boundary conditions

$$p(R) = 0, \quad \phi(R) = \phi_{\rm S}, \quad \psi(R) = \frac{R^2+\alpha l_{\rm P}^2}{R l_{\rm P}^2}\left[\sqrt{1 + \frac{R^2}{R^2+\alpha l_{\rm P}^2}\frac{C(R)}{1-C(R)}} - 1\right], \tag{14}$$

and a given value of ρ and $C(R)$. Here, the parameter $\phi_{\rm S}$ is obtained through a numerical integration of the vacuum equations from the asymptotic region inwards.

Plugging the boundary conditions (14) in the field equations (12, 13) we obtain expressions for $\psi'(R)$ and $C'(R)$. Then, the semiclassical energy density and radial pressure at $r = R$ are

$$\begin{aligned}
\rho_{\rm sc} &= -\langle\hat{T}_t^t\rangle^{(\rm P)} = -\frac{1}{8\pi R^2} + \rho + \mathcal{O}\left(\sqrt{1-C}\right), \\
p_{\rm sc}^r &= \langle\hat{T}_r^r\rangle^{(\rm P)} = -\frac{1}{8\pi R^2} + \mathcal{O}\left(\sqrt{1-C}\right), \\
p_{\rm sc}^\theta &= \langle\hat{T}_\theta^\theta\rangle^{(\rm P)} = -\frac{\alpha l_{\rm P}^2}{8\pi R^2\left(R^2+\alpha l_{\rm P}^2\right)} + \mathcal{O}\left(\sqrt{1-C}\right).
\end{aligned} \tag{15}$$

The RSET components are comparable in magnitude to the classical SET at the surface. In fact, as long as $\rho \lesssim 1/8\pi R^2$ the total RSET violates energy conditions at the surface. Additionally, for more realistic equations of state with a classical energy density that vanishes at the surface, the total RSET will violate all pointwise energy conditions there.

Vacuum polarization provides an extra contribution to the Misner-Sharp mass of the spacetime. This contribution is negative in the vacuum region and permeates it entirely. In the interior of the star it can be overall positive or negative depending on the value of ρ. The equivalent to formula (10) in the semiclassical theory is

$$M_{\rm ADM} = \int_0^\infty 4\pi r^2\left[\Theta\left(R-r\right)\rho + \rho_{\rm sc}\right] dr + m_0, \tag{16}$$

where Θ is the Heaviside step function. Since the total energy density is now intertwined to the pressure and redshift of the geometry through Eq. (13), the critical

value of the classical density (recall, the value that corresponds to a vanishing m_0) cannot be determined analytically. In turn, a numerical exploration of the space of solutions is needed. We dedicate the rest of this note to highlight the chief results from our exploration[c].

Concerning the Buchdahl limit, we have found that the classical Buchdahl bound of $C(R) = 8/9$ gets perturbatively modified by semiclassical corrections. These correction makes the most compact configuration which is regular in p and C have $C(R) < 8/9$. This result follows from $\rho_{\rm sc}$ in (16) amounting to an overall positive contribution throughout the interior of the structure. In fact, the greatest positive contribution comes from the region $r \sim \sqrt{\alpha} l_{\rm P}$, precisely where the physics of the Polyakov RSET is driven by the regulator function. Using a local, more refined approximation to the RSET[16] the energetic contribution near the center of constant-density stars that are approaching Buchdahl limit turns out to be negative. The cutoff-Polyakov RSET could be incorrectly estimating the magnitude and sign of the energetic contribution from the vacuum near the center of compact fluid spheres.

In our exploration of the semiclassical space of solutions (see Fig. 3 for a pictorical representation) we found the following regimes

- Sub-critical regime ($\rho \ll \rho_{\rm crit}$, regions I and III of the diagram in Fig. 3): These solutions are asymmetric wormholes with characteristics akin to the vacuum solution, but filled with a classical fluid of diverging pressures. As ρ is increased, the throat of the wormhole progressively shrinks. When the throat is very small compared to the overall size of the star, we identify a new regime not present in the classical theory.
- Quasi-regular regime ($\rho \sim \rho_{\rm crit}$, narrow orange band in Fig. 3): This subfamily is comprised by super-critical solutions that lie below Buchdahl limit and sub-critical solutions of any compactness with an extremely tiny wormhole throat. In this regime, we can always identify a central core of radius $r_{\rm core} \ll R$. At the boundary of this core the pressure remains finite and the Misner-Sharp mass can be made as small as desired.
- Critical regime ($\rho = \rho_{\rm crit}$, black line in Fig. 3): Sub-Buchdahl stars amount to a perturbative correction over the classical geometries and are regular. Super-Buchdahl stars are irregular but extend all the way to $r = 0$, contrary to their classical counterparts. These solutions have infinite positive pressure and infinite negative mass at $r = 0$.
- Super-critical regime ($\rho > \rho_{\rm crit}$, regions II and IV of the diagram in Fig. 3): They correspond to perturbative corrections over the classical solutions, with the caveat that the Misner-Sharp mass is now infinite and negative at $r = 0$, which strengthens the central singularity. Pressure is finite everywhere.

[c]We refer the reader to[11] for details.

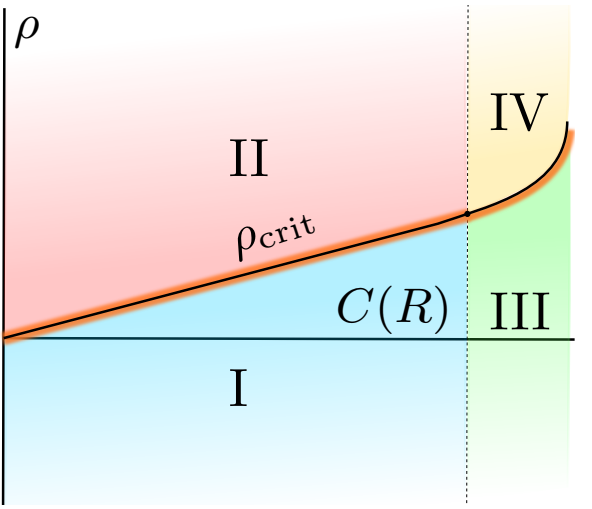

Fig. 3. Pictorial representation of an $R = \text{const.} \gg l_{\rm P}$ slice of the semiclassical constant-density stellar space of solutions. The vertical and horizontal axes represent the energy density and surface compactness of stars. The black curve denotes critical configurations. Its intersection with the vertical, dotted line represents the Buchdahl limit, or the most compact structure regular in both p and C. We distinguish four regions: regions I and II for sub- and super-critical stars below Buchdahl limit and regions III and IV for sub- and super-critical stars above Buchdahl limit. The narrow orange band that surrounds the $\rho_{\rm crit}$ line denotes the quasi-regular regime which spans through regions I, II and III.

Figure 4 shows the pressure and mass profiles for various configurations surrounding the critical solution of a star that surpasses the Buchdahl limit (rightmost portion of diagram 3). There are several crucial differences between these diagrams and those from Figures 1 and 2. Firstly, the critical solution (thick line), albeit singular, coincides with the separatrix solution for the pressure. In the classical case, the critical solution and the separatrix in the pressure were distant in the space of parameters. Here, because of the way quantum corrections operate, we find a coincidence between these two solutions. Secondly, quasi-regular configurations (thin lines) for which the Misner-Sharp mass vanishes near the center of spherical symmetry are very different from their classical counterparts. Enforcing the mass function to vanish at $r = 0$ no longer requires the introduction of arbitrarily high masses inside small cores: Semiclassical corrections already provides a significant part of this contribution.

5. Conclusions

In this work we have reviewed the classical stellar solutions of constant density under our particular scope, with the aim of understanding properly the solutions that incorporate vacuum polarization contributions. We have not been able to find strictly regular configurations that surpass a Buchdahl limit (which receives perturbative

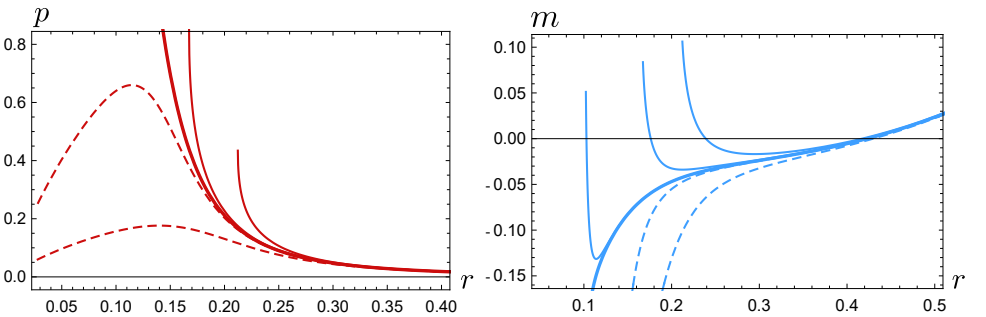

Fig. 4. Pressure (left panel) and Misner-Sharp mass (right panel) profiles surrounding the critical solution of a semiclassical star with $C(R) = 0.92, R = 1$ and $\alpha = 1.01$. The thick line denotes the critical solution (the separatrix between distinct compactness behaviors), while the thin lines are sub-critical and the dashed lines are super-critical. In the right panel the quasi-regular regime can be observed. Quasi-regular solutions are characterized by a mass function that vanishes in the innermost regions of the star. By a suitable choice of ρ, this vanishing can be achieved as close to $r = 0$ as desired. From right to left (top to bottom) the densities utilized are $\rho/\rho_{\rm crit} = \{0.9990, 0.9998, 0.9999, 1, 1.0001, 1.0010\}$, where the critical density $\rho_{\rm crit} \simeq 0.1214$ is determined numerically within a precision of 10^{-6}.

corrections). However, the study of singular solutions hints towards semiclassical gravity being able to regularize at the same time the pressure and mass of ultracompact configurations. This notion is what we have attempted to capture in the notiont of quasi-regular configurations.

We believe that the crudity of the approximations used here for the semiclassical source could be preventing the quasi-regular solutions from appearing as regular in the first place. Ideally, these analyses should be revisited when more accurate approximations to the RSET are available. As an intermediate step in this direction, it is possible to ask whether a deformation of the regulator function from its cutoff-regulator form $F_{\rm CP}$ just inside the central core of the structure is sufficient to generate entirely regular and ultracompact configurations. The results of this ongoing investigation will appear in a forthcoming publication.

**E-mail: 191d9021@st.kumamoto-u.ac.jp*

By applying the covariant Taylor expansion method to the heat kernel, Einstein anomaly associated with the Weyl fermion of spin 1/2 interacting with tensor fields of 1 and 3 order in six dimensional curved space are given. From the relation between Einstein and Lorentz anomalies, which are the gravitational anomalies, all terms of the Einstein anomaly should form total derivatives.

Keywords: Einstein anomaly

1. Introduction

The gravitational anomalies are the Lorentz anomaly that appears from the local Lorentz transformation and the general coordinate anomaly that appears from the covariant general coordinate transformation, in the model for the Weyl fermion in even dimensional curved space. The Lorentz anomaly can be canceled by appropriately replacing the expectation value of the energy-momentum tensor, and then the general coordinate anomaly, called the Einstein anomaly, remains.

The Lagrangian in $N = 1$ supergravity coupled to supersymmetric Yang-Mills theory has some four-Fermi interactions, in addition to the minimal couplings of the fermion with the gravitational and gauge fields. The gravitino field with an irreducible element of spin $\frac{3}{2}$ exists in the supergravity. The kinetic part of the gravitino is treated as that for a fermion of spin $\frac{1}{2}$, fixing the field by a suitable gauge, and the spacetime index of the gravitino may be regarded as that of the representation matrix elements of a gauge group in vector and odd order tensor type couplings. Then the tensor may not commute with the vector.

2. Heat kernel

In this article, in order to apply for the above model, we consider the covariant gravitational anomalies for a Weyl fermion with spin $\frac{1}{2}$, interacting with both the vector field V_μ and the totally antisymmetric tensor $C_{\mu\alpha\beta}$, in even $2n$-dimensional Riemannian space. The concrete form of the anomalies may directly be calculated by using the heat kernel $K^{(2n)}(x, x'; t)$ for the fermion, which is defined as[1]

$$\begin{aligned} -\frac{\partial}{\partial t}K^{(2n)}(x,x';t) &= \not{D}^2 K^{(2n)}(x,x';t), \\ K^{(2n)}(x,x';0) &= \mathbf{1}|h(x)|^{-\frac{1}{2}}|h(x')|^{-\frac{1}{2}}\delta^{(2n)}(x-x'), \end{aligned} \tag{1}$$

where $\mathbf{1}$ is the spinor unit matrix, $\delta^{(2n)}(x-x')$ denotes the delta function, and $h(x)$ stand for the determinant $\det h^m{}_\mu$ of a vielbein $h^m{}_\mu$. Note that the metric tensor is $g_{\mu\nu} = h^m{}_\mu h^n{}_\nu \eta_{mn}$ with $\eta_{mn} = -\delta_{mn}$ in flat tangent space. Moreover, the square of the Dirac operator $\not{D}$ for fermion ψ is written as follows,

$$\begin{aligned}
&\not{D}^2 = D_\mu D^\mu + X,\ \not{D} = \gamma^\mu \nabla_\mu + Y,\ D_\mu = \nabla_\mu + Q_\mu,\ Q_\mu = \frac{1}{2}\{\gamma_\mu, Y\},\\
&X = Z - \nabla_\mu Q^\mu - Q_\mu Q^\mu,\ \nabla_\mu \psi = \partial_\mu \psi + \frac{1}{4}\gamma_{mn}\omega^{mn}{}_\mu \psi,\ \gamma_{\mu_1\cdots\mu_n} = \gamma_{[\mu_1}\cdots\gamma_{\mu_n]},\\
&Z = \frac{1}{2}\gamma^{\mu\nu}[\nabla_\mu, \nabla_\nu] + \gamma^\mu(\nabla_\mu Y) + Y^2,\ [D_\mu, D_\nu]\psi = \Lambda_{\mu\nu}\psi,\\
&Y = \gamma^\mu V_\mu + \gamma^\mu \gamma^{\alpha\beta} C_{\mu\alpha\beta},\ V_\mu \equiv V_\mu^a T^a,\ C_{\mu\alpha\beta} \equiv C_{\mu\alpha\beta}^a T^a,
\end{aligned} \tag{2}$$

where $\omega^{mn}{}_\mu$ is the spin connection. The interaction term Y of the boson in $\not{D}$ is given by vector and tensor fields, and T^a is the matrix representation of the nonabelian gauge group. The γ-matrix valued Q_μ, X and $\Lambda_{\mu\nu}$ in (2) are rewritten in the following form,

$$\begin{aligned}
Q_\mu &= V_\mu + 3\gamma^{\alpha\beta} C_{\mu\alpha\beta},\ F_{\mu\nu} \equiv \partial_\mu V_\nu - \partial_\nu V_\mu + [V_\mu, V_\nu],\\
X &= -\frac{1}{4}R + 12 C^{\alpha\beta\gamma} C_{\alpha\beta\gamma} + \gamma^{\mu\nu}\left(\frac{1}{2}F_{\mu\nu} + 18 C_\mu{}^{\alpha\beta} C_{\nu\alpha\beta}\right)\\
&\quad - \gamma^{\alpha\beta\gamma\delta} C_{\alpha\beta\gamma;\delta} + \gamma^{\mu\nu\alpha\beta\gamma\delta} C_{\mu\alpha\beta} C_{\nu\gamma\delta},\\
\Lambda_{\mu\nu} &= \frac{1}{4}\gamma^{\rho\sigma} R_{\rho\sigma\mu\nu} + F_{\mu\nu} - 18[C_\mu{}^{\alpha\beta}, C_{\nu\alpha\beta}] - \gamma^{\alpha\beta}(6 C_{\alpha\beta[\mu;\nu]} + 72 C^\rho{}_{\alpha[\mu|} C_{\rho\beta|\nu]})\\
&\quad + 18\gamma^{\alpha\beta\gamma\delta} C_{[\mu|\alpha\beta} C_{|\nu]\gamma\delta},\ \gamma_{2n+1} = i^n \gamma^1\gamma^2\cdots\gamma^{2n},
\end{aligned} \tag{3}$$

where the semi-colon ';μ' denotes the covariant differentiation $\nabla_\mu + V_\mu$ for the vector gauge transformation in curved space, $R_{\rho\sigma\mu\nu}$ is the Riemann curvature tensor, and $R = g^{\rho\mu} g^{\sigma\nu} R_{\rho\sigma\mu\nu}$. The antisymmetric product $\gamma^{\alpha\beta\gamma\delta}$ and $\gamma^{\mu\nu\alpha\beta\gamma\delta}$ of X can be replaced by $-\frac{i}{2}\gamma_7\gamma^{\rho\sigma}\epsilon_{\rho\sigma\alpha\beta\gamma\delta}$ and $i\gamma_7\epsilon^{\mu\nu\alpha\beta\gamma\delta}$ in 6 dimensions, respectively.

It is difficult to obtain the exact form of the heat kernel. In order to perform the concrete calculation, the following ansatz by DeWitt is applied to the heat kernel.[2]

$$K^{(2n)}(x, x'; t) \sim \frac{\Delta^{\frac{1}{2}}(x, x')}{(4\pi t)^n} \exp\left\{\frac{\sigma(x, x')}{2t}\right\} \sum_{q=0}^{\infty} a_q(x, x') t^q, \tag{4}$$

where $\sigma(x, x')$ is half of the square of the geodesic distance between x and x', $\Delta(x, x') = |h(x)|^{-1}|h(x')|^{-1} \det \sigma_{;\mu\nu'}$, and $a_q(x, x')$ is a bispinor. The coincidence limit of a_n appears in formal expression of the anomaly, and is defined by $\lim_{x'\to x} a_n(x, x') \equiv [a_n](x)$.[3] The orthonormal bases $|n\rangle \equiv |\mu_1\cdots\mu_n\rangle$ being the

eigenfunctions belonging to the eigenvalue n for $\sigma^\nu D_\nu$ consist of n products of $\sigma_{\mu'}(=\nabla_{\mu'}\sigma)$, and a_q can be expanded by the bases,

$$\begin{aligned} a_q &= \sum_{n=0}^{\infty} |n\rangle\langle n|a_q\rangle \ = \sum_{n=0}^{\infty} \frac{(-1)^n}{n!}\sigma^{\mu'_1}\cdots\sigma^{\mu'_n} \lim_{x\to x'}[D_{(\mu_1}\cdots D_{\mu_n)}a_q], \\ \langle n|a_q\rangle &= [a_{q!(\mu_1\cdots\mu_n)}] = \lim_{x\to x'}[D_{(\mu_1}\cdots D_{\mu_n)}a_q],\ \langle 0|a_q\rangle = [a_q], \end{aligned} \tag{5}$$

where the exclamation mark '$!\mu$' means the covariant differentiation D_μ modified in (2).

3. Einstein anomaly

The formal forms of the general coordinate anomaly $\mathcal{A}^{(2n)}_\nu$ and the Lorentz anomaly $\mathcal{A}^{(2n)}_{\mu\nu}$ are obtained from the path integral measure of left-handed Weyl fermion in 2n dimensions, in Fujikawa's method,[4] and are expressed by the heat kernel after regularized by the Gaussian cut-off differential operator.

$$\begin{aligned} &D^\mu \langle T_{\mu\nu}\rangle = \mathcal{A}^{(2n)}_\nu, \quad \langle T_{\mu\nu}\rangle_{\mathrm{A}} \equiv \frac{1}{2}\left(\langle T_{\mu\nu}\rangle - \langle T_{\nu\mu}\rangle\right) = \mathcal{A}^{(2n)}_{\mu\nu}, \\ &\mathcal{A}^{(2n)}_\nu(x) = \frac{1}{2}\lim_{t\to 0}\lim_{x'\to x}\mathrm{Tr}\left\{\gamma_{2n+1}\left(D_\nu - D_{\nu'}\right)K^{(2n)}\left(x,x';t\right)\right\}, \\ &\mathcal{A}^{(2n)}_{\mu\nu}(x) = \frac{1}{4}\lim_{t\to 0}\lim_{x'\to x}\mathrm{Tr}\left\{\gamma_{2n+1}\gamma_{\mu\nu}K^{(2n)}\left(x,x';t\right)\right\}, \end{aligned} \tag{6}$$

where 'Tr' runs over both indices of γ-matrix and T^a. These anomalies seem to break the general covariance and the local Lorentz symmetry simultaneously, but one of the symmetries is restored by using the relation $2D^\mu\mathcal{A}^{(2n)}_{\mu\nu} = \mathcal{A}^{(2n)}_\nu$ and redefining the expectation value of the energy-momentum tensor.[5] Einstein anomaly $G^{(2n)}_\nu$ is given by $\langle T'_{\mu\nu}\rangle = \langle T_{\mu\nu}\rangle - \mathcal{A}^{(2n)}_{\mu\nu}$. Thus, the local Lorentz symmetry is preserved.

$$D^\mu\left\langle T'_{\mu\nu}\right\rangle_S = G^{(2n)}_\nu = D^\mu\mathcal{A}^{(2n)}_{\mu\nu} = \frac{1}{2}\mathcal{A}^{(2n)}_\nu, \quad \left\langle T'_{\mu\nu}\right\rangle_A = 0, \tag{7}$$

where $\left\langle T'_{\mu\nu}\right\rangle_S$ is the symmetric part of $\left\langle T'_{\mu\nu}\right\rangle$. From (7), it is expected that the concrete form of the Einstein anomaly becomes the total derivative of the Lorentz anomaly. Substituting (4) into (6), $G^{(2n)}_\nu$ is rewritten by the coincidence limit of a_n and its first order derivative in (5),

$$G^{(2n)}_\nu(x) = \frac{1}{4(4\pi)^n}\mathrm{Tr}\left\{2\gamma_{2n+1}[a_{n!\nu}](x) - \gamma_{2n+1}[a_n]_{!\nu}(x)\right\}. \tag{8}$$

The tensorial form of the anomaly in 6 dimensions is obtained from

$$
\begin{aligned}
G_\nu^{(6)} &= \frac{1}{256\pi^3}\,\mathrm{Tr}\left\{\gamma_7\left(2\left[a_{3!\nu}\right]-\left[a_3\right]_{!\nu}\right)\right\} \\
&= \frac{1}{256\pi^3}\,\mathrm{Tr}\left\{\gamma_7\left[\frac{1}{6}\Lambda_{\mu\nu}\left(\frac{1}{6}R+X\right)^2+\frac{1}{45}J_{[\mu}X_{!\nu]}-\frac{1}{60}J_{[\mu!\nu]}X\right.\right. \\
&\quad +\frac{1}{15}\Lambda_{\mu\nu}X_{!\rho}{}^{\rho}+\frac{2}{45}\Lambda_{\mu\nu!\rho}X^{!\rho}+\frac{1}{40}\Lambda_{\mu\nu!\rho}{}^{\rho}X+\frac{1}{180}\left[\Lambda_{\mu\rho},\Lambda_\nu{}^{\rho}\right]X \\
&\quad +\frac{1}{180}R^{\rho}{}_{[\mu}\Lambda_{\nu]\rho}X+\frac{17}{360}R_{\mu\nu\rho\sigma}\Lambda^{\rho\sigma}X+\frac{1}{36}\Lambda_{\mu\nu}\Lambda_{\rho\sigma}\Lambda^{\rho\sigma} \\
&\quad \left.\left.+\frac{1}{45}\Lambda_{[\mu}{}^{\rho}\Lambda_{\nu]}{}^{\sigma}\Lambda_{\rho\sigma}-\frac{1}{90}\Lambda_{\mu\nu!\rho}J^{\rho}-\frac{1}{45}\Lambda_{\rho[\mu}J_{\nu]}{}^{!\rho}\right]^{;\mu}\right\}, \qquad (9)
\end{aligned}
$$

where $J_\mu \equiv \Lambda^{\rho}{}_{\mu!\rho}$. Since $\mathrm{Tr}\gamma_7 X = \mathrm{Tr}\{\gamma_7\Lambda_{\mu\nu}\} = 0$, terms containing X and $\Lambda_{\mu\nu}$ of one degree do not contribute to the anomaly. The concrete form of $G_\nu^{(6)}$ becomes some total derivatives before the trace operation of γ-matrices. Substituting (3) into (9) and performing the trace operation, $G_\nu^{(6)}$ yields many terms in tensorial form.

In this talk, we discuss the effect of BMS symmetries on quantum entanglement and its implications in the context of the black hole information paradox. In particular, we illustrate the gravitational memory effect for linear uniformly accelerated observers in a physical process involving a BMS shock-wave without planar/spherical symmetry. This classical memory is accompanied by a quantum memory that modulates the quantum entanglement between the opposing Rindler wedges in quantum field theory. A corresponding phenomenon across the Schwarzschild black hole horizon suggests that the Negativity measure of entanglement between infalling and outgoing Hawking pair should be degraded due to an infalling BMS shockwave while there should be linear order generation of Negativity between two outgoing Hawking particles. Implications are discussed.

Keywords: Gravitational memory effect, BMS, Negativity

1. Introduction

Bondi-Metzner-Sachs (BMS) showed that asymptotically flat spacetimes possess an infinite number of symmetries now known as the BMS supertranslations.[1] These diffeomorphisms extend the symmetry group of the standard four global translations at the asymptotic boundary. The BMS supertranslations are related to the gravitational memory effect and also the Weinberg's soft theorems via the so called Universal triad relations.[4–8] Based on these relations Hawking et. al. conjectured that applying these relations to an asymptotically flat spacetime with a black hole in the interior would imply the existence of an infinite number of soft hairs[2,3] for the black hole which can have possible implications in the context of the black hole information paradox.

One can analyse the process of implanting soft hairs on a black hole through a physical process involving a BMS type shock wave without spherical symmetry infalling into the horizon.[3] In this talk, we consider a simplified and analogous setting consisting of the Rindler horizon and the linearly uniformly accelerated (LUA) observers, but, in the presence of a BMS type shock wave, having planar asymmetry, and impinging onto the Rindler horizon; so as to analyse the effect of Rindler BMS

type supertranslations on LUA observers and on the Unruh thermal bath. The former constitutes the classical version of the gravitational memory effect on uniformly accelerated observers[9] while the effect on the latter is the quantum memory effect which modulates the quantum entanglement between the opposing Rindler wedges in quantum field theory.[10] A corresponding phenomenon across the Schwarzschild black hole horizon suggests that the Negativity measure of entanglement between infalling and outgoing Hawking pair should be degraded due to an infalling BMS shockwave while there should be linear order generation of Negativity between two outgoing Hawking particles. Implications are discussed.

2. Implanting supertranslational hair: Physical process

We work with the advanced Bondi-type co-ordinates (v, r, x, y) and write the metric of the Rindler spacetime as

$$ds^2 = -2\kappa r dv^2 + 2dvdr + \delta_{AB} dx^A dx^B \tag{1}$$

where $\kappa > 0$, $-\infty < v < \infty$ and $-\infty < r < \infty$. The BMS-type supertranslation diffeomorphism vector for the Rindler horizon which preserves the Bondi-type gauge and also the structure of the Rindler horizon is given by[11–15]

$$\Xi^a = \frac{1}{\kappa}[f(x,y), 0, -r\partial^A f(x,y)] \tag{2}$$

where $f(x, y)$ depends only on the transverse co-ordinates. The Rindler spacetime with a BMS type null shock wave at $v = v_0$ having non-planar symmetry infalling on the Rindler horizon at $r = 0$ is then defined to be[9]

$$\begin{aligned} ds^2 = &-2\kappa r dv^2 + 2dvdr + 4rh(v-v_0)\partial_A f dv dx^A \\ &+\left(\delta_{AB} + 2h(v-v_0)\frac{r}{\kappa}\partial_A\partial_B f\right)dx^A dx^B \end{aligned} \tag{3}$$

where $h(v - v_0)$ is the Heaviside step function. Essentially, the above metric is obtained by joining the Rindler supertranslated metric to the one described in Eq.(1) along the shock wave at $v = v_0$. The stress energy tensor including a surface energy term satisfying the null energy conditions is non zero along the shockwave at $v = v_0$ while it vanishes elsewhere for $v \neq v_0$.

3. Gravitational memory for LUA observers

The linearly uniformly accelerated (LUA) observers are the generalisation of the flat spacetime Rindler trajectories to the case of a curved background spacetime. As the name suggests, the LUA trajectories have constant magnitude of 4 vector acceleration and are also linear, in the sense of the Letaw-Frenet equations in a curved spacetime with vanishing torsion and hyper-torsion.[9] The linearity is essential since it guarantees that the LUA trajectory is locally hyperbolic in all local inertial frames at each point on the trajectory. Such trajectories satisfy the condition

$$u^b \nabla_b a^a = w^a = |a|^2 u^a \tag{4}$$

where u^i and a^i are the 4-velocity and the uniform magnitude 4-acceleration vectors respectively. The constraint in Eq.(4) guarantees that any change in the velocity and acceleration vectors lie in the same plane along the trajectory.

To address the question of finding the LUA trajectories for the case of infalling supertranslated BMS type shock wave on the Rindler horizon as described in section 2, we choose a representative family of orbits of the boost Killing vector $\bar{\xi}^a = \kappa^{-1}(1,0,0,0)$ in the advanced Bondi-type co-ordinates for $v < v_0$, the region before the wave. The worldline for such a family of trajectories is given by $x^a(\tau) = [\tau/\sqrt{2\kappa r_c}, r_c, x_c^A]$ where τ is the proper time and r_c, x_c^A are some fixed constants. These worldline can be extended over the BMS tyoe shock wave at $v = v_0$ by demanding that the constraint in Eq.(4) holds all along the trajectory. Working to linear order in the perturbation, the solution for the 4 velocity can be found to be

$$u^a = \left[\frac{1}{\sqrt{2\kappa r}}, 0, -h(v-v_0)\cosh[\kappa(v-v_0)]\frac{\sqrt{2\kappa r}}{\kappa}\partial^A f\right] \tag{5}$$

while the trajectories are found by integrating with respect to τ to be

$$x^a(\tau) = \left[\frac{\tau}{\sqrt{2\kappa r_c}}, r_c, x_c^A - h\left(\frac{\kappa(\tau-\tau_0)}{\sqrt{2\kappa r_c}}\right)\partial^A f(x_c^A) 2r_c \sinh\left(\frac{\kappa(\tau-\tau_0)}{\sqrt{2\kappa r_c}}\right)\right] \tag{6}$$

where τ_0 is the proper time at $v = v_0$. When the velocity vector in Eq.(5) is transformed to a set of standard Minkowski co-ordinates (T, X, Y^A), it takes the form

$$\begin{aligned} U^a = \Bigg[&\cosh\left(\frac{\kappa\tau}{\sqrt{2\kappa r_c}} - \frac{\log[\kappa r_c]}{2}\right), \sinh\left(\frac{\kappa\tau}{\sqrt{2\kappa r_c}} - \frac{\log[\kappa r_c]}{2}\right), \\ &h\left(\frac{\kappa(\tau-\tau_0)}{\sqrt{2\kappa r_c}}\right)\alpha^A \cosh\left(\frac{\kappa\tau}{\sqrt{2\kappa r_c}} - \kappa v_0\right)\Bigg] \end{aligned} \tag{7}$$

where $\alpha^A = \frac{\sqrt{2\kappa r_c}}{\kappa}\partial^A f(x_c^A)$. Interestingly one can check that a trajectory with given r_c, x_c^A is an integral curve of a boost Killing vector that is obtained by applying to $\bar{\xi}^a$ the Lorentz boost

$$\Lambda^a{}_b = \begin{pmatrix} 1 & 0 & \alpha^Y \cosh\beta & \alpha^Z \cosh\beta \\ 0 & 1 & -\alpha^Y \sinh\beta & -\alpha^Z \sinh\beta \\ \alpha^Y \cosh\beta & \alpha^Y \sinh\beta & 1 & 0 \\ \alpha^Z \cosh\beta & \alpha^Z \sinh\beta & 0 & 1 \end{pmatrix} \tag{8}$$

where $\beta = (1/2)\log[\kappa r_c] - \kappa v_0$. Note that the magnitude and direction of the boost (8) depend on r_c and x_c^A. Hence, we can conclude that even though, before the wave, we started with a family of solutions with the same boost killing vector $\bar{\xi}^a$, after the wave, each trajectory is an orbit of a different boost Killing vector as determined by the Lorentz boost in Eq.(8); thus implanting a supertranslational hair on the Rindler horizon by the non-planar BMS type matter shock wave and boosting a family of Rindler trajectories in a way that differs from trajectory to trajectory through their initial conditions. The trajectory-dependence essentially carries a memory of the

planar inhomogeneity of the wave and constitutes the gravitational memory effect for uniformly linearly accelerated observers.

4. Quantum memory

We consider a real massless Klein Gordon scalar field in the background of the shockwave metric of section 2. We only need to write down the solution of the perturbed Klein Gordon field upto the first order in the supertranslation field f. The Klein-Gordon field equation, $\nabla_a \nabla^a \phi = 0$ for the metric in Eq.(3), becomes

$$\begin{aligned} 0 = {} & 2\kappa r \partial_r^2 \phi + 2\partial_r \partial_v \phi + \partial_x^2 \phi + \partial_y^2 \phi + 2\kappa \partial_r \phi \\ & - 4rh(\partial^A f)\partial_r \partial_A \phi - 2\kappa^{-1} rh(\partial^A \partial^B f)\partial_A \partial_B \phi - 2h(\partial^A f)\partial_A \phi \\ & - 2\kappa^{-1} rh(\partial^A \partial_B \partial^B f)\partial_A \phi + \kappa^{-1} h(\partial_B \partial^B f)\partial_v \phi + \kappa^{-1} rh'(\partial_B \partial^B f)\partial_r \phi \ . \end{aligned} \tag{9}$$

The solution before the wave can be written as a complete set for positive frequency with respect to $\bar{\xi}$ as

$$\phi^0_{\omega,\mathbf{k}} = \sqrt{\frac{\sinh(\pi\omega/\kappa)}{4\pi^4\kappa}}\, e^{-i\omega v} \left(\frac{2k\sqrt{r}}{\sqrt{2\kappa}}\right)^{i\omega/\kappa} K_{i\omega/\kappa}\left(\frac{2k\sqrt{r}}{\sqrt{2\kappa}}\right) e^{ik_A x^A} \ , \tag{10}$$

where $\omega > 0$ and $\mathbf{k} = (k_x, k_y)$ and the mode functions satisfying the usual Klein Gordon inner product rules. For the $v > v_0$ region, we exploit the fact that the the metric in Eq.(3) is obtained as a diffeomorphism generated by the Rindler supertranslation vector field Ξ to obtain the solution in linear order of perturbation using the supertranslated vector as

$$\begin{aligned} \phi^1_{\omega,\mathbf{k}} &= (1 - \Xi^a \partial_a)\, \phi^0_{\omega,\mathbf{k}} \\ &= \left(1 + i\kappa^{-1}\omega f + i\kappa^{-1} r k_A \partial^A f\right) \phi^0_{\omega,\mathbf{k}} \ . \end{aligned} \tag{11}$$

We can now expand the solution at $v > v_0$ in the basis $\left\{\phi^1_{\omega,\mathbf{k}}\right\}$ to get

$$\widehat{\phi}_{\omega,\mathbf{k}} = \begin{cases} \phi^0_{\omega,\mathbf{k}} & \text{for } v < v_0; \\ \displaystyle\int_0^\infty d\omega' \int d^2\mathbf{k}' \left(\alpha_{\omega,\mathbf{k};\omega',\mathbf{k}'} \phi^1_{\omega',\mathbf{k}'} + \beta_{\omega,\mathbf{k};\omega',\mathbf{k}'} \phi^{1*}_{\omega',\mathbf{k}'}\right) & \text{for } v > v_0, \end{cases} \tag{12}$$

where the αs and βs are the Bogoliubov coefficients between the $\left\{\phi^0_{\omega,\mathbf{k}}\right\}$ basis and the $\left\{\phi^1_{\omega,\mathbf{k}}\right\}$ basis. Imposing the proper the matching conditions at $v = v_0$, one can evaluate the Bogoliubov coefficients in a perturbation series, the linear order form of which is presented in.[10] The explicit form shall not be needed here except for one significant detail that both the Bogoliubov coefficients are non-vanishing. We can then quantise the field in the standard way which would then imply that the Rindler vacuum in the $v < v_0$ region before the wave is not same as the vacuum in the $v > v_0$ region, that is, the presence of the asymmetric supertranslated shock wave changes the background Rindler vacuum. We next address the question how

the non-zero Bogoliubov coefficients affect the entanglement between the modes in the left and right Rindler wedge.

Before the shock wave we consider a two mode entangled state comprising of the left and right Rindler modes given by

$$|\Phi\rangle = |\phi_1\rangle \otimes |\phi_2\rangle \ , \tag{13}$$

where

$$|\phi_1\rangle = \frac{1}{\sqrt{1+p^2}} \left(|0\rangle_A \otimes |0\rangle_B + p|1\rangle_A \otimes |1\rangle_B\right) \ , \tag{14a}$$

$$|\phi_2\rangle = \frac{1}{\sqrt{1+q^2}} \left(|0\rangle_C \otimes |0\rangle_D + q|1\rangle_C \otimes |1\rangle_D\right) \ , \tag{14b}$$

and p and q are real-valued parameters. We have labelled the two modes as 1 and 2 and their corresponding left and right mode pairs as (A, B) and (C, D). The choice of such a particular state is motivated from the form of low frequency expansion of the entanglement between left and right Rindler modes in the Minkowski vacuum state and hence is also related to the low energy Hawking spectra in Black holes. We use the entanglement monotone of Negativity[16–23] to quantify the entanglement between different pairs of modes. The initial nonvanishing negativities are

$$\mathcal{N}_{A\leftrightarrow B} = \frac{p}{1+p^2} \ , \tag{15a}$$

$$\mathcal{N}_{C\leftrightarrow D} = \frac{q}{1+q^2} \ . \tag{15b}$$

After the wave, One can compute the Negativity between the different pairs of particles using the Bogoliubov coefficients in terms of their perturbative orders to get

Negativity	**Before wave** $v < v_0$	**After wave** $v > v_0$
A $\leftrightarrow$ B	$\frac{p}{1+p^2}$	$\downarrow \mathrm{O}(\lambda^2)$
B $\leftrightarrow$ D	0	$\uparrow \mathrm{O}(\lambda)$
B $\leftrightarrow$ C	0	$\uparrow \mathrm{O}(\lambda^2)$

The complete expressions are provided in.[10] One can observe from the above table that the negativity between the left and right modes A and B respectively is decreased by $\mathrm{O}(\lambda^2)$ while there is linear order generation of Negativity between the right Rindler modes B and D. We have further checked that this is consistent with the quantum monogamy relation for Negativity.

5. Discussion

We have investigated the gravitational memory effect for the Rindler family of uniformly linearly accelerated observers using the BMS-type symmetries of the Rindler horizon. We described a physical process analogous to that proposed by HPS[3] that

implants supertranslational hair on a Rindler horizon by a matter shock wave without planar symmetry. Before the wave, a family of observers are considered which are orbits of a single boost Killing vector. After the wave has passed, each observer satisfying the constraint of local hyperbolicity in Eq.(4) is found to be an orbit of a different boost Killing vector which differs from trajectory to trajectory. This is the classical memory effect for Rindler observers since the different boosts retains a memory of the planar inhomogeneity of the wave. The Classical memory is also accompanied by a supertranslation quantum memory which is found to modulate the entanglement between the opposing Rindler wedges in quantum field theory. A corresponding phenomenon across the Schwarzschild black hole horizon indicates that the Negativity measure of entanglement between infalling and outgoing Hawking pair should be degraded due to an infalling soft hair implanting shockwave while there should be linear order generation of Negativity between two outgoing Hawking particles Fig. 1.

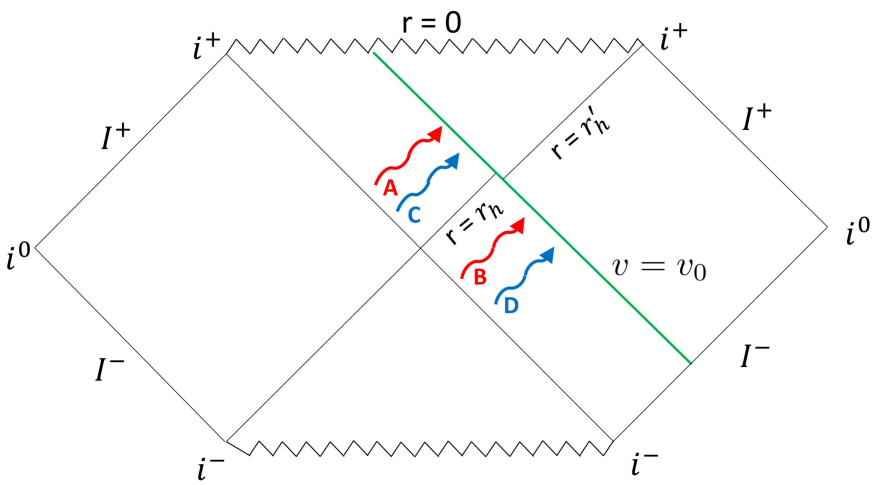

Fig. 1. The extended Schwarzschild spacetime with an infalling, supertranslation-implanting shock wave at $v = v_0$. Two Hawking pairs are shown, $A \leftrightarrow B$ (red) and $C \leftrightarrow D$ (blue).

Gravitational singularities, scattering maps for bouncing, and structure-preserving algorithms

Philippe G. LeFloch

Laboratoire Jacques-Louis Lions and Centre National de la Recherche Scientifique
Sorbonne Université, 4 Place Jussieu, 75252 Paris, France
Email: contact@philippelefloch.org. Blog: philippelefloch.org

This note emphasizes the role of multi-scale wave structures and junction conditions in many fields of physics, from the dynamics of fluids with non-convex equations of state to the study of gravitational singularities and bouncing cosmologies in general relativity. Concerning the definition and construction of bouncing spacetimes, we review the recent proposal in collaboration with B. Le Floch and G. Veneziano based on the notion of singularity scattering maps. We also present recent numerical investigations of small-scale phenomena arising in compressible fluid flows on FRLW or Kasner geometries for which we developed structure-preserving algorithms.

Keywords: Gravitational singularity; scattering map; small-scale phenomenon; structure-preserving algorithm.

1. Introduction

Recent advances on the mathematical modeling of complex fluid flows containing nonlinear waves and gravitational singularities lead to new challenges for numerical relativity. New ideas and techniques to analyze and compute the asymptotic behavior of multi-physics and multi-scale nonlinear waves have been introduced in the context of classical fluid dynamics but is relevant also for the dynamics of self-gravitating fluids. In this short note, we show some numerical results based on structure-preserving numerical algorithms for a few model problems describing multi-scale nonlinear waves on a fixed background. We also present a recent proposal for defining bouncing cosmologies, which is based on the notion of universal scattering maps for gravitational singularities.

This presentation uses material from joint collaborations, especially with B. Le Floch and G. Veneziano (scattering maps) and with F. Beyer (Fuchsian algorithm). It is based on a lecture entitled *"On the scattering laws of bouncing universes"* given at the *Sixteenth Marcel Grossmann Meeting* in July 2021. It is also based on a lecture entitled *"Gravitational singularities, massive fields, and asymptotic localization"* given at the Workshop *"Computational Challenges in Multi-Messenger Astrophysics",* held at IPAM, University of California at Los Angeles, in October 2021.

Only few references are included in this short note and, for our motivations to study bouncing cosmologies and relativistic fluids with complex equation of state,

we refer to the review papers by Ashtekar,[2] Blaschke,[7] Font,[11] as well as the recent papers by Ibánez et al.[10] and Wilson-Ewing.[23]

An outline is as follows. In Section 2 our standpoint concerning problems involving viscosity-capillarity waves and other multi-scale interfaces is discussed. In Section 3, numerical observations obtained with structure-preserving algorithms are overviewed for fluid problems in the vicinity of gravitational singularities. In Section 4, the scattering laws for gravitational singularities are presented and we distinguish between their universal and model-dependent properties.

2. Structure of multi-physics and multi-scale waves

2.1. *Multi-scale wave phenomena*

Systems of balance laws. The models of interest are formulated from first principles of continuum physics (that is, conservation laws or more generally balance laws) when suitable physics features are taken into account.

- Several parameters are often relevant in order to fully describe the fine dynamics of the fluid flows of interest: viscosity, surface tension, heat conduction, Hall effect, friction, etc. Various competitive effects take place, due to the presence of several very different scales in, both, the fluid unknowns and the geometry unknowns of the problem.
- These nonlinear systems of partial differential equations, in the course of the time evolution, exhibit a formation of interfaces, shocks, oscillating patterns, etc. Fluids, gases, plasmas, solid materials, etc. all exhibit fine structures that form dynamically. This is the case of liquid-vapor flows, thin liquid films, combustion wave problems, bores in shallow water, astrophysical flows, neutron stars, phase transformations (austenite-martensite), etc.
- Very often, a *fine-scale structure* (oscillations, turbulence) arises asymptotically (for instance in the vicinity of a singularity hypersurface) which is challenging to analyze mathematically and to compute numerically.

Asymptotic analysis. The ideas and techniques developed in the context of fluid dynamics are relevant for the modeling of the global dynamics of massive fields (Klein-Gordon), complex fluids, as well as models of modified gravity beyond Einstein gravity. In addition to the shock waves observed in fluid dynamics one must also encompass impulsive gravitational waves and cosmological singularities.

In order to understand the global dynamics of these *scale-sensitive nonlinear waves,* a novel perspective is required which is based on an asymptotic analysis of the physical models.

- We restrict attention to the regime where we can extract variables with well-defined limits, even though persistent oscillations in some other variables may be observed as the singularity is approached.

- We seek junction laws or scattering laws, which in the case of fluid take the form of jump laws for (subsonic) liquid-gas boundaries, for combustion waves, etc.
- The interfaces that require additional junction laws are typically *undercompressive waves* and turn out to enjoy (saddle) stability properties.

2.2. *Regime of small viscosity and capillarity*

Non-convex equation of state. One of the simplest partial differential equation that exhibits small-scale dependent interfaces is the following model in plane-symmetry formulated as a hyperbolic conservation law with non-convex equation of state $p(\rho) = \rho^3$

$$\frac{\partial}{\partial t}\rho + \frac{\partial}{\partial x}\rho^3 = \varepsilon\,\frac{\partial^2}{\partial x^2}\rho + \kappa\,\frac{\partial^3}{\partial x^3}\rho, \tag{1}$$

for a fluid density unknown $\rho = \rho(t,x)$ (with $t \geq 0$ and $x \in \mathbb{R}$, say). This equation describes certain phase transition phenomena, but also arises as a simplified model of magnetohydrodynamics. Here, a small viscosity coefficient $\varepsilon > 0$ and a surface tension/capillarity coefficient $\kappa > 0$ are given, the latter representing the intermolecular forces between a liquid and its surroundings.

The Riemann problem consists of an initial value problem associated with a single initial discontinuity (also called the dam breaking problem). Interestingly, in the limit of arbitrarily small $\varepsilon, \kappa \to 0$, the equation (1) exhibits complex wave patterns, which are more involved than the ones usually observed with (polytropic perfect, say) compressible fluids. See the illustration in Figure 1. Many scalar wave models exhibit the same features, for instance the so-called thin liquid film model and the so-called Benjamin–Bona–Mahony model. Let us for instance give here a class of fourth-order models (with $\varepsilon, \kappa, \lambda > 0$):

$$\frac{\partial}{\partial t}\rho + \frac{\partial}{\partial x}p(\rho) = \varepsilon\,\frac{\partial^2}{\partial x^2}\rho + \kappa\,\frac{\partial^3}{\partial x^3}\rho - \lambda\,\frac{\partial^4}{\partial x^4}\rho. \tag{2}$$

Three possible asymptotic regimes. In the limit $\varepsilon \to 0$ in (1), we should distinguish between three behaviors depending upon the capillarity parameter κ:

- $\kappa << \varepsilon^2$: the viscosity is then dominant, and no oscillations are observed while a single limit is reached. The solutions (sometimes referred to as classical weak solutions) are characterized by standard Rankine-Hugoniot relations and entropy criteria.
- $\kappa = \alpha\,\varepsilon^2$: this is the *balanced regime* of main interest in the present discussion. The numerical solutions converge in a strong sense, despite some mild oscillations in the limit. (See again Figure 1.) Interestingly, the limit (now sometimes referred to as a nonclassical weak solution) *depends upon the ratio* $\alpha = \kappa/\varepsilon^2$ of the viscosity and capillarity parameters. (See also Figure 3 for van der Waals fluids.)

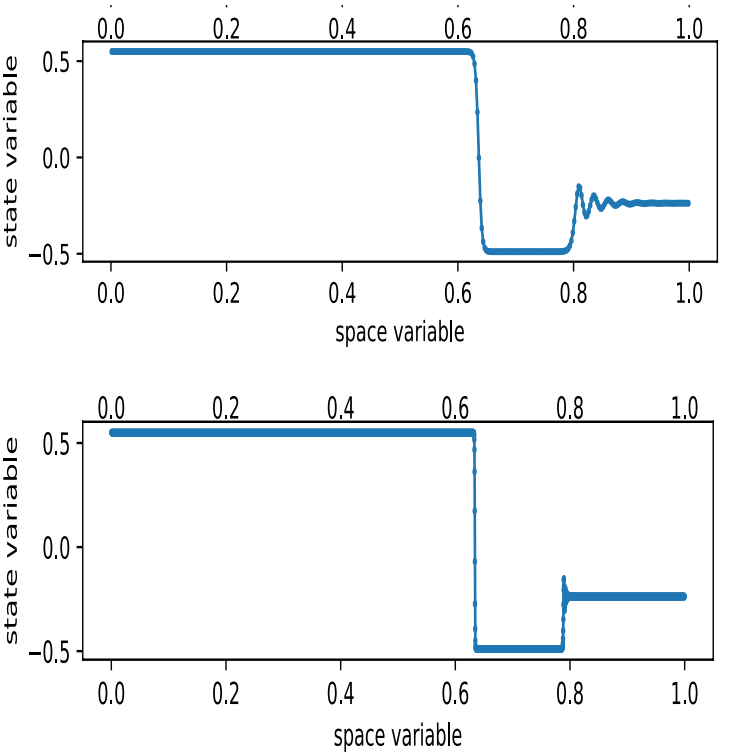

Fig. 1. The Riemann problem for a non-convex equation of state.

- $\kappa >> \varepsilon^2$: in this regime, the effect of the surface tension is dominant and wild oscillations arise as $\varepsilon \to 0$. There is no well-defined limit, unless weak convergence techniques or a suitable turbulence-like theory are introduced.

Wave structure of van der Waals fluids. Let us provide a further illustration with the system of isothermal compressible fluids which is closest to the interest of the GR community. We consider a Van der Waals fluid, in a non-relativistic setup, whose dynamics is modeled by the following two conservation laws (continuity equation, conservation of momentum) :

$$\frac{\partial}{\partial t}\tau - \frac{\partial}{\partial x}u = 0, \qquad \frac{\partial}{\partial t}u + \frac{\partial}{\partial x}p(v) = \varepsilon\,\frac{\partial^2}{\partial x^2}u - \kappa\,\frac{\partial^3}{\partial x^3}\tau, \tag{3}$$

in which $\tau = 1/\rho$ represents the specific volume and u denotes the velocity component for plane-symmetric solutions to the Euler equations. The viscosity parameter ε and the capillarity parameter κ are taken to be small. We assume that the temperature T remains constant (in a suitable approximation) and we model liquid-vapor phase transitions by the non-convex pressure law (after normalization)

$$p(\tau) = \frac{8T}{3\tau - 1} - \frac{3}{\tau^2}. \tag{4}$$

The equations (3)-(4) are nonlinear hyperbolic when T is sufficiently large, but of mixed (hyperbolic-elliptic) type otherwise. The typical Riemann wave structure for van der Waal fluids is shown in Figure 2.

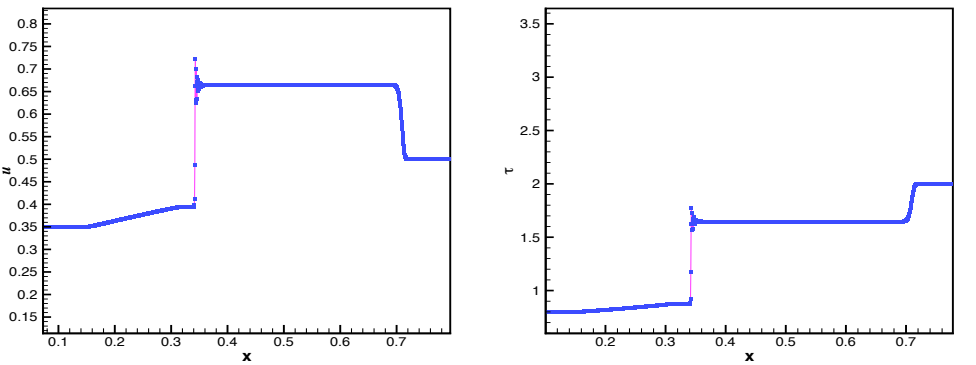

Fig. 2. Van der Waals fluids: velocity (left-hand) and specific volume (right-hand).

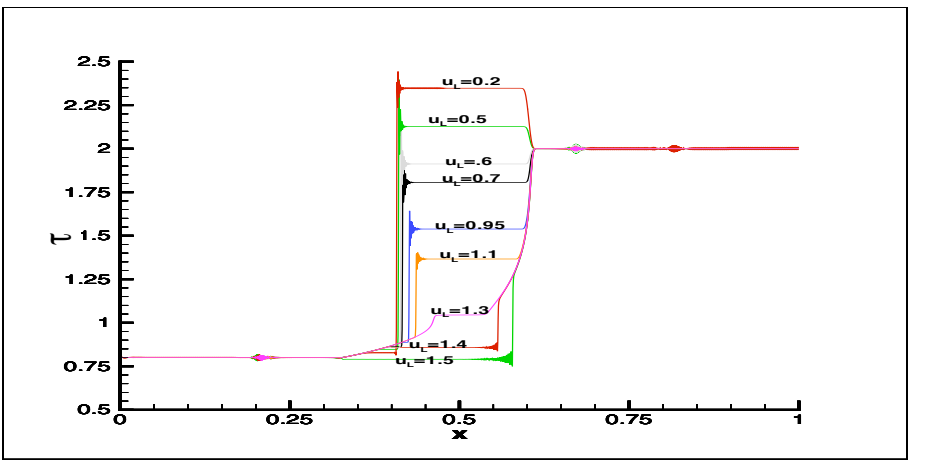

Fig. 3. Van der Waals fluids: specific volume for different ratios of the viscosity and capillarity.

Proposed standpoint: hidden junction conditions. Small-scale dependent, shock waves enjoy a structure that is not properly captured by the standard Rankine-Hugoniot junction conditions of fluid dynamics, even when a suitable entropy condition is enforced. Further analytical work is required which shows that

the wave structure strongly depends upon varying the ratio surface tension/viscosity $\kappa = \alpha\,\varepsilon^2$ (in the balanced regime). (See again Figure 3 for van der Waals fluids.) Suitable rules for connecting left- and right-hand state values from both sides of the interface is necessary, beyond the standard Rankine-Hugoniot relations. These *scattering laws* take the form, in this context, of *kinetic functions for interfaces*. It is outside the scope of this short Note to explain this notion here, and we refer the reader to the textbook[13] and the lecture notes[12,14] and the historical references therein. Importantly, based on these scattering maps we need to design structure-preserving algorithms, which are typically of front tracking type, or of shock capturing type with well-controlled dissipation.[15] The algorithms are designed in order to *mimic analytical properties at the discrete level* and this requirement may take very different flavors: divergence form, spacelike decay, timelike decay shock-capturing, energy balance laws, asymptotics on singularities, etc.

3. Structure-preserving algorithms for fluids near gravitational singularities

3.1. *Preserving the asymptotic structure on a Kasner background: evolution from the singularity*

Evolution in the vicinity of a gravitational singularity. In a joint work with F. Beyer,[6] I have studied the evolution of a compressible fluid on a Kasner geometry, namely on a spatially homogeneous, anisotropic vacuum background described by the metric

$$g = t^{(K^2-)/2}\big(-dt^2 + dx^2 + t^{1-K}dy^2 + t^{1+K}dz^2\big), \qquad M = (0,+\infty)\times\mathbb{T}^3 \tag{5}$$

Here, we set $t \in (0,\infty)$ and $x, y, z \in (0, 2\pi)$ and we introduce the parameter $K \in \mathbb{R}$ and the Kasner exponents

$$p_1 = \frac{K^2-1}{K^2+3}, \quad p_2 = \frac{2(1-K)}{K^2+3}, \quad p_3 = \frac{2(1+K)}{K^2+3}. \tag{6}$$

The free parameter $K \in \mathbb{R}$ is sometimes referred to as the *asymptotic velocity*. Except for the three flat Kasner cases given by $K = 1$, $K = -1$, and (formally) $|K| \to \infty$, the Kasner metrics g have a curvature singularity in the limit $t \searrow 0$. We treat a compressible fluid flow with pressure law

$$p = (\gamma-1)\rho \quad \text{ with } \gamma \in (1,2). \tag{7}$$

Fuchsian analysis for the Euler equations of compressible fluids. In[6] we discovered a *characteristic fluid exponent* defined as

$$\Gamma = \frac{1}{4}\big(3\gamma - 2 - K^2(2-\gamma)\big) \in (0,1), \tag{8}$$

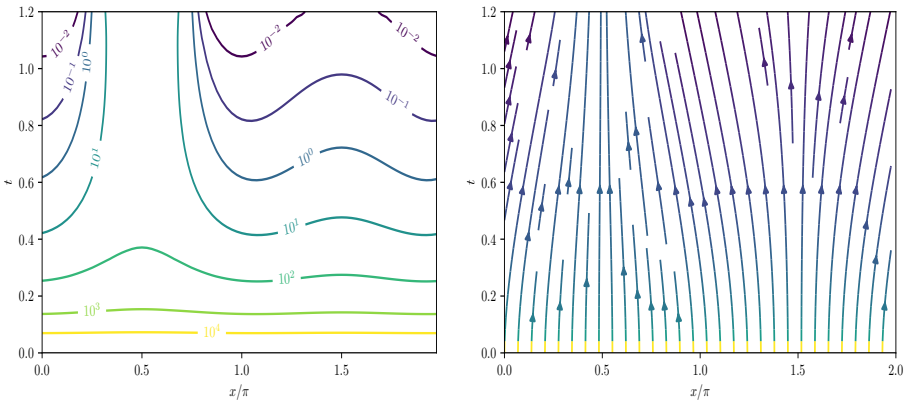

Fig. 4. Evolution of a compressible fluid **from** a gravitational singularity: Kasner background.

which compares the geometry and fluid behaviors:

- $\Gamma > 0$: this is a sub-critical regime which is dynamically stable.
- $\Gamma \leq 0$: this is a super-critical (or critical) regime which is dynamically unstable.

This (positivity/negativity) condition arises by plugging an expansion in power of t for the fluid unknown variables of the Euler equations, and attempting to validate this expansion in t via the Fuchsian method.

The Fuschian method concerns the evolution problem *from* the cosmological singularity $t = 0$ (rather than *towards* it). We formulate a singular initial value problem of the form

$$B^0(U,t,x)\frac{\partial}{\partial t}U + B^1(U,t,x)\frac{\partial}{\partial x}U = f(U,t,x) \tag{9}$$

with suitable "singular initial data" prescribed at $t = 0$. Fuchsian-type expansions are then derived from an ODE approximation near the cosmological singularity. In the present work, we focus on the sufficiently regular, shock-free regime for the Euler equations.

Algorithm preserving the Fuchsian structure. We approximate the singular Cauchy problem of Fuchsian type by a sequence of regular Cauchy problems, which we next discretize by the pseudo-spectral method of lines, say $U(t,x) \simeq V(t) = (V_j(t))$ with

$$\partial_t V - AV = h(V,t). \tag{10}$$

A high-order Runge-Kutta discretization is used in time. Importantly, we introduce *suitably rescaled variables* and next careful study of the numerical error. To this

end, we take into account the Fuchsian expansion available near the singularity. We observe that there are two sources of approximation error, namely continuum and discrete.

Our proposal in order to get an efficient algorithm is to *keep the two error sources asymptotically in balance*. With this numerical strategy, we can demonstrate the *nonlinear stability of the flow* near the cosmological singularity in the sub-critical regime. See Figure 4 for a numerical simulation on a Kasner background for a typical evolution from the singularity. The fluid density is shown in contour plot while the normalized velocity field is shown in flow lines.

The density ρ unbounded as the time $t \to 0$, and we carefully checked the numerical error in order to produce quantitative error control. In turn we arrive at reliable and accurate algorithm, despite the solutions being *highly singular*.

3.2. *Preserving the asymptotic structure on an inhomogeneous FLRW background*

Evolution of fluid with shock waves. In a joint work[8,9] with Y. Cao and M. Ghazizadeh, I have considered the evolution of a compressible fluid *toward* a cosmological singularity. Therein, we consider the Cauchy problem i isothermal, relativistic compressible flow with linear pressure law $p(\rho) = k^2\rho$. The background geometry is taken to be a contracting (or expanding) inhomogeneous background with torus topology $\mathbb{T}^2$, corresponding to a FLRW-type cosmological background with small inhomogeneities. For isothermal fluids, the Euler equations take the form of a system of two nonlinear hyperbolic balance laws, which we treat in one and in two space dimensions under symmetry assumptions. Let us focus here on the future-contracting direction ($t < 0$ with $t \to 0$) and we observe that the mass energy density $\rho \to +\infty$. The expanding direction is also treated in.[8,9] The challenge is to design a scheme that preserves the structure of the solutions as the singularity is approached and the unknown variables become singular.

We analyze the asymptotic behavior of the fluid variables toward the cosmological singularity, by rewriting first the equations as a nonlinear hyperbolic systems on a curved geometry, say

$$\partial_t U + \partial_x F(t, x, U) = H(t, x, U). \tag{11}$$

Two *competitive effects* take place in this problem which concern the contracting geometry and the shock propagation. The nonlinear wave interactions give rise to a small-scale structure, which in the present setup is simply driven by the background geometry. Yet, we can keep in mind the analogy with phase transition dynamics which involves multiple scales as explained in Section 2. Extensive numerical experiments were performed in one and in two space dimensions are performed in order to investigate the fine behavior of the solutions in the vicinity of the singularity.

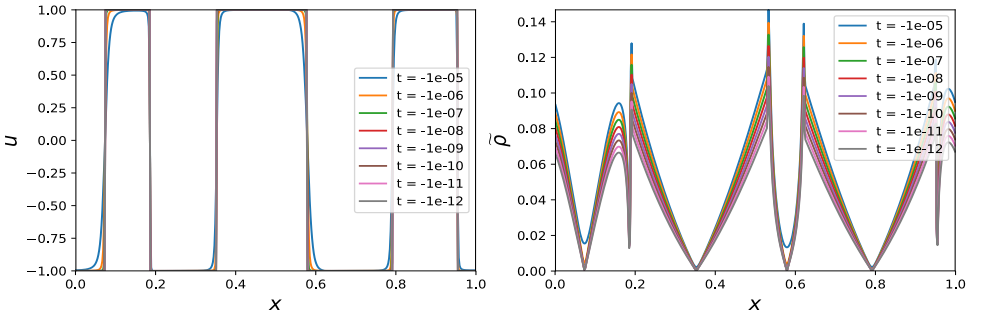

Fig. 5. Evolution of a compressible fluid **toward** a gravitational singularity. Left-hand: velocity scalar. Right-hand: rescaled mass energy density.

Structure-preserving methodology. We formulate a shock-capturing scheme in divergence form, based on the finite volume methodology. The shock-capturing property ensures that the shock waves will propagate with the correct speed given by the Rankine-Hugoniot condition. We require high accuracy and use a discretization which is 4th-order in time and 2nd-order in space, hence ensure that the numerical solution is oscillation-free. In order to guarantee the *well-balanced property* we proceed as follows:

- We introduce suitably *rescaled unknowns* which are directly motivated by a Fuchsian analysis of the problem.
- The discrete form of the balance laws is designed in order to enforce the correct *asymptotic state equations at the discrete level*.
- In turn , we enforce the *commutation property*

$$\lim_{t\to 0}\lim_{\Delta x\to 0} U = \lim_{\Delta x\to 0}\lim_{t\to 0} U \tag{12}$$

relating the limits of the numerical solution $U_{\Delta x}(t,x)$

The typical behavior that we observed *toward* the cosmological singularity are sharp transitions with spikes, and these spikes turn out to be well capured by our numerical method in the asymptotic limit $t \to 0$. See the plots of the rescaled velocity component u and rescaled density $\widetilde{\rho}$. See Figure 5 for the evolution of a compressible fluid **toward** a gravitational singularity.

4. On the scattering laws of bouncing universes

4.1. *Seeking a formulation of bouncing laws*

Bouncing cosmologies. In a joint work in collaboration with B. Le Floch (Paris) and G. Veneziano (Geneva) I considered gravitational singularities in the context of the Einstein equations coupled to a self-gravitating scalar field. More generally, our ideas apply to a stiff fluid or a compressible fluid. We are interested in analyzing

bouncing cosmologies involving a contracting phase and an expanding phase of evolution, connected across a singularity hypersurface. Our analysis takes place in the vicinity of such a singularity hypersurface, and we focus on the jump relations that should hold at that interface. Recall that in presence of strong fields or away from the near-Minkowski regime of evolution, Penrose and Hawking's singularity theorems (or incompleteness theorems) suggest that gravitational singularities (or other incompleteness phenomena) are expected to occur, although very little is known on the actual asymptotic behavior beyond the classical BKL conjecture.

Physics literature on bouncing. We build upon a large literature on bouncing cosmologies by Penrose, Tod, Lübbe, Turok, Barrow, and many others. We emphasize that existing proposals are based on the analysis of symmetric spacetimes and/or the formulation of special junctions. In order to define the bouncing, a large number of proposals are found in the literature, including the pre-Big Bang scenario (Gasperini, Veneziano, etc.), a variety of models of modified gravity-matter (Brandenberger, Chamseddine, Cotsakis, Mukhanov, Peter, Steinhardt, Turok, etc.), and the theory of loop quantum cosmology (Asthekar, de Cesare, Gupt, Pawlowski, Singh, Wilson-Ewing, etc.).

Proposed standpoint. Our aim is to propose a formulation of the problem of junction at singularities and to perform a systematic investigation of such junction conditions. This is motivated by the ideas discussed in Section 2. We expect to derive classes of physically meaningful junction conditions which depend upon certain (limited) degrees of freedom and constraints at the singularity. Interestingly, based on the scattering maps we propose we can also define and construct classes of cyclic spacetimes. Here, we only outline a selection of our results and refer the reader to[18–20] for the complete definitions and further material.

We study the class of (past, future) *singularity data* denoted by $(g^{\pm}, K^{\pm}, \phi_0^{\pm}, \phi_1^{\pm})$ and defined after a suitable rescaling (see below). We then introduce a *singularity scattering map* $(g^-, K^-, \phi_0^-, \phi_1^-) \mapsto (g^+, K^+, \phi_0^+, \phi_1^+)$ in order to cross the singularity hypersurface. Our main contribution is a full classification of the possible bouncing conditions. We are able to distinguish between *universal* scattering laws and *model-dependent* scattering maps.

We thus provide a flexible framework and a classification which uncovers all possible classes of junctions that are geometrically and physically meaningful. We also exhibit several sub-classes of particular interest, namely the conformal/non-conformal maps, the spacelike/null/timelike maps, and we encompass different models of matter (scalar field, stiff fluid, compressible fluid). In the course of establishing our classification, we also discover three universal laws that put constrains on the macroscopic aspects of spacetime bounces, *regardless of their origin from different microscopic corrections*. Our classification provides one with a guide in order to uncover relevant structures, described by scattering maps associated with specific theories.

4.2. *Proposed formulation of the bouncing problem*

The field equations. We consider a local ADM formulation near a singularity hypersurface, based on a Gaussian foliation (local patch) $\mathcal{M}^{(4)} = \bigcup_{\tau\in[\tau_{-1},\tau_1]} \mathcal{H}_\tau$ by spacelike hypersurfaces (diffeomorphic to $\mathcal{H}_0$). We write

$$g^{(4)} = \big(g^{(4)}_{\alpha\beta}\big) = -d\tau^2 + g(\tau) \qquad g(\tau) = g_{ij}(\tau)dx^i dx^j, \tag{13}$$

and we impose Einstein's evolution equations for the unknown metric g and the unknown extrinsic curvature K

$$\partial_\tau g_{ij} = -2\,K_{ij} \qquad \partial_\tau K^i_j = \mathbf{Tr}(K)K^i_j + R^i_j - 8\pi\, M^i_j. \tag{14}$$

Here, $M^i_j = \frac{1}{2}\rho g^i_j + T^i_j - \frac{1}{2}\mathbf{Tr}(T)g^i_j$ is the matter contribution. These equations are supplemented with Einstein's constraint equations

$$R + |K|^2 - \mathbf{Tr}(K^2) = 16\pi\rho \qquad \nabla_i K^i_j - \nabla_j(\mathbf{Tr}K) = 8\pi J_j, \tag{15}$$

which are nonlinear elliptic equations. Finally, we assume that the energy-momentum tensor is given by a massless scalar field ϕ whose evolution is given by the wave equation

$$\Box_{g^{(4)}}\phi = 0. \tag{16}$$

Near a singularity hypersurface, it is standard to rely on the Fuchsian method (Baouendi, Goulaouic, Rendall, Isenberg, Moncrief, etc.):

- We solve locally from $\tau = 0$ toward the past ($\tau < 0$) or the future ($\tau > 0$).
- We apply the so-called "velocity dominated" Ansatz, which tells us that in the gauge under consideration all spatial derivatives (except for the momentum equations) can be neglected.
- In turn, we must solve a system of nonlinear coupled differential equations in the time variable with nonlinear source-terms (containing spatial derivatives) and by a suitable iteration scheme we generate solutions to the full Einstein equations.

Singularity data and asymptotic profiles. A 3-manifold $\mathcal{H}$ is fixed throughout and represents the singularity hypersurface.

1. An **asymptotic profile** associated with data $(g^-, K^-, \phi_0^-, \phi_1^-) \in \mathbf{I}(\mathcal{H})$ is the flow on $\mathcal{H}$
$$\begin{aligned} \tau \in (-\infty, 0) \mapsto \big(g^*, K^*, \phi^*\big)(\tau), \qquad & g^*(\tau) = |\tau|^{2K^-} g^-, \\ K^*(\tau) = \frac{-1}{\tau} K^-, \qquad & \phi^*(\tau) = \phi_0^- \log|\tau| + \phi_1^-, \end{aligned} \tag{17}$$
in which $|\tau|^{2K^-}$ is defined by exponentiation.
2. A **singularity initial data set** $(g^-, K^-, \phi_0^-, \phi_1^-)$, consists of two tensor fields (rescaled metric and extrinsic curvature) and two scalar fields defined on $\mathcal{H}$.

3. The **asymptotic version of the Einstein constraints** reads as follows:

$$\begin{array}{ll} \text{Riemannian metric} & g^- = (g^-_{ij}) \text{ on } \mathcal{H}. \\ \text{CMC symmetric } (1,1)\text{-tensor} & K^- = (K_i^{-j}) \text{ with } \mathbf{Tr}(K^-) = 1 \text{ on } \mathcal{H}. \\ \text{Hamiltonian constraint} & 1 - |K^-|^2 = 8\pi\,(\phi_0^-)^2 \text{ on } \mathcal{H}. \\ \text{momentum constraints} & \mathbf{Div}_{g^-}(K^-) = 8\pi\,\phi_0^-\, d\phi_1^- \text{ on } \mathcal{H}. \end{array} \tag{18}$$

We denote by $\mathbf{I}(\mathcal{H})$ the set of space of all singularity data.

Junction conditions. The notion of a *scattering map* arises naturally from earlier considerations about fluid interfaces. We think of a singularity hypersurface as a fluid-like interface between two "phases", across which the geometry and the matter field encounter a "jump". Small-scale physics phenomena are not directly modeled at this stage. We are only interested in the "average" effect rather than the detailed physics that may take place "within" this interface. This is a standard strategy in fluid dynamics and material science in presence of phase transition phenomena, especially when some (micro-scale) parameters (viscosity, surface tension, heat conduction, etc.,) can be neglected in the modeling. Macro-scale effects are captured by jump conditions such as Rankine-Hugoniot, kinetic relations, Dal Maso-LeFloch-Murat's paths, etc. For instance, kinetic relations in material science (martensite-austenite) and in two-phase liquid-vapor flows have been extensively studied. In this context, hypersurfaces are timelike; in the present discussion of gravitational singularities we focus our attention on spacelike hypersurfaces and refer the reader to[19] for the treatment of timelike singularity hypersurfaces.

Bounce based on a singularity scattering map. A (past-to-future) **singularity scattering map** on $\mathcal{H}$ is defined as a diffeomorphism-covariant map on $\mathbf{I}(\mathcal{H})$

$$\mathbf{S} : \mathbf{I}(\mathcal{H}) \ni \left(g^-, K^-, \phi_0^-, \phi_1^-\right) \mapsto \left(g^+, K^+, \phi_0^+, \phi_1^+\right) \in \mathbf{I}(\mathcal{H}) \tag{19}$$

satisfying the *ultra-locality property*: for all $x \in \mathcal{H}$

$$\mathbf{S}(g^-, K^-, \phi_0^-, \phi_1^-)(x) \text{ depends only on } (g^-, K^-, \phi_0^-, \phi_1^-)(x) \tag{20}$$

Thanks to the locality condition, it is natural to identify singularity scattering maps $\mathbf{S}$ on all 3-manifolds and suppress the dependence on $\mathcal{H}$.

The map $\mathbf{S}$ is said to be a **tame-preserving map** if it preserves positivity, in the sense that

$$\text{if } K^- > 0 \text{ then } K^+ > 0, \text{ where } K^+ \text{ is defined from the image of } \mathbf{S}. \tag{21}$$

It is said to be a **rigidly-conformal map** if

$$g^+ \text{ and } g^- \text{ only differ by a conformal factor.} \tag{22}$$

Observations. We emphasize that the asymptotic profiles with $K^-, K^+ > 0$ describe a "bounce" at which

- volume element decreases to zero as $\tau \to 0^-$, and
- then increases back to finite values for $\tau > 0$.

For further notions and constructions of *cyclic spacetimes* containing many singularity hypersurfaces, we refer to[19] and, in this short Note, we focus on the issue of defining a proper junction at the bouncing.

The regime of quiescent singularities $K > 0$ is motivated by the absence of BKL oscillations in this case (named after Belinsky, Khalatnikov, and Lifshitz). This quiescent regime exhibits a monotone behavior which has received a lot of attention by mathematicians in recent years (Rendall, Andersson, Lott, Fournodavlos, Luk, Rodnianksi, Speck, etc.).

4.3. *Classification of bouncing laws*

Rigidly conformal maps. We discover that *only two classes* of ultra-local spacelike and rigidly conformal, singularity scattering maps exist for self-gravitating scalar fields, namely:

- The maps describing **isotropic rigidly conformal bounces** $\mathbf{S}^{\text{iso, conf}}_{\lambda,\varphi}$:

$$g^+ = \lambda^2 g^-, \qquad K^+ = \delta/3, \qquad \phi_0^+ = 1/\sqrt{12\pi}, \qquad \phi_1^+ = \varphi, \tag{23}$$

  parametrized by a conformal factor $\lambda = \lambda(\phi_0^-, \phi_1^-, \det K^-) > 0$ and a constant φ.
- The maps describing **non-isotropic rigidly conformal bounces** $\mathbf{S}^{\text{ani, conf}}_{f,c}$:

$$\begin{aligned} g^+ &= c^2\mu^2 g^-, & K^+ &= \mu^{-3}(K^- - \delta/3) + \delta/3, \\ \phi_0^+ &= \mu^{-3}\phi_0^-/F'(\phi_1^-), & \phi_1^+ &= F(\phi_1^-), \end{aligned} \tag{24}$$

  parametrized by a constant $c > 0$ and a function $f\colon \mathbb{R} \to [0, +\infty)$:

$$\mu(\phi_0, \phi_1) = \big(1 + 12\pi(\phi_0)^2 f(\phi_1)\big)^{1/6}, \; F(\phi_1) = \int_0^{\phi_1} (1 + f(\varphi))^{-1/2} d\varphi. \tag{25}$$

General classification. *Only two classes* of ultra-local spacelike singularity scattering maps exist for self-gravitating scalar fields, which we denote by $\mathbf{S}^{\text{iso}}_{\lambda,\varphi}$ (isotropic bounce) and $\mathbf{S}^{\text{ani}}_{\Phi,c}$ (non-isotropic bounce). Now, λ is a two-tensor, Φ a "canonical transformation", c a constant. For the detailed expressions we refer the reader to.[19]

Three universal laws of quiescent bouncing cosmology. Interestingly our conclusions can be restated in terms of universal laws obeyed by any ultra-local bounce, as follows.

- **First law. Scaling of Kasner exponents**:

$$\begin{aligned} &\text{There exists a (dissipation) constant } \gamma \in \mathbb{R} \text{ such that} \\ &|g^+|^{1/2}\mathring{K}^+ = -\gamma\,|g^-|^{1/2}\mathring{K}^- \end{aligned} \tag{26}$$

  for the spatial metric g in synchronous gauge with volume factor $|g|^{1/2}$, where $\mathring{K}$ denotes the traceless part of the extrinsic curvature (as a $(1,1)$ tensor).
- **Second law. Canonical transformation of matter:** by denoting the conjugate matter momentum by $\pi_\phi \sim \phi_0$,

$$\begin{aligned} &\text{there exists a nonlinear map } \Phi\colon (\pi_\phi, \phi)^- \mapsto (\pi_\phi, \phi)^+ \\ &\text{preserving the volume form in the phase space } d\pi_\phi \wedge d\phi \\ &\text{and depending solely on the scalar invariant } \mathbf{det}(\mathring{K}_-). \end{aligned} \tag{27}$$

- **Third law. Directional metric scaling:**

$$\begin{aligned} &g^+ = \exp\bigl(\sigma_0 + \sigma_1 K + \sigma_2 K^2\bigr) g^-, \\ &\text{which is a nonlinear scaling in each proper direction of } K. \end{aligned} \tag{28}$$

  We have either $\gamma = 0$ in the isotropic scattering and no restriction $\sigma_0, \sigma_1, \sigma_2$, or else $\gamma \neq 0$ for non-isotropic scattering and explicit formulas are available in terms of Φ, γ.

4.4. *Ongoing work*

Our next task will be the derivation of scattering maps associated with specific theories taking small-scale physical modeling into account. Mathematical investigations as well as numerical investigations are required. We emphasize that our methodology is based on a class of *general* spacetimes without symmetry restrictions. Earlier approaches relied on classes of symmetric spacetimes or on special junction proposals, and therefore could not single out the three universal laws we have derived. The recent developments overviewed in the present Note suggest to perform numerical simulations of cyclic spacetimes with a bounce using some of the techniques discussed in Sections 2 and 3. We refer the reader to[18–20] and to.[17]

We present recent results on the asymptotics of a brane-world that consists of a flat 3-brane embedded in a five-dimensional bulk. The bulk matter is modelled by a fluid that satisfies a nonlinear equation of state of the form $p = \gamma\rho^{\lambda}$, where p is the 'pressure' and ρ is the 'density' of the fluid. We show that for appropriate ranges of the parameters γ and λ, it is possible to construct a regular solution, compatible with energy conditions, that successfully localizes gravity on the brane. These results improve significantly previous findings of the study of a bulk fluid with a linear equation of state.

Keywords: Brane-worlds, singularities

1. Introduction

In this paper, we review very recent work, presented in,[1] on the asymptotic behaviors of a class of brane-worlds. The models consist of a flat 3-brane embedded in a five-dimensional bulk filled with a fluid that satisfies a nonlinear equation of state $p = \gamma\rho^{\lambda}$, where p is the 'pressure' and ρ is the 'density' of the fluid and γ, λ are constants.

Such an equation of state, has been studied in cosmology for its contribution in avoiding big-rip singularities during late time asymptotics,[2–4] in obtaining inflationary models with special properties,[5] in unifying models of dark energy and dark matter,[6,7] as well as in studies of singularities.[8–10]

Our goal in studying these brane-world models, is to find a solution that is regular and meets physical requirements set by energy conditions and localization of gravity on the brane. In our previous work in,[11–16] which extended work done

in brane-worlds with scalar fields,[17–19] we studied a 3-brane (flat or curved) and a fluid with a linear equation of state $p = \gamma\rho$. We found that such a solution becomes possible only for the special value of $\gamma = -1$ and only for a flat brane. These results gave us the motivation to explore whether the generalization of the linear equation of state to a nonlinear one, could have a decisive impact in finding a solution with all required properties and valid for a wide range of γ and λ. This exploration turned out to be very fruitful, and we were able to find in[1] such solutions for a flat brane and a fluid with $\gamma < 0$ and $\lambda > 1$.

As the analysis of the nonlinear equation of state is quite complicated, for the most part of this paper, we will focus on the study of a specific value of $\lambda = 3/2$, which is simpler for illustration and offers important insight on the behavior of solutions for general $\lambda > 1$.

The structure of this paper is the following: In Section 2, we set up our model and derive the field equations. In Section 3, we formulate the null energy condition which we embody in our solutions later in Section 4. In Section 5, we derive a matching solution for the specific value of $\lambda = 3/2$ and based on this solution, we calculate, in Section 6, the four-dimensional Planck mass. Finally, in Section 7, we discuss briefly the asymptotic behaviors of solutions for general λ.

2. Setup of brane-world

To set up our model, we start by considering a flat 3-brane embedded in a five-dimensional bulk with a metric of the form,

$$g_5 = a^2(Y)g_4 + dY^2, \tag{1}$$

where $a(Y)$ is the warp factor and g_4 is the four-dimensional flat metric, *i.e.*,

$$g_4 = -dt^2 + dx_1^2 + dx_2^2 + dx_3^2. \tag{2}$$

The timelike coordinate is denoted by t and the spacelike ones by (x_1, x_2, x_3, Y). In our notation, Capital Latin indices are taken as $A, B, \cdots = 1, 2, 3, 4, 5$ while lowercase Greek indices range as $\alpha, \beta, \cdots = 1, 2, 3, 4$. The 5-dimensional Riemann tensor is defined by the formula,

$$R^A{}_{BCD} = \partial_C \Gamma^A{}_{BD} - \partial_D \Gamma^A{}_{BC} + \Gamma^M_{BD}\Gamma^A_{MC} - \Gamma^M_{BC}\Gamma^A_{MD} \tag{3}$$

the Ricci tensor is the contraction,

$$R_{AB} = R^C{}_{ACB}, \tag{4}$$

and the five-dimensional Einstein equations on the bulk space are given by,

$$G_{AB} = R_{AB} - \frac{1}{2}g_{AB}R = \kappa_5^2 T_{AB}. \tag{5}$$

Next, we set up the bulk matter component by considering a bulk fluid with an energy-momentum tensor of the form,

$$T_{AB} = (\rho + p)u_A u_B - p g_{AB}, \tag{6}$$

where p is the 'pressure' and ρ is the 'density' which we take as functions only of the extra dimension Y. In (6), the velocity vector field is $u_A = (0, 0, 0, 0, 1)$, that is $u_A = \partial/\partial Y$, parallel to the Y-dimension. We assume that the pressure and density are interconnected by the following nonlinear equation of state

$$p = \gamma \rho^{\lambda}, \tag{7}$$

with γ and λ constants.

The Einstein equations can be written as

$$\frac{a'^2}{a^2} = \frac{\kappa_5^2}{6}\rho, \tag{8}$$

$$\frac{a''}{a} = -\frac{\kappa_5^2}{6}(2\gamma\rho^{\lambda} + \rho), \tag{9}$$

with the prime ($'$) denoting differentiation with respect to Y. The equation of energy-momentum conservation, on the other hand,

$$\nabla_A T^{AB} = 0,$$

becomes

$$\rho' + 4(\gamma\rho^{\lambda} + \rho)\frac{a'}{a} = 0. \tag{10}$$

At this point, it is useful to clarify the terminology that we use in what follows. We use the term *finite-distance singularities* to refer to the following singular behaviors of a, occurring within a finite distance Y_s:

- $a \to 0^+$, as $Y \to Y_s$ (collapse singularity),
- $a \to \infty$, as $Y \to Y_s$ (big-rip singularity).

With Y_s, we denote a finite value of Y designating the position of the singularity. The above behaviors may be accompanied, in general, by a divergence in the density, or, even in the pressure of the fluid. Note that, these singularities are not related to geodesic incompleteness as in standard cosmology, but rather on a pathological behavior of the warp factor. In the absence of finite-distance singularities, we call the solutions regular and include in this category the behaviors of the warp factor given above, provided that these occur *only* at infinite distance, *i.e* $Y \to \pm\infty$.

We are interested to see, if it is possible to find solutions of Eqs. (8)-(10) that rectify previous findings of solutions of brane-worlds with linear bulk fluids studied in.[11–16] As mentioned in the introduction, excepting the case of a flat brane and a fluid with $\gamma = -1$, the main problem that we faced in the study of a linear bulk fluid, is that regular solutions that exist in the case of curved branes, or even singular ones out of which we can construct a regular matching solution for both flat and curved branes, lead to a challenging compromise: they either satisfy energy conditions, or, localize gravity on the brane. Therefore, a solution arising from the consideration of this different and more complicated type of fluid would be preferable and worth

examining in detail, if it has each one of the following characteristics:

- it is regular (no finite-distance singularities)
- it satisfies physical conditions, such as energy conditions
- it leads to a finite four-dimensional Planck mass, thus, it localizes gravity on the brane.

We can simplify the situation of finding such a solution, by incorporating, for example, the energy conditions a priori. As we show in the next Sections this is indeed possible. The regular nature as well as the requirement of a finite four-dimensional Planck mass can be checked as a subsequent step, since to accomplish that, we first need to find the exact form of the warp factor and density.

3. The null energy condition

We are going to derive the null energy condition for our type of nonlinear bulk fluid described by (6) and (7) and transform it to a condition imposed on the density ρ and parameters γ and λ of the equation of state.

To achieve this, we follow the technique analysed in.[14,16] We start by recalling that the metric (1) and the bulk fluid (6) and (7) depend only on the extra dimension Y and they are therefore static with respect to the time coordinate t. Such fluid can be viewed as an anisotropic one with energy-momentum tensor

$$T_{AB} = (\rho^0 + p^0)u^0_A u^0_B - p^0 g_{\alpha\beta}\delta^\alpha_A \delta^\beta_B - p_Y g_{55}\delta^5_A \delta^5_B, \tag{11}$$

where $u^0_A = (a(Y), 0, 0, 0, 0)$, $A, B = 1, 2, 3, 4, 5$ and $\alpha, \beta = 1, 2, 3, 4$. As a next step, we compare (6) with (11) and find that the following relations should hold

$$p_Y = -\rho \tag{12}$$

$$\rho^0 = -p \tag{13}$$

$$p^0 = p. \tag{14}$$

We note that once we combine the last two relations we get

$$p^0 = -\rho^0, \tag{15}$$

which means that this type of matter satisfies a cosmological constant-like equation of state. Substituting (12)-(15) in (11), we find that

$$T_{AB} = -p g_{\alpha\beta}\delta^\alpha_A \delta^\beta_B + \rho g_{55}\delta^5_A \delta^5_B. \tag{16}$$

Here, we focus only on the null energy condition according to which, every future-directed null vector k^A should satisfy[20]

$$T_{AB}k^A k^B \geq 0. \tag{17}$$

This means that we should have

$$p + \rho \geq 0, \tag{18}$$

from which we find

$$\gamma\rho^{\lambda} + \rho \geq 0, \tag{19}$$

after inputting the equation of state $p = \gamma\rho^{\lambda}$. Now, Eq. (19) can be written as

$$\rho^{\lambda}(\gamma + \rho^{1-\lambda}) \geq 0 \tag{20}$$

and since $\rho \geq 0$ from Eq. (8), we arrive at the the final form of the null energy condition, which reads

$$\gamma + \rho^{1-\lambda} \geq 0. \tag{21}$$

In the next Section, we are going to incorporate this condition in the process of deriving our solutions.

4. Regular solution

We start solving the system of Eqs. (8)–(10), by first integrating the continuity equation (10) to find the relation between the warp factor and the density. In the integration process we arrive at a logarithmic term of the form $\ln|\gamma + \rho^{1-\lambda}|$. To incorporate from the beginning the null energy condition (21), we choose to ignore the absolute value and simply put this term equal to $\ln(\gamma + \rho^{1-\lambda})$. The resulting relation between ρ and a is

$$\rho = \left(-\gamma + c_1 a^{4(\lambda-1)}\right)^{1/(1-\lambda)}, \tag{22}$$

where

$$c_1 = \frac{\gamma + \rho_0^{1-\lambda}}{a_0^{4(\lambda-1)}}, \tag{23}$$

with $\rho_0 = \rho(Y_0), a_0 = a(Y_0)$ being the initial conditions. According to (21) this translates to $c_1 \geq 0$.

It is crucial to note that there is a singularity in the density ($\rho \to \infty$) for $\lambda > 1$ and

$$a^{4(\lambda-1)} = \frac{\gamma}{c_1}. \tag{24}$$

However, it is possible to avoid this singularity, by restricting the range of the parameter γ, only to negative values, which we do in the analysis that follows.

Substituting Eq. (22) in Eq. (8) and integrating, we obtain,

$$\int \frac{a}{(c_1 - \gamma a^{4(1-\lambda)})^{1/(2(1-\lambda))}}\, da = \pm\frac{\kappa_5}{\sqrt{6}} \int dY. \tag{25}$$

The complicated integral on the LHS of Eq. (25), can be greatly simplified for those values of λ that make $1/(2(1-\lambda))$ a negative integer. This is possible when $\lambda = (n+1)/n$, with $n = 2k$ and k a positive integer.

Clearly, the simplest case is for $n = 2$ which corresponds to $\lambda = 3/2$. Then $1/(2(1-\lambda)) = -1$ and we can directly integrate Eq. (25) to get the solution in the following implicit form

$$\pm Y + c_2 = \frac{\sqrt{6}}{\kappa_5}\left(\frac{c_1}{2}a^2 - \gamma \ln a\right), \tag{26}$$

where c_2 is an integration constant. It is straightforward to see that this solution is regular: all possible singular behaviors of a, namely $a \to 0$ and $a \to \infty$ happen only for infinite values of Y with p and ρ either vanishing there, or, approaching finite nonzero values. In particular, we have

$$a \to \infty, \quad \rho \to 0, \quad p \to 0, \quad \text{as} \quad Y \to \pm\infty \tag{27}$$

$$a \to 0^+, \quad \rho \to 1/\gamma^2, \quad p \to -1/\gamma^2, \quad \text{as} \quad Y \to \pm\infty. \tag{28}$$

Summarizing, the solution for $\lambda = 3/2$ has already two out of the three good qualities mentioned in the previous Section: it is regular and at the same time satisfies the null energy condition. In the following section, we construct an appropriate matching solution out of this solution, which leads to a finite four-dimensional Planck mass, thus fitting perfectly the profile of a plausible solution.

As for the asymptotics for general values of λ, it is interesting to note here that even though the case of $\lambda = 3/2$ is the simplest possible one for the nonlinear fluid, further analysis performed in,[1] shows that this case is significant in the sense that it can act as a guide for the whole range of values of $\lambda > 1$. This follows from the fact that all of its good physical properties are, in a way, inherited to all cases with $\lambda > 1$.

5. Matching solution for $\lambda = 3/2$

For $\lambda = 3/2$, a matching solution that leads to a finite four-dimensional Planck mass, can be constructed in the following way: First, we write down the two different branches of solution of Eq. (26),

$$Y^+ = h_+(a) = \frac{\sqrt{6}}{\kappa_5}\left(\frac{c_1^+}{2}a^2 - \gamma \ln a\right) + C_2^+ \tag{29}$$

$$Y^- = h_-(a) = \frac{\sqrt{6}}{\kappa_5}\left(-\frac{c_1^-}{2}a^2 + \gamma \ln a\right) + C_2^-, \tag{30}$$

using the notation $Y^\pm$ to describe the solutions for the $(\pm)$ choice of sign in Eq. (26). Similarly, the notation $c_1^\pm$, $C_2^\pm$ describes the values of c_1 and $\mp c_2$, respectively, on the $(\pm)$ branch of Y.

Second, in order to gain a complete idea of the behavior of $h_+(a)$, we study the shape of the curve of $h_+(a)$ by calculating the first and second derivative of $h_+(a)$.

These read

$$h'_+(a) = \frac{\sqrt{6}}{\kappa_5}\left(\frac{c_1^+ a^2 - \gamma}{a}\right) \tag{31}$$

$$h''_+(a) = \frac{\sqrt{6}}{\kappa_5}\frac{c_1^+}{a^2}\left(a^2 + \frac{\gamma}{c_1^+}\right). \tag{32}$$

For our choice of integration constants and parameters, $c_1^+ > 0$ and $\gamma < 0$, Eq. (31) shows that h_+ is strictly increasing for all values of a. Also, Eq. (32) shows that the graph of h_+ changes from concave downward on $(0, \sqrt{-\gamma/c_1^+})$ to concave upward on $(\sqrt{-\gamma/c_1^+}, \infty)$, making the point $(\sqrt{-\gamma/c_1^+}, -\sqrt{6}/\kappa_5(\gamma/2 + \gamma \ln \sqrt{-\gamma/c_1^+}) + C_2^+)$, an inflection point of the graph of h_+.

On the other hand, the first two derivatives of $h_-(a)$ are exactly the opposites of the ones of h_+ given in Eq. (31) and Eq. (32). This means that h_- is strictly decreasing and the graph of h_- changes from concave upward on $(0, \sqrt{-\gamma/c_1^-})$ to concave downward on $(\sqrt{-\gamma/c_1^-}, \infty)$, with $(\sqrt{-\gamma/c_1^-}, \sqrt{6}/\kappa_5(\gamma/2 + \gamma \ln \sqrt{-\gamma/c_1^-}) + C_2^-)$ being an inflection point of the graph of h_-.

We can match the two branches at their common inflection point by making an appropriate choice of the constants $c_1^\pm$ and $C_2^\pm$. This is a third step in the matching process. Naturally, we assume that the warp factor is continuous

$$\sqrt{\frac{-\gamma}{c_1^+}} = \sqrt{\frac{-\gamma}{c_1^-}}, \quad \text{or,} \quad c_1^+ = c_1^- = c_1 \tag{33}$$

and that, of course, the inflection point has the same Y coordinate through the two branches, which leads to

$$h_+\left(\sqrt{\frac{-\gamma}{c_1}}\right) = h_-\left(\sqrt{\frac{-\gamma}{c_1}}\right) \tag{34}$$

and yields the following relation between C_2^+ and C_2^-,

$$-\frac{\sqrt{6}}{\kappa_5}\left(\frac{\gamma}{2} + \gamma \ln \sqrt{\frac{-\gamma}{c_1}}\right) + C_2^+ = \frac{\sqrt{6}}{\kappa_5}\left(\frac{\gamma}{2} + \gamma \ln \sqrt{\frac{-\gamma}{c_1}}\right) + C_2^-, \tag{35}$$

or,

$$C_2^+ = \frac{\sqrt{6}}{\kappa_5}\left(\gamma + 2\gamma \ln \sqrt{\frac{-\gamma}{c_1}}\right) + C_2^-. \tag{36}$$

There is an axis of symmetry at $Y = Y_s$, with Y_s given by

$$Y_s = h_\pm(\sqrt{-\gamma/c_1}) = -\frac{\sqrt{6}}{\kappa_5}\left(\frac{\gamma}{2} + \gamma \ln \sqrt{\frac{-\gamma}{c_1}}\right) + C_2^+ = \frac{\sqrt{6}}{\kappa_5}\left(\frac{\gamma}{2} + \gamma \ln \sqrt{\frac{-\gamma}{c_1}}\right) + C_2^-. \tag{37}$$

Since the embedding of the brane introduces a $Y \to -Y$ symmetry in the bulk, it is natural to position the brane at $Y = Y_s$. Without loss of generality and in order to simplify our expressions, we can place the brane at $Y = 0$, that is we take $Y_s = 0$ in (37). This will set the values of $C_2^{\pm}$ to

$$C_2^+ = \frac{\sqrt{6}}{\kappa_5}\left(\frac{\gamma}{2} + \gamma \ln\sqrt{\frac{-\gamma}{c_1}}\right) = -C_2^-. \tag{38}$$

The matching solution described by Eq. (29) and (30) that satisfies the above boundary condition can be written as

$$|Y| = \frac{\sqrt{6}}{\kappa_5}\left(-\frac{c_1}{2}a^2 + \gamma \ln a - \frac{\gamma}{2} - \gamma \ln\sqrt{\frac{-\gamma}{c_1}}\right), \quad 0 < a \leq \sqrt{\frac{-\gamma}{c_1}}. \tag{39}$$

It is essential that the density is well defined and continuous at the position of the brane $Y = 0$. Here, we find

$$\rho\left(\sqrt{\frac{-\gamma}{c_1}}\right) \equiv \rho(0) = \frac{1}{4\gamma^2}, \tag{40}$$

where $\rho(0)$ denotes $\rho(Y = 0)$ and it is an abbreviation of $\rho(h_{\pm}^{-1}(\sqrt{-\gamma/c_1}))$.

The graph of h_+ is depicted in Fig. 1 with a thick solid and dashed line, while the graph of h_-, in the same Figure, is depicted with a thin solid and dashed line. The matching solution is build up only from the solid parts of both graphs, as this is the only choice that leads to a solution with a finite four-dimensional Planck mass. In Fig. 2, we have rotated the axes of Fig. 1, for a more convenient view of the evolution of the warp factor as a function of Y.

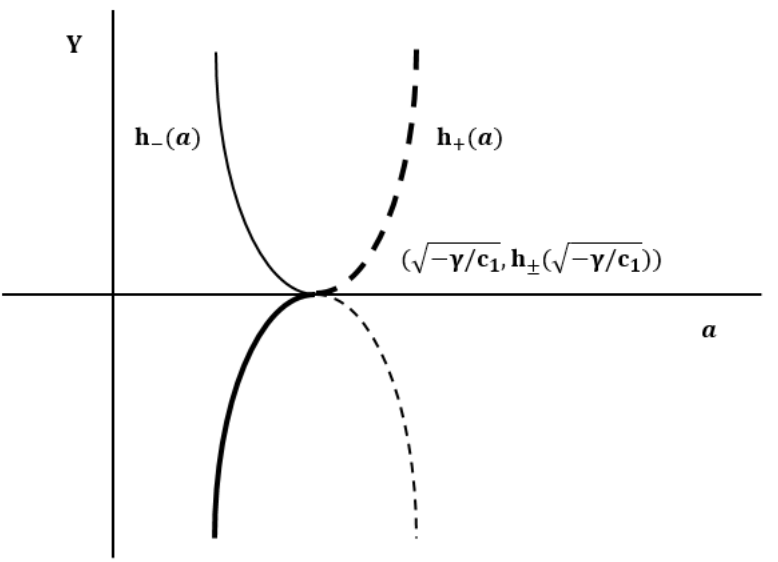

Fig. 1. Matching graphs of $h_{\pm}(a)$ for $\lambda = 3/2$.

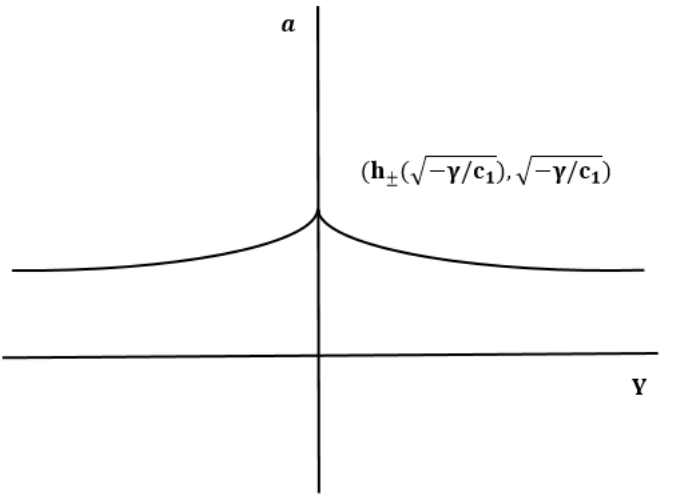

Fig. 2. Graph of $a(Y)$ for the matching solution for $\lambda = 3/2$.

Finally, we take into account the jump of the derivative of the warp factor across the brane and find, for our type of geometry, the following junction condition

$$a'(0^+) - a'(0^-) = 2a'(0^+) = -\kappa_5^2 \frac{f(\rho(0))a(0)}{3}, \tag{41}$$

where $f(\rho(0))$ is the tension of the brane. Using Eq. (39) in the above equation we can deduce the form of the brane tension, this reads

$$f(\rho(0)) = -\frac{\sqrt{6}}{2\kappa_5\gamma} = \frac{\sqrt{6\rho(0)}}{\kappa_5}, \tag{42}$$

where the last equality is derived by using Eq. (40).

This completes the construction of a viable matching solution for $\lambda = 3/2$. In the next Section, we are going to show that this solution also leads to a finite four-dimensional Planck mass.

6. Localization of gravity for $\lambda = 3/2$

To calculate the value of the four-dimensional Planck mass, $M_p^2 = 8\pi/\kappa$, we use the following integral (see[1, 14, 16, 21]),

$$\frac{\kappa_5^2}{\kappa} = \int_{-Y_c}^{Y_c} a^2(Y)dY. \tag{43}$$

We can deduce the behaviour of a^2 as $Y \to -\infty$ from Eq. (39). We find

$$a^2 \sim e^{-(\sqrt{6}\kappa_5/(3\gamma))Y}, \tag{44}$$

where the symbol $\sim$ is used to signify 'behaves according to', and using the symmetry of Eq. (39), we can write the above integral in the following form

$$\int_{-Y_c}^{Y_c} a^2 dY = 2\int_{-Y_c}^{0} a^2 dY \sim 2\int_{-Y_c}^{0} e^{-(\sqrt{6}\kappa_5/(3\gamma))Y} dY = -\sqrt{6}\frac{\gamma}{\kappa_5}(1-e^{(\sqrt{6}\kappa_5/(3\gamma))Y_c}). \tag{45}$$

Taking $Y_c \to \infty$ and keeping in mind that $\gamma < 0$, it follows that the four-dimensional Planck mass remains finite and is proportional to

$$-\sqrt{6}\frac{\gamma}{\kappa_5}.$$

In conclusion, we have seen a specific example of the nonlinear equation of state $p = \gamma\rho^{3/2}$, for which it is possible to construct a regular matching solution compatible with the null condition and which also localizes gravity on the brane. In the discussion below, we outline what happens for extended ranges of values of λ.

7. Discussion

We briefly review in this Section, the behavior of solutions for general λ, a detailed analysis can be found in.[1]

The key factor that determines whether a solution of Eqs. (8)-(10), is regular, or, singular, is the ordering of λ with respect to the value one: for $\lambda < 1$, we encounter singular solutions, whereas, for $\lambda > 1$ the solutions are regular.

Before presenting the solutions for general λ, we emphasize that for $\lambda \neq 1 + 1/(2k)$, where k is a positive integer, the integral on the LHS of Eq. (25) cannot in general be calculated directly. However, we can still deduce the behaviors of solutions by expressing them in terms of the Gaussian hypergeometric function ${}_2F_1(\alpha, b, c; z)$.

In particular, for $\lambda < 1$, the solution is given implicitly in terms of a hypergeometric function and reads

$$\pm Y + c_2 = \frac{\sqrt{6}}{2\kappa_5} c_1^{1/(2(\lambda-1))} a^2 \, {}_2F_1\left(\frac{1}{2(1-\lambda)}, \frac{1}{2(1-\lambda)}, \frac{1}{2(1-\lambda)} + 1; \frac{\gamma}{c_1} a^{4(1-\lambda)}\right). \tag{46}$$

As shown in,[1] this solution has a finite-distance singularity at $Y \to \pm c_2$, with

$$a \to 0^+, \quad \rho \to \infty, \quad p \to 0, \quad \text{if} \quad \lambda < 0 \tag{47}$$

$$a \to 0^+, \quad \rho \to \infty, \quad p \to \infty, \quad \text{if} \quad 0 < \lambda < 1. \tag{48}$$

The behaviors of p and ρ above, have been deduced from Eq. (7) and Eq. (22).

For $\lambda > 1$, on the other hand, we have the following types of solution. First, we have the general form of solution for $\lambda = 1 + 1/(2k)$, with k a positive integer, which is

$$\pm Y + c_2 = \frac{\sqrt{6}}{\kappa_5}\left(\sum_{s=0}^{k-1} \frac{k!}{(k-s)!s!} \frac{c_1^{k-s}}{2-2s/k} a^{2-2s/k}(-\gamma)^s + (-\gamma)^k \ln a\right). \tag{49}$$

Second, for $\lambda > 3/2$ we have the following solution

$$\pm Y + c_2 = \frac{\sqrt{6}}{\kappa_5}\left(\frac{a^2}{2}(c_1 - \gamma a^{4(1-\lambda)})^{1/(2(\lambda-1))} - \frac{\gamma c_1^{(3-2\lambda)/(2(\lambda-1))}}{2(3-2\lambda)}a^{2(3-2\lambda)} \times {}_2F_1\left(\frac{3-2\lambda}{2(1-\lambda)}, \frac{3-2\lambda}{2(1-\lambda)}, \frac{3-2\lambda}{2(1-\lambda)}+1; \frac{\gamma}{c_1}a^{4(1-\lambda)}\right)\right), \tag{50}$$

Finally, the case of $1 < \lambda < 3/2$ is more complicated: we have forms of solutions valid for $1+1/(2k) < \lambda < 1+1/2(k-1)$, with k a positive integer such that $k \geq 2$, and given by

$$\pm Y + c_2 = \frac{\sqrt{6}}{\kappa_5}\left(\sum_{s=0}^{n/2-1}\frac{(-\gamma)^s}{2(1-2s(\lambda-1))}\left(c_1 a^{4(\lambda-1)} - \gamma\right)^{1/(2(\lambda-1))-s} + \frac{(-\gamma)^{n/2}(c_1)^{((n+1)-n\lambda)/(2(\lambda-1))}}{2((n+1)-n\lambda)}a^{2((n+1)-n\lambda)} \times {}_2F_1\left(\frac{(n+1)-n\lambda}{2(1-\lambda)}, \frac{(n+1)-n\lambda}{2(1-\lambda)}, \frac{(n+1)-n\lambda}{2(1-\lambda)}+1; \frac{\gamma}{c_1}a^{4(1-\lambda)}\right)\right). \tag{51}$$

All solutions for $\lambda > 1$ are free from finite-distance singularities, and their asymptotic behaviors are

$$a \to \infty, \quad \rho \to 0, \quad p \to 0, \quad \text{as} \quad Y \to \pm\infty \tag{52}$$

$$a \to 0^+, \quad \rho \to (-\gamma)^{1/(1-\lambda)}, \quad p \to -(-\gamma)^{1/(1-\lambda)}, \quad \text{as} \quad Y \to \pm\infty. \tag{53}$$

The procedure for deriving a matching solution with a finite four-dimensional Planck mass, presented in the previous Sections, can still be performed for all solutions with $\lambda > 1$ and can be found in.[1]

Summarizing, the effect of the nonlinear equation of state is catalytic in the process of creating a regular solution with essential physical properties and valid for a wide range of parameters. It is left to be seen from a physics point of view, what are the possible field realizations that could lead to such an equation of state.

We review recent work on the possibility of primordial synchronization of different Mixmaster regions in generic inhomogeneous spacetime. It is shown that inhomogeneous domains undergoing chaotic oscillations may synchronize themselves exponentially fast and proceed in perfect symphony asymptotically in the past direction. Implications of this result for the structure and evolution of an early phase of the universe are briefly discussed.

Keywords: Nature of the cosmological singularity; structure of primordial states; chaotic synchronization

1. Introduction

Recently, we introduced a dynamical mechanism via chaotic synchronization of different spatial point of Mixmaster type as a new factor governing the global structure and evolution of primordial cosmology.[1] We have shown that a pair of spatial Mixmaster points in generic inhomogeneous spacetime coupled to each other and one of them ('the transmitter') communicating to the other ('the receiver') only part of the information necessary to determine its state, evolves in such a way that the receiver becomes able to completely reconstruct the remaining information and synchronize its chaotic evolution with that of the transmitter point.

This mechanism radically changes the structure of the early universe and provides a novel setting for the consideration of a number of fundamental issues in cosmology, such as the homogeneity ('horizon') problem, and the unexplained behaviour of the entropy in the early universe. In this contribution, we shall briefly recall the main features of the proposed cosmological sync mechanism.[1]

2. Evolution of inhomogeneous Mixmaster points

Our results concern the so-called G_0 cosmologies that admit no isometries and may be described in vacuum by the dimensionless state vector field X along the orbit of a fixed spatial point A. This is given by,[2]

$$X_A(\tau) = (\Sigma_+, \Sigma_-, N_1, N_2, N_3), \quad \Sigma_\pm = \frac{\sigma_\pm}{H}, \; N_\alpha = \frac{n_\alpha}{H}, \tag{1}$$

where H denotes the Hubble scalar function equal to $1/3\Theta$ and is taken with respect to the fundamental 4-velocity timelike vector field $u^a, a = 0, 1, 2, 3$. The expansion scalar is defined by $\Theta = \nabla_a u^a$. Derivatives are taken with respect to the dimensionless τ-time related to the proper (clock) time by $dt/d\tau = 1/H$, the variables $\Sigma_\pm$ describe the anisotropy in the Hubble flow, while the N_α's are related to the spatial curvature and the Bianchi type of the isometry group associated with the evolution of the spatial point.

We assume that different spatial points evolve in the past direction as separate homogeneous Mixmaster universes coupled to each other in inhomogeneous spacetime. For any pair of spatial points A, B, we have a pair of dynamical equations, namely, for the point A we have equations for the (N, Σ) variables, and for the point B similar equations for the different (M, Π) variables as follows[3–5]:

System A:

$$N_1' = (q - 4\Sigma_+)N_1, \tag{2}$$

$$N_2' = (q + 2\Sigma_+ + 2\sqrt{3}\Sigma_-)N_2, \tag{3}$$

$$N_3' = (q + 2\Sigma_+ - 2\sqrt{3}\Sigma_-)N_3, \tag{4}$$

$$\Sigma_+' = -(2 - q)\Sigma_+ - 3S_+, \tag{5}$$

$$\Sigma_-' = -(2 - q)\Sigma_- - 3S_-, \tag{6}$$

with the constraint,

$$\Sigma_+^2 + \Sigma_-^2 + \frac{3}{2}\left(N_1^2 + N_2^2 + N_3^2 - 2(N_1N_2 + N_2N_3 + N_3N_1)\right) = 1, \tag{7}$$

where,

$$q = 2(\Sigma_+^2 + \Sigma_-^2), \tag{8}$$

$$S_+ = \frac{1}{2}\left((N_2 - N_3)^2 - N_1(2N_1 - N_2 - N_3)\right), \tag{9}$$

$$S_- = \frac{\sqrt{3}}{2}(N_3 - N_2)(N_1 - N_2 - N_3), \tag{10}$$

and a prime denoting differentiation with respect to the τ-time.

System B: We have the unknowns $y = (M, \Pi)$, the variables $M = (M_1, M_2, M_3)$ satisfy similar equations to the Eqns. (2)-(4), and the shear variables $\Pi = (\Pi_+, \Pi_-)$ satisfy the system,

$$\Pi_+' = -(2 - p)\Pi_+ - 3Q_+, \tag{11}$$

$$\Pi_-' = -(2 - p)\Pi_- - 3Q_-, \tag{12}$$

with $p = 2(\Pi_+^2 + \Pi_-^2)$, the Q's are like the variables S's in the Eqns. (9), (10) but with the M's in the corresponding places of N's. The constraint is identical to (7) but with the (M, Π)'s in the places of the (N, Σ)'s.

3. The problem of cosmological sync

We shall be interested in the possibility that the spatial points A, B, with A in the causal past of B, can influence each other by sending signals from A to B and sync with each other in the past direction, while chaotically oscillating in inhomogeneous Mixmaster spacetime.

We imagine that the A-system in the form $x' = f(x)$ for the variables $x = (N, \Sigma)$, breaks into two 'subsystems', with the N variables satisfying the first three equations ('sys-1') and the Σ's the last two ('sys-2'), namely,

$$N' = g(N, \Sigma), \quad \Sigma' = h(N, \Sigma), \tag{13}$$

where $N = (N_1, N_2, N_3)$, $\Sigma = (\Sigma_+, \Sigma_-)$. We then set the B-system (receiver) variables M simply equal to the corresponding A-transmitter variables N (that is to those in sys-1). Then the B-system equations break into the pair consisting of the sys-1 equations, and those identical to sys-2 but for the Π variables, the 'sys-3' system:

$$M_i = N_i, \quad i = 1, 2, 3 \tag{14}$$

$$\Pi'_+ = -(2-p)\Pi_+ - 3S_+, \tag{15}$$

$$\Pi'_- = -(2-p)\Pi_- - 3S_-. \tag{16}$$

Following,[6,7] we introduce the synchronization (error) function $\Omega = (\Omega_+, \Omega_-)$, which in the present case we take it to be: $\Omega = \Sigma - \Pi$, that is,

$$\Omega_+ = \Sigma_+ - \Pi_+, \quad \Omega_- = \Sigma_- - \Pi_-. \tag{17}$$

Then we say that there is complete synchronization of the two Mixmaster oscillating spatial points (that is of systems A and B) provided we can show that,

$$\Omega \to (0, 0), \quad \text{as} \quad \tau \to -\infty. \tag{18}$$

If this happens, we say that system A is synchronized with system B. Otherwise, the two oscillating spatial points corresponding to systems A and B will evolve autonomously, out of sync.

In general, we expect the appearance of extra coupling terms in the dynamical equations which describe the evolution of the sync function Ω during the past evolution the Mixmaster oscillating spatial points, the latter evolution given by Eqns. (5), (6), and (11), (12). The question then arises as to whether or not a system of spatial points chaotically oscillating in the past direction may sync and evolve in unison thereafter.

This is the problem of cosmological sync for the case of spatial points satisfying Mixmaster-type evolution equations. As shown in,[1] there are indeed different types of sync possible in this problem depending on the form of the coupling between different spatial points.

4. Generic sync

Let us suppose that there is a linear in the sync function Ω coupling between the two spatial points. In this case, the evolution equations become,

$$\Sigma' = -(2-q)\Sigma - 3S + \alpha(\Pi - \Sigma) \tag{19}$$

$$\Pi' = -(2-p)\Pi - 3Q + \alpha(\Sigma - \Pi), \tag{20}$$

where Q is the analogous expression of S for the Π system, and α is some coupling between the two oscillators.

Then if the orbit Σ has Lyapunov exponent λ, we find that the associated Ω-evolution equation leads to the result,[1]

$$|\Omega| \leq Ce^{(\lambda - 2\alpha)\tau}, \tag{21}$$

with C an integration constant.

Therefore if we set $\alpha_c = \lambda/2$, for the critical coupling strength, we conclude that when $\alpha > \alpha_c$, we have complete synchronization of the Mixmaster oscillating regions.

A typical value of the Lyapunov exponents for Mixmaster orbits is (see, e.g.,[8]) $\lambda \sim 0.45$, so that when $\alpha > 0.225$, we have synchronization between the two spatial Mixmaster points A, B.

5. Lyapunov function sync

As is further shown in,[1] there is in fact a Lyapunov function for the dynamics of sync, for a general coupling $g(\Omega)$ satisfying a positivity condition, and under the further condition that,

$$\Omega' \cdot \nabla g \leq 0, \tag{22}$$

where Ω' is the orbital derivative of Ω. The Lyapunov function is given by,

$$V(\Omega_+, \Omega_-) = \frac{1}{2}\left(\Omega_+^2 + \Omega_-^2\right) + g(\Omega), \tag{23}$$

This implies that the state $\Omega = 0$ is asymptotically stable, making synced spatial regions globally asymptotically stable in the past direction.

As an example, consider the simplest, uncoupled, case. The sync equations of the dynamics take the form,

$$\Omega_+' = -(2-q)\Omega_+ \tag{24}$$

$$\Omega_-' = -(2-q)\Omega_-. \tag{25}$$

Then the function,

$$V(\Omega_+, \Omega_-) = \frac{1}{2}\left(\Omega_+^2 + \Omega_-^2\right), \tag{26}$$

is a Lyapunov function for the dynamics and satisfies,

$$V \leq V_0 e^{-4\tau}. \tag{27}$$

where V_0 is a constant. We conclude that Mixmaster regions in inhomogeneous spacetime synchronize exponentially fast.

6. Phase sync

A different characterization of the possibility of cosmological sync in the assumed primordial chaotic state of the universe may be effected when considering any number of oscillating domains having their own frequencies. This leads to different dynamical evolution of their phases, and the question arises as to whether we can have phase sync between them in this situation.

This problem was shown to have an affirmative answer in two steps. In the first step,,[9] Barrow wrote down the equation describing the phase evolution of a spatial Mixmaster point as a response of the system in terms of the mean field amplitude and phase r, ψ respectively,

$$\theta' = \frac{3}{\rho}\sqrt{S_+^2 + S_-^2}\,\sin(\theta - \psi), \quad \tan\psi = S_-/S_+, \tag{28}$$

with ρ being the polar coordinate in the pair (ρ, θ) in the (Σ_+, Σ_-) plane. A further elaboration using these dynamical equations shows that sync is indeed possible.

It can be further shown[1] that this equation leads to a direct coupling between the oscillating domains, precisely given by a time-dependent Kuramoto-like coupling of spontaneous synchronization. For any partition of N regions, we can show that the i-th domain responds directly to the j-th domain in the partition via the equation,[1]

$$\theta_i' = \frac{3}{N\rho_i}\sqrt{S_+^2 + S_-^2}\sum_{j=1}^{N}\sin(\theta_j - \theta_i). \tag{29}$$

7. Physical meaning of sync

We are led to the following physical interpretation[1] of the process of sync in the present context. The spatial point B will synchronize with the point A lying in B's past after receiving a signal from A. This will be so because their sync function $\Omega \to 0$, and sync will become progressively apparent when their corresponding BKL[10–12] parameter u values for A and B become equal with each other in the sense that the numbers of Kasner epochs and eras for the two evolutions of the spatial points A, B become identical to each other exponentially fast. Thereafter the two points will start oscillating in perfect unison.

This process will lead to the simplest possible initial state of the universe, characterized by a perfect sync between its different but correlated spatial regions. This will be so because, according to the results reported here, every spatial point will continually send and receive signals from other spacetime points shifting their state

of oscillation, adjusting them to that of the other points, and resetting their motion, until sync organizes them all in perfect harmony. In turn, this may have important implications some of which will be discussed elsewhere.

Quintessential inflation from Lorentzian slow roll

David Benisty

DAMTP, Centre for Mathematical Sciences, University of Cambridge, Wilberforce Road, Cambridge CB3 0WA, UK
Institute of Astronomy, University of Cambridge, Madingley Road, Cambridge, CB3 0HA, UK

From the assumption that the slow roll parameter ϵ has a Lorentzian form as a function of the e-folds number N, a successful model of a quintessential inflation is obtained. The form corresponds to the vacuum energy both in the inflationary and in the dark energy epochs. The form satisfies the condition to climb from small values of ϵ to 1 at the end of the inflationary epoch. At the late universe ϵ becomes small again and this leads to the Dark Energy epoch. The observables that the models predicts fits with the latest Planck data: $r \sim 10^{-3}, n_s \approx 0.965$. Naturally a large dimensionless factor that exponentially amplifies the inflationary scale and exponentially suppresses the dark energy scale appears, producing a sort of *cosmological see saw mechanism*. We find the corresponding scalar Quintessential Inflationary potential with two flat regions - one inflationary and one as a dark energy with slow roll behavior.

Keywords: Dark Matter; Dark Energy

1. Introduction

The inflationary paradigm is considered as a necessary part of the standard model of cosmology, since it provides the solution to the fundamental puzzles of the old Big Bang theory, such as the horizon, the flatness, and the monopole problems.[1–9] It can be achieved through various mechanisms, for instance through the introduction of a scalar inflaton field.[10–25] Almost twenty years after the observational evidence of cosmic acceleration the cause of this phenomenon, labeled as dark energy", remains an open question which challenges the foundations of theoretical physics: why there is a large disagreement between the vacuum expectation value of the energy momentum tensor which comes from quantum field theory and the observable value of dark energy density.[26–28] One way to parametrize dynamical dark energy uses a scalar field, the so-called quintessence model for canonical scalar fields.[29–31] In such a way that the cosmological constant gets replaced by a dark energy fluid with a nearly constant density today.[32–36] For the slow roll approximation the scalar field behaves as an effective dark energy. The form of the potential is clearly unknown and many different potentials have been studied and confronted to observations.

These two regimes of accelerated expansion are treated independently. However, it is both tempting and economical to think that there is a unique cause responsible for a quintessential inflation[37–42, 42–48] which refers to unification of both concepts

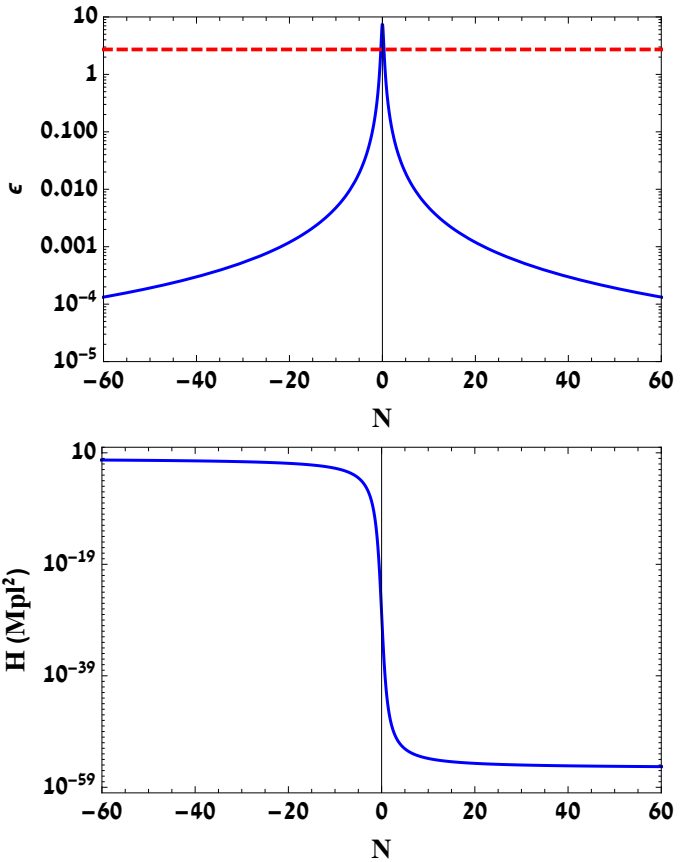

Fig. 1. The upper panel shows the slow roll parameter ϵ vs. the number of e-folds for the ansatz (1), in a logarithmic scale. The lower panel shows the corresponding Hubble function of the vacuum vs. the number of e-folds.

using a single scalar field. Consistency of the scenario demands that the new degree of freedom, namely the scalar field, should not interfere with the thermal history of the Universe, and thereby it should be "invisible" for the entire evolution and reappear only around the present epoch giving rise to late-time cosmic acceleration.

2. Lorentzian Ansatz

In order to formulate an ansatz for the Hubble function that treats symmetrically both the early and late times we use the Lorentzian function for the slow roll parameter:

$$\epsilon(N) = \frac{\xi}{\pi} \frac{\Gamma/2}{N^2 + (\Gamma/2)^2} \tag{1}$$

as a function of the number of e-folds $N = \log(a/a_i)$, where a_i is the scale parameter at some time (which we may choose as the initial state of the inflationary phase). ξ is the amplitude of the Lorentzian, Γ is the width of the Lorentzian. In that way the ϵ parameter increases from the initial value to 1 at the end of inflation, then continues to increase, peak and then decreases until it gets down to the value 1 and this represents the beginning of a the new Dark Energy phase that will eventually dominate the late evolution of the Universe. The upper panel of Fig. 1 presents the qualitative shape of this behavior.

The strong energy condition yields another bound on the coefficients. The equation of states w is in the range $|w| \leq 1$. From the relation $\epsilon = \frac{3}{2}(w+1)$ we obtain the bound $0 \leq \epsilon \leq 3$. The ansatz for the vacuum energy evolution (1) positive always, hence the lower bound is preserved. The largest value of the ansatz (1) is $2\xi/\pi\Gamma$. From the the upper bound of ϵ we obtain the condition:

$$\Gamma < 2\xi/3\pi. \tag{2}$$

In general, the calculation of the above observables demands a detailed perturbation analysis. Nevertheless, one can obtain approximate expressions by imposing the slow-roll assumptions, under which all inflationary information is encoded in the slow-roll parameters. In particular, one first introduces[49]

$$\epsilon_{n+1} = \frac{d}{dN} \log |\epsilon_n|, \tag{3}$$

where $\epsilon_0 \equiv H_i/H$ and n a positive integer. The slow roll parameters read:

$$\epsilon \equiv \epsilon_1 = -\frac{H'}{H}, \quad \epsilon_2 = \frac{H''}{H'} - \frac{H'}{H},$$

and so on. From the first slow roll parameter definition with the ansatz (1), we obtain the solution:

$$H = \sqrt{\frac{\Lambda_0}{3}} \exp\left[-\frac{\xi}{\pi} \tan^{-1}\left(\frac{2N}{\Gamma}\right)\right], \tag{4}$$

where Λ_0 is an integration constant. The Hubble function interpolates from the inflationary values $H_{-\infty}$ to the dark energy value $H_{+\infty}$ that corresponds to:

$$H_{\pm} = \sqrt{\frac{\Lambda_0}{3}} \exp^{\mp \xi/2}. \tag{5}$$

The magnitude of the vacuum energy at the inflationary phase reads $10^{-8} Mpl^4$, while the magnitude of the vacuum energy at the present slowly accelerated phase of the universe is $10^{-120} Mpl^4$. From the Friedmann equations the values of the energy density is $3H^2$ in the Planck scale. Therefore, the coefficients of the model are:

$$\xi \approx 129, \quad \Lambda_0 = 1.7 \cdot 10^{-32} Mpl^4. \tag{6}$$

We calculate the other slow roll parameters using (3):

$$\epsilon_2 = -\frac{8N}{\Gamma^2 + 4N^2}, \quad \epsilon_3 = \frac{1}{N} - \frac{8N}{\Gamma^2 + 4N^2}. \tag{7}$$

For $\Gamma \to 0$ all of the slow roll parameters with $n \geq 3$ yields the value $-1/N$. However in the general case, all of the slow parameters have small values if the ϵ_2 is small.

As usual inflation ends at a scale factor a_f where $\epsilon_1(a_f) = 1$ and the slow-roll approximation breaks down. Therefore the end of inflation takes place when the number of e-folds reads:

$$N_f = \pm\sqrt{\frac{\Gamma}{4\pi}(2\xi - \pi\Gamma)}. \tag{8}$$

Notice that with the condition (2) it gets a definite value. In order to have an inflationary phase the condition $2\xi > \pi\Gamma$ must be satisfied. The negative value of N_f is the final state of the inflationary phase, while the positive value of N_f is the initial value of the slow rolling Dark Energy at the late universe. Therefore, in order to calculate the inflationary observables, we must take the minus sing of N_f. Consequently the initial N_i satisfies the condition: $N_f - N_i = \mathcal{N} \approx 50 - 60$, where we impose 60 e-folds for the inflationary phase. Hence, the initial state of the inflationary phase reads:

$$N_i = -\sqrt{\frac{\Gamma}{4\pi}(2\xi - \pi\Gamma)} - \mathcal{N}. \tag{9}$$

The inflationary observables are expressed as[49]

$$r \approx 16\epsilon_1, \quad n_{\rm s} \approx 1 - 2\epsilon_1 - \epsilon_2, \quad \alpha_{\rm s} \approx -2\epsilon_1\epsilon_2 - \epsilon_2\epsilon_3, \quad n_{\rm T} \approx -2\epsilon_1, \tag{10}$$

where all quantities are calculated at N_i. Therefore the tensor to scalar ratio and the primordial tilt give:

$$r = \frac{32\Gamma\xi}{\pi\Gamma^2 + 4\pi N_i^2}, \quad n_s = \frac{\pi\left(\Gamma^2 + 4N_i(N_i+2)\right) - 4\Gamma\xi}{\pi\left(\Gamma^2 + 4N_i^2\right)}. \tag{11a}$$

For 60 e-folds and $\Gamma = 0.1$ the observables read:

$$r = 0.0076, \quad n_s = 0.961754. \tag{12}$$

These values in agreement with the latest 2018 Planck data[50,51]:

$$0.95 < n_s < 0.97, \quad r < 0.064. \tag{13}$$

Fig. 2 shows the predicted distribution of the observables.[52] We assume a uniform prior: $N \in [50; 70]$, $\xi \in [100; 200]$, $\Gamma \in [0; 1]$, with 10^7 Markov Chain Monte Carlo samples. We find the posterior yields:

$$r = 0.045^{+0.065}_{-0.053}, \tag{14}$$

$$n_s = 0.9624^{+0.0087}_{-0.011}, \tag{15}$$

$$\alpha_s = -\left(33^{+27}_{-30}\right) \cdot 10^{-5}, \tag{16}$$

in good agreement with the recent Planck values.

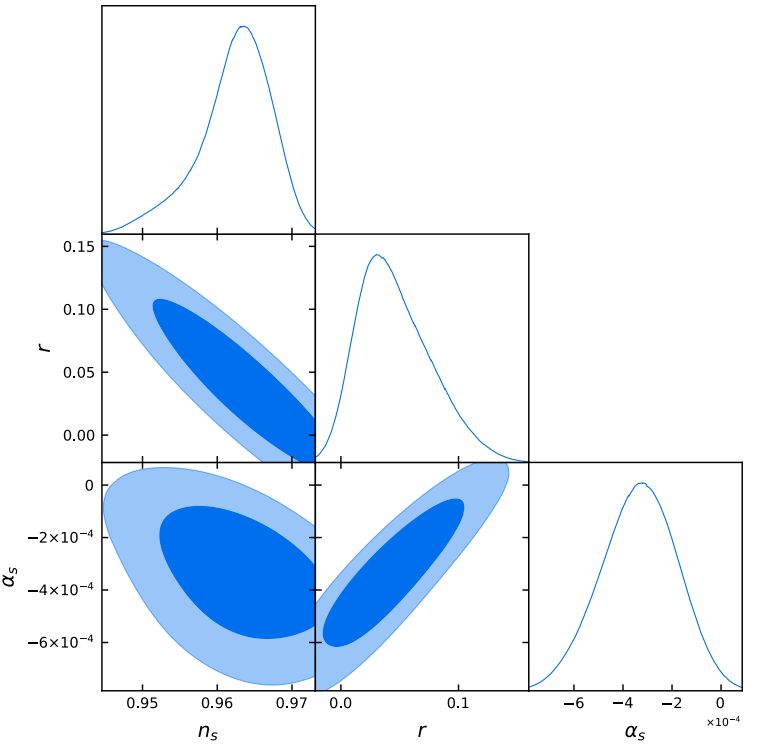

Fig. 2. The predicted scalar to tensor ratio vs. the primordial tilt of the model.

3. Scalar field dynamics

The above ansatz is of general applicability in any inflation realization, whether this is driven by a scalar field, or it arises effectively from modified gravity, or from any other mechanism. In order to provide a more transparent picture let us consider a realization of these ideas in the context of a canonical scalar field theory ϕ moving in a potential $V(\phi)$. The Friedmann equations are

$$H^2 = \frac{8\pi G}{3}\left[\frac{1}{2}\dot{\phi}^2 + V(\phi)\right], \quad \dot{H} = -4\pi G\dot{\phi}^2, \tag{17}$$

while that for the scalar field is

$$\ddot{\phi} + 3H\dot{\phi} + V'(\phi) = 0. \tag{18}$$

Let us apply the ansatz in order to reconstruct a physical scalar-field potential that can generate the desirable inflationary observables. From the Friedmann equation (17) that holds in every scalar-field inflation, we extract the following solutions

$$\phi = \int_0^N \sqrt{-2\frac{H'}{H}}\, dN, \quad V(\phi) = HH' + 3H^2, \tag{19}$$

with $8\pi G = 1$. From the integration of the Hubble parameter we get:

$$N = \frac{\Gamma}{2}\sinh\left(\sqrt{\frac{\pi}{\xi\Gamma}}\phi\right), \quad V(N) = \Lambda_0 e^{-\frac{2\xi}{\pi}\tan^{-1}\left(\frac{2N}{\Gamma}\right)}\left(1 - \frac{2\Gamma\xi}{3\pi\Gamma^2 + 12\pi N^2}\right). \quad (20)$$

Relations (20) can be used in order to write V in terms of ϕ analytically

$$V(\phi) = \Lambda_0 e^{-\frac{2\xi}{\pi}\tan^{-1}(\sinh x)}\left(1 - \frac{2\xi}{3\pi\Gamma}\mathrm{sech}^2 x\right), \quad (21)$$

with $x \equiv \sqrt{\pi/\Gamma\xi}\phi$. Fig. 3 shows the scalar potential $V(\phi)$. The universe in this picture begins with $\phi \to \infty$ with a slow roll behavior and goes to the left-hand side. After approaching the minimum the universe evolves with another slow roll behavior that corresponds to the dark energy epoch when $\phi \to -\infty$. The asymptotic values of the potential are:

$$V_{+\infty} = \Lambda_0 e^{\xi}, \quad V_{-\infty} = \Lambda_0 e^{-\xi}. \quad (22)$$

Notice that this represents a see saw cosmological effect, that is if Λ_0 represents an intermediate scale, we see that in order to make the inflationary scale big forces the present vacuum energy to be small. Λ_0 represents the geometric average of the inflationary vacuum energy and the present Dark Energy vacuum energies.

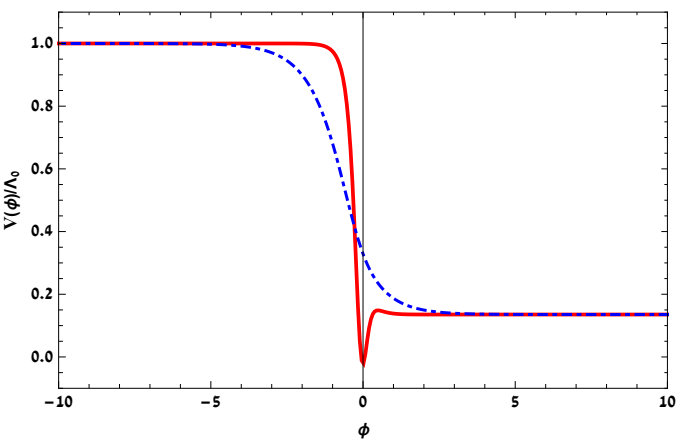

Fig. 3. The corresponding scalar field potential for the Lorenzian ansatz, with different values of Γ: 0.1 red smooth line, 1 blue dashed line.

4. Discussion

This essay introduces a model where we start with an ansatz for the slow roll parameter ϵ for the whole history of the Universe. We choose a Lorentzian form for ϵ, which peaks at some point and goes to zero for the early and late Universe, so these two epochs have an accelerated phase. The magnitude of the vacuum energies

at the early and late Universe obeys a see saw mechanism: since the asymptotic values of the potential are $\Lambda_0 e^{\pm\xi}$ this represents a see saw cosmological effect, where the requirement that one scale (the inflationary scale) be large pushes the Dark Energy scale to be very low. See saw cosmological effects in modified measure theories with spontaneously broken scale invariance have been studied in.[53–55] For the situation presented in this paper to work, we must choose Λ_0 as an intermediate scale, and indeed then we see that in order to make the inflationary scale big, this forces the present vacuum energy to be small. Λ_0 represents the geometric average of the inflationary vacuum energy and the present Dark Energy vacuum energies.

The model formulates the vacuum energies both in the inflationary epoch and in the dark energy epoch. However to compare the basis of the model with the whole history of universe, we have to take into account particle creation models with temperature, as well as radiation production.

Condensed light, quantum black holes and L-CDM cosmology: Experimentally suggested and tested unified approach to dark matter, dark energy, cosmogenesis and two-stage inflation

Victor Borsevici

International Informatization Academy, branch Rep. of Moldova, Chisinau, Rep. of Moldova
E-mail: borsevici@mail.ru

Based on the fundamental last discoveries (such as gravitational waves, Higgs field, gravitating Bose-Einstein photon condensates etc.), guided by the last A. Einstein's conjecture (about algebraic approach to the combined quantum and continuum description of reality) and directed by the J. Bekenstein-V. Mukhanov approach to the quantum black holes physics and astrophysics, the L. Susskind's "one photon – one bit" principle and V. Gribov-S. Hawking tunneling effect, one can easily find the simple but consistent algebraic relations and physical laws that govern birth and death of black holes in the Early Universe, its accretion and two-particle emitting (both outside black hole) accompanied with gravitational radiation.

From these basic relations in a natural way derive the Planck units system that confirm the theoretical consistence of presented approach and directly leads to the Planck Scale physics where standard models of the particle physics and cosmology are "blinded". Presented approach elucidates the physical background of dark matter (black holes), dark energy (gravitational waves), hot Big Bang and two-stage inflation of the Universe. Moreover, it solves many old unsolved problems, such as "cosmic censorship" conjecture, information loss paradox, black hole "end-point" problem, "cosmological constant" problem and so on.

The great importance for the validation of presented approach and it results had the comparison with "Planck-2018" data and other relevant information from the sources of observational cosmology, astrophysics, gravitational waves astronomy and numerical relativity.

Keywords: Planck scale physics, dark matter, dark energy, Bose–Einstein photon condensates, Cosmology.

To the blessed memory of Jacob Bekenstein and Steven Weinberg

Introduction

"Raffiniert ist der HerrGott, aber boshaft ist er nicht."
(A. Einstein)

What "banged"? What is dark matter? What is dark energy? What caused two-stage inflation? *etc.* Such problematic questions that provoked a lot of troubles for L-CDM cosmology are a consequence of unsolved problems in physics. L. Smolin called this stagnant situation "Einstein's unfinished revolution" and the more critical theoreticist S. Hossenfelder called it "Lost in math".

But over the last decade, experimental physics and observational cosmology have made many fundamental discoveries: gravitational waves (LIGO), Higgs boson (LHC), photon condensates with rest energy and rest mass trapped in "mirror cavities" (Bonn University).[1,2]

Through these remarkable results, Nature suggests that at pressures and temperatures well above the Higgs field level (246 GeV), only the 2-d and 3-d photon condensates trapped in their own "gravitational cavities" should be unique sources of gravity during the Early Universe. Moreover, we conclude that the real *"prima materia"* at the "beginning of the times" was a 3-dimensional Planck photonic condensate as "explosive" accompanied by Planck fluctuations as "fuse". This unambiguously postulates the fundamental role of the laws of conservation of energy and momentum in cosmology, as well as reflect the decisive role of quantum fluctuation in the formation of the modern Universe (see V. Mukhanov-G. Chibisov and S. Hawking – B. Carr approaches).

Note that after the discovery of gravitational waves, the famous Nobel Prize winner P. W. Anderson, in his prophetic "Four Last Conjectures" (2018), argues that "dark energy" is gravitational radiation which causes irreversible loss of mass in the Universe.

It is quite clear that in the swift initial process of Hot Bing Bang we have only three kinds of "actors" at the Planck scale: the 2-d spherical self-gravitating photonic condensates (primordial quantum black holes as "dark matter"), free hot photons and gravitational waves (both acting as massless stretched "dark energy" forces). Note that only gravitational radiation represents one irreversible repulsive force. According to our calculations, only a part of relic gravitational waves with Planck energies E_p and $E_p/2$ make up 93.38% of the dark energy in the modern Universe. As you can see, S. Weinberg was absolutely right: only the energy of Hot Bing Bang causes the universal expansion process.

Moreover, the irreversibility of the gravitational radiation energy prohibits all kind of "big crunch" and "bouncing" (cyclic) cosmological theories, proving instead the Hot Big Bang approach to the cosmogenesis.

We must point out separately that at the end of the initial phase of the Hot Big Bang process (at about $50\pi \times 5.391 \times 10^{-44}$ sec), when the strongest inequality $\Omega_M \ll \Omega_\Lambda$ was reached and stage I of hyperinflation began, a part of the surviving primordial black holes became "seed" of the primordial Cosmic Web, in which baryogenesis occurs and all astrophysical objects are formed.

Where do these conclusions follow? Taking into account the quantum nature of the 2-d spherical photon condensates, trapped in their own gravitational fields, guided by the J. Bekenstein's fundamental dependence between the Compton wavelength and the gravitational radius,[3] L. Susskind's principle "one photon — one bit",[4] the V. Mukhanov's quantum black holes "degeneracy" principle[5] and the modified V. Gribov–S. Hawking tunneling effect,[6,7] one can easily find any exact and adequate laws that govern birth and death, rise and downfall, accretion of light

and quantum two-particle emission (both outside black holes). All these processes are accompanied by the emission of gravitational waves.[8]

In what follows, we will demonstrate that the most important thing that distinguishes such natural black holes modelling from all other "membrane models" (see K. S. Thorne, F. Wilczek and M. Maggiore approaches) is that tremendous gravitational squeezed force is perfectly equilibrated by repulsive ("antigravitational") quantum-mechanical one.

Note that only the 2-d photon condensate "construct" with its tremendous "band" of possible wavelengths can explain the incredibly wide range of sizes, lifetimes and masses of black holes, ranging from the Planck scale to tens of Pluto orbits and tens of billions of masses of the Sun (see the quasar *TON 618*). We will demonstrate that this approach is free from the "cosmic censorship" principle, the "no hair" theorem and the information loss paradox.

Using this unified approach, we can calculate that at the end of the epoch of baryogenesis, when stage I of inflation ends, the rest energies of black holes (dark matter) and energy of gravitational waves (dark energy) are 28.62% and 66.42%, respectively. After this epoch, there came a non-accelerated expansion. But 6–8 billion years ago, the II stage of inflation began. Now, accordingly to "Planck-2018" data, we find the 26.57% and 68.47%, respectively. Comparison with the end of the stage I clearly shows that the increase in dark energy is caused by a decrease in the energy associated with dark matter. This leads to the unambiguous conclusion that stage II of inflation is provided by binary coalescences of black holes.

The greatest discoveries of L-CDM cosmologies are namely such epiphenomenons as "dark matter", "dark energy", "Hot Big Bang" and "two-stage inflation". It remains to find the deep physical background of these unsolved phenomenologies. The "Einstein's Unfinished Revolution" must be continued. However, it is quite clear that this is impossible without taking into account the new discoveries of modern physics and cosmology, including the self-gravitating Bose–Einstein photonic condensates. We must demonstrate the new approach to the Planck Scale Physics, where standard models of physics and cosmology was "blinded".

The new theoretical approach is consistent, when from it basic relations and equations directly derive any fundamental constants. In what follows, we will demonstrate that proposed basic equations generate the fundamental system of Planck units. This directly leads to the Terra Incognita of Planck Scale Physics and solves many puzzles of black hole physics, astrophysics and cosmology, such as "cosmic censorship" problem, information loss paradox, black hole "end-point" problem, "cosmological constant" problem, dark matter and dark energy problems and so on.

1. Principia

In 1916 A. Einstein wrote: "... das die Quantentheorie nicht nur die Maxwellische Elektrodynamik, ... auch die neue Gravitationstheorie wird modifizieren mussen".[9]

Already in those distant times, under the influence of Bohr's theory of hydrogen atom, he came to the conclusion that a spherical system should emit not only quanta of light, but also any portions of gravitational waves. This led him to believe that the new theory of gravity should be modified taking into account quantum electrodynamics.

Many years later, in 1954, in his last work, he wrote the closing lines that sound like a testament: "... a finite system with its finite energy can be described in full by a finite set of numbers (quantum numbers). Seemingly, it cannot be compliant with the continuum theory and requires a purely algebraic theory for a reality description. However now nobody knows, how to find a basis for such a theory".[10] Actually, A. Einstein explicitly clamed in his "last will" that just the algebraic approach must be the magistral way to unify quantum physics and continuum general relativity.

Only two decades later, it was the young Israeli physicist J. Bekenstein who turned out to be the "nobody" who found a way to do this. In his revolutionary work "Black Holes and Entropy"[3] he gave an amazing formula for the entropy of a black hole

$$S_s \text{ (Bekenstein)} = \frac{\ln 2}{8\pi} k c^3 \hbar^{-1} G^{-1} A_S \ ,$$

which unites all world constants: Boltzmann's constant (k), speed of light (c), reduced Plank constant ($\hbar$), gravitational constant (G), as well as the area of the Schwarzschild spherical singularity

$$A_S = 4\pi R_S^2 \ ,$$

where R_S is the Schwarzschild gravitational radius.

Bekenstein's formula was striking in that it linked together thermodynamics, quantum physics, the theory of gravity, and geometry. But the most surprising thing was that he connected all this within the framework of a unified information approach to the physics and astrophysics of black holes. In his famous formula, he associated the multiplier $\ln 2$ with Shannon's "bit". And this is not accidental, because he followed the famous principle of his great teacher J. A. Wheeler: "It from bit".

In 1986, the young Russian physicist V. Mukhanov, guided (as A. Einstein) by hydrogen atom analogy, came to the irrefutable conclusion that the emission mechanism of quantum black holes must obey the "degeneracy" principle.[11] He turns to J. Bekenstein and in 1995 their common outstanding work "Spectroscopy of the quantum black hole"[12] is published. In this work, it was shown that the true emission spectrum of quantum black holes *is discrete*.

With the advent of new fundamental experimental discoveries, this work of J. Bekenstein and V. Mukhanov began to acquire fundamental significance for physics and cosmology. Moreover, it turned out to be not just a "window" (as its authors was believed), but a whole "gateway" to *Terra Incognita* of Planck Scale Physics.

2. Basic Relations

With the discovery of 2-d photonic Bose-Einstein condensate[1] it became clear that the rejected Schwarzshild spherical singularity was becoming an obvious alternative to the black hole model in the form of a "point singularity" surrounded by an "event horizon" of Schwarzschild radius.

The biggest problem of all "membrane models" was their physical inconsistence. No one has been able to prove their resilience when facing the tremendous gravitational squeezed forces. From the "relativistic" point of view, this seemed to be an unsolvable problem. That is why, first of all, after justifying our approach, we will prove the strong equilibrium between squeezed gravitational forces and repulsive "antigravitational" quantum mechanical forces of quantum black hole. Note, that this strong equilibrium may be broken only by V. Mukhanov's "degeneracy" effect.

Based on the Bekenstein–Mukhanov approach, we will show how all these unsolved problems are solved in terms of the original basic system of equations for spherical 2-d photon condensates, trapped in their own gravitational field:

$$\begin{cases} \bar{\lambda}_{sm} = R_s \ , & (1) \\ \bar{\lambda}_{sm} = \dfrac{\hbar}{M_{sm}c} = \dfrac{\hbar c}{E_{sm}} \ , & (2) \\ R_s = \dfrac{2G}{c^2} M_s = \dfrac{2G}{c^4} E_s \ , & (3) \\ N_s = \dfrac{M_s}{M_{sm}} = \dfrac{E_s}{E_{sm}} \ , & (4) \\ N_s(min) = 2 \ . & (5) \end{cases}$$

Equations (1)–(3) bind together the reduced Compton wavelength, $\bar{\lambda}_{sm}$, which is associated to one photon with rest mass M_{sm} and rest energy E_{sm}, and Schwarzschild radius, R_s, which is expressed in terms of M_s (total rest mass of the condensate) and E_s (total rest energy).

Note that relation of the type of Eq. (1) was first time discovered by Bekenstein in his remarkable work Ref. 3 to determine the largest Compton wavelength of a particle absorbable by a black hole. In essence, general Eq. (1) can be called "Bekenstein relation". This is the only one equation known to us that organically interconnects Quantum Physics and General Relativity. In fact, it reflect the deepest equivalence between the "quantum wavelength geometry" ($\bar{\lambda}_{sm}$) and the "relativistic geometry" (R_s) that occurs in black holes as spherical 2-d photon condensates trapped in their own gravitational fields.

Equation (4) organically make links between the number of photons in the condensate, N_S, and the quantities expressing its "individual" rest mass, M_{sm}, and rest energy, E_{sm}, as well as with "total" rest mass, M_s, and rest energy, E_s. We note in particular that N_s is a natural integer, that reflect a quantum nature of black holes physics.

Equation (5) sets a natural limit on the minimum number of photons in the condensate, equal to two: $N_S(min) = 2$.

Note that for the evident lower boundary condition, system Eqs. (1)–(5) gives us (it is easy to verify) the following solutions:

$$M_s(min) = \sqrt{\frac{\hbar c}{G}} = M_p\,, \quad E_s(min) = \sqrt{\frac{\hbar c^5}{G}} = E_p\,, \quad R_s(min) = 2\sqrt{\frac{\hbar G}{c^3}} = 2l_p\,, \tag{6}$$

where M_p and E_p are the Planck mass and energy, respectively, l_p — Planck length.

It is striking that we unexpectedly found ourselves in the field of Planck Scale Physics and absolutely accurately described the Planck black hole without any preliminary assumptions, hypotheses and conjectures. We have used only the most basic information from Quantum Physics and General Relativity enclosed in the base system Eqs. (1)–(5).

Note that we do not use the "quantum gravity" approach based on the "gravitons" hypothesis because of the gravitational waves (the "ripples" of spacetime) radically differ from the quantum-mechanical waves (the "waves of probability").

3. Equilibrium

In order to make certain that a quantum black hole taken as spherical self-gravitating 2-d photon condensate is a quasi-stable astrophysical object, from all the solutions of the system Eqs. (1)--(5) we will pick the following one:

$$M_{sm} = \frac{\hbar}{cR_s} = \frac{\hbar c}{2GM_s} = \frac{M_p^2}{2M_s}\,, \tag{7}$$

$$E_{sm} = \frac{\hbar c}{\overline{\lambda}_{sm}} = \frac{\hbar c}{R_s} = \frac{\hbar c^5}{2GE_s} = \frac{E_p^2}{2E_s}\,. \tag{8}$$

As we can see, according to Birkhoff's Theorem the attractive gravitational force for one photon with rest mass M_{sm} is equal to

$$F_{sm,\,gr} = \frac{2GM_{sm}M_s}{R_s^2} = \frac{\hbar c}{R_s^2}\,. \tag{9}$$

But this attractive gravitational force must be perfectly equilibrated by quantum-mechanical "antigravitational" force:

$$F_{sm,\,qu} = \frac{\mathrm{d}E_{sm}\left(\overline{\lambda}_{sm}\right)}{\mathrm{d}\overline{\lambda}_{sm}} = \frac{\mathrm{d}\left({}^{\hbar c}/_{R_s}\right)}{\mathrm{d}R_s} = -\frac{\hbar c}{R_s^2}\,. \tag{10}$$

4. Quantum Information and Entropy: The Downfall of the "Point-Centered" Model

In his remarkable book "The Cosmic Landscape",[4] L. Susskind convincingly demonstrates that every photon is a carrier of one bit of quantum information. The point is that a photon can be in two spin states, $|0\rangle$ or $|1\rangle$.

In the case of a quantum black hole consisting of N_s photons, this means that the power of the set of its possible quantum states is 2^{N_s}. From the point of view

of information theory, a quantum black hole can be represented as a binary text consisting of N_s positions filled with symbols from the alphabet $\{|0\rangle, |1\rangle\}$. To each such text, θ_i, a probability, p_i, can be attributed. The maximum of C. E. Shannon's entropy is achieved for an uniform distribution $p_i = 2^{-N_s}$:

$$H_s \text{ (Shannon)} \underset{max}{=} -\sum_{i=1}^{2^{N_s}} 2^{-N_s} \log_2 2^{-N_s} = N_s \text{ (bit)} \ . \tag{11}$$

According to Shannon's approach, the maximum amount of quantum information, I_s, contained in a quantum black hole does not exceed this value. Moreover, it is equal to it:

$$I_s = H_s \text{ (Shannon)}_{\max} = N_s \text{ (bit)} \ . \tag{12}$$

Now let's calculate the thermodynamic entropy of the black hole. To do this, we first need to calculate the temperature of the quantum black hole from the relation

$$E_{sm} = 2 \times kT_s \ , \tag{13}$$

where kT_s is the energy corresponding to vibrational freedom degree, 2 is the multiplier due to the two spin states, $|0\rangle$ and $|1\rangle$. From Eq. (13) directly follows the wanted relationship for the temperature

$$T_s = \frac{E_{sm}}{2k} = \frac{E_p^2}{4kE_s} = \frac{\hbar c^3}{4kGM_s} \ . \tag{14}$$

It is easy to see that we have obtained an expression very close to the one of S. Hawking:

$$T_s \text{ (Hawkinhg)} = \frac{1}{2\pi} T_s \ . \tag{15}$$

However, the essential difference lies in the fact that the temperature T_s (Hawkinhg) is the typical temperature of the black hole taken as a "black body", whereas we are dealing with a quantum black hole. On the other hand, this similitude of the results suggests that we are acting in the right direction.

From the Clausius relation $\mathrm{d}S = \mathrm{d}E/T$ and Eq. (14), by integration, we easily find the required expression for the thermodynamic entropy:

$$S_s = \int_0^{E_s} \frac{4k}{E_p^2} E \, \mathrm{d}E = k2\frac{E_s^2}{E_p^2} = kN_s \ . \tag{16}$$

In other words, we get a direct connection between the entropy of a black hole and the Shannon's entropy:

$$S_s = kH_s \text{ (Shannon)}_{\max} = kN_s \ . \tag{17}$$

From Eqs. (3), (4) and (16) we can get another important relation:

$$S_s = kN_s = k\frac{R_s^2}{2l_p^2} = \frac{1}{8\pi} kc^3\hbar^{-1}G^{-1}A_s \ , \tag{18}$$

where A_s is the area of the Schwarzschild spherical singularity. This immediately implies a connection with the cited above Bekenstein formula:

$$S_s \text{ (Bekenstein)} = \ln 2 \cdot S_s \ . \tag{19}$$

The remarkable physicist S. Hawking relied on a model of a black hole in the form of a "point-singularity" surrounded by a "event-horizon". Actually, this means that in the center of symmetry of any black hole there should be matter with the limiting Planck density. Only 3-d Planck photon condensate can have such a density. It is not difficult to calculate the amount of quantum information, I_{s*}, in this model:

$$I_{s*} = N_{s*} = \frac{M_s}{M_p} \ . \tag{20}$$

For a 2-d model, as we already know, this quantity will be equal to

$$I_s = N_s = 2M_s^2/M_p^2 \ .$$

Let's compare these amounts of quantum information for a black hole of solar mass $M_\odot$:

$$I_s/I_{s*} = 2M_\odot/M_p = 1.827 \times 10^{38} \ (sic!) \ .$$

As we can see, in the light of modern discoveries, this difference in the amounts of quantum information, is simply monstrous. That clearly shows the invalidity of "point-model".

5. Natural Quantum Black Hole Description

We can continue J. Bekenstein–V. Mukhanov approach that in fact derive from the A. Einstein "testament" that was cited above.

From (4) and (5) we can conclude that the number of photons in quantum black hole taken as a spherical self-gravitating 2-d photon condensate must be presented in the following form:

$$N_s = 2n_s, \quad n_s = 1, 2, 3, \ldots \tag{21}$$

where n_s is *the principal quantum number*.

Then it is easy to show that all our previous results can be represented as follows:

$$\overline{\lambda}_{sm} = R_s = 2l_p\sqrt{n_s} \ ; \tag{22}$$

$$M_s = M_p\sqrt{n_s} \ , \qquad E_s = E_p\sqrt{n_s} \ ; \tag{23}$$

$$M_{sm} = M_p/2\sqrt{n_s} \ , \qquad E_{sm} = E_p/2\sqrt{n_s} \ ; \tag{24}$$

$$\omega_{sm} \text{ (ciclic frequence)} = E_{sm}/\hbar = \omega_p/2\sqrt{n_s} \ , \tag{25}$$

where $\omega_p = 1/t_p$ is the Planck frequency, $t_p = \sqrt{\hbar G/c^5}$ is the Planck time;

$$A_s = 16\pi l_p^2 n_s \ ; \tag{26}$$

$$I_s = N_s = 2n_s \text{ (bit)} \ ; \tag{27}$$

$$S_s = kI_s = 2kn_s \ ; \tag{28}$$

$$T_s = E_p/4k\sqrt{n_s} = T_p/4\sqrt{n_s} \ , \tag{29}$$

where $T_p = E_p/k$ is the Planck temperature;

$$\rho^I_{sh}\ (\text{surface information density}) = I_s/A_s = 1/8\pi l_p^2 = \frac{c}{\hbar\varkappa}\ \left(\frac{\text{bit}}{\text{m}^2}\right)\ , \tag{30}$$

where $\varkappa = 8\pi G/c^2$ is the Einstein constant;

$$g_{sh}\ (\text{surface gravity}) = G\frac{M_s}{R_s^2} = a_p/4\sqrt{n_s}\ , \tag{31}$$

$a_p = F_p/M_p = c/t_p$ is the Planck gravity *etc.*

Note, that this natural "emergence" of Planck Scale Physics, that was "automatically" arised from basics system Eqs. (1)–(5), clearly shows, that Planck Units System as such was organically and naturally emerge from experimental physics and observational cosmology. Moreover, as we see, the "great" unity between Quantum Physics and General Relativity was reached in natural way.

The famous physicist J. A. Wheeler once said: "Mass tells spacetime how to curve; spacetime tells mass how to move." Inspired by this example, we can coin a new one: "Light quanta tells spacetime how to quantize; spacetime tells light quanta how to curve."

6. Quantum Black Hole "Evaporation": Two-Particle Emission and Gravitational Waves Radiation

As shown above, quantum black hole has the property of strong equilibrium between squeezed gravitational force and repulsive ("antigravitational") quantum-mechanical force. This state of strong equilibrium can be broken only by the V. Mukhanov's degeneracy effect, which consists in spontaneous quantum jump from n_s state to $n_s - 1$ state. In our case this means that in all relations Eqs. (21)–(31) the argument n_s must be replaced by $n_s - 1$. It's obvious that quantum energy corresponding to the level $E_p\sqrt{n_s}$ must reduce to the one corresponding to the level $E_p\sqrt{n_s - 1}$. The difference

$$\Delta E_{s,s-1} = E_p\left(\sqrt{n_s} - \sqrt{n_s - 1}\right) = \frac{E_p}{2\sqrt{n_s}}\left(1 + \frac{1}{4n_s} + \frac{1}{8n_s^2} + ...\right) \tag{32}$$

is equal to the sum of radiance energy of two-particle emission

$$\Delta E_{s,s-1\,qu} = \frac{E_p}{2\sqrt{n_s}}$$

and gravitational waves radiation energy

$$\Delta E_{s,s-1\,gr} = \Delta E_{s,s-1} - \Delta E_{s,s-1\,qu} = \frac{E_p}{2\sqrt{n_s}}\left(\frac{1}{4n_s} + \frac{1}{8n_s^2} + ...\right)\ . \tag{33}$$

Note that energy of the quadrupolar mode is represented by term:

$$\left|\frac{\hbar}{c}\frac{\mathrm{d}g_{sh}(n_s)}{\mathrm{d}n_s}\right| = \frac{E_p}{2\sqrt{n_s}} \times \frac{1}{4n_s}\ . \tag{34}$$

From this result we easily understand that the next term ${}^{1}/_{8n_s^2}$ from the sequence in parentheses from Eq. (33) corresponds to octupolar mode and so on.

We come to the conclusion that in the parenthesis

$$\left(1+\frac{1}{4n_s}+\frac{1}{8n_s^2}+...\right)$$

of the main expansion of polynomial in Eq. (32), the first term refers to the dipolar mode, the second term — to the quadrupolar mode, the third — to the octupolar and so on. In other words, all the terms, except the first one, are directly related to the gravitational radiation of a quantum black hole. It only remains to find out the physical nature of the dipolar mode. For this, we turn to the data of experimental physics. In 2011, physicists from Chalmers University of Technology experimentally proved the existence of Casimir–Unruh dynamical effect in the squeezed vacuum excited by the "moving mirror" with frequency ω, that produce a pair of non-entangled photons with associated frequency $\omega/2$ each.[13]

By this experiment Nature suggests that in general case the energy $\Delta E_{s,s-1\,qu}$ of two-particle emission, $\left(X_s,\bar{X}_s\right)$, must be presented by the following form:

$$\Delta S_{s,s-1\,qu}=\hbar\omega_{sm}=\hbar\omega_{sx}+\hbar\omega_{s\bar{x}}=E\left(X_s\right)+E\left(\bar{X}_s\right)\ , \tag{35}$$

where ω_{sm} is the cyclic frequency Eq. (36),

$$\omega_{sx}=\omega_{s\bar{x}}={}^{\omega_{sm}}/_{2}\ ,\qquad E\left(X_s\right)=E\left(\bar{X}_s\right)={}^{E_{sm}}/_{2}\ , \tag{36}$$

where ω_{sx}, $\omega_{s\bar{x}}$ are the frequencies associated with emitted particles.

The following quantum black hole "degeneracy" diagram can illustrate all these results:

$$BH_s\longrightarrow BH_{s-1}+X_s+\bar{X}_s+\Gamma_s\ , \tag{37}$$

where Γ_s is the generated gravitational wave with energy Eq. (33).

Note that the pair $\left(X_s,\bar{X}_s\right)$ of non-entangled particles, depending on their energy, can be a pair of hot photons, this being especially important at energies well above the Higgs field level (246 GeV).

Remark 6.1. Using the expressions obtained above, it is easy to calculate the energy structure of quantum black hole at its "end-point" ($n_s=1$):

$$BH_p\longrightarrow 2\gamma_{p,0}+\Gamma_{p,0} \tag{38}$$

with energies:

$$E\left(BH_p\right)=E_p\sqrt{1}=E_p\ ,\qquad 2E\left(\gamma_{p,0}\right)={}^{E_p}/_{2\sqrt{1}}={}^{E_p}/_{2}\ , \tag{39}$$

$$E\left(\Gamma_{p,0}\right)=E_p\left(\sqrt{1}-\sqrt{1-1}-{}^{1}/_{2\sqrt{1}}\right)={}^{E_p}/_{2}\ . \tag{40}$$

As it can be observed, at the "end-point" of the existence of any black hole, all ends with a spectacular explosion with emission of half of energy, $\left({}^{E_p}/_{2}\right)$, as quantum electromagnetic radiation and another half, $\left({}^{E_p}/_{2}\right)$ — as gravitational

radiation. Note that these last two photons carry the last two bits of quantum information. As we can see, in the presented unified approach so called "end-point" problem is solved.

In general case we can find that the total energy radiated by a quantum black hole "evaporating" from the state n_s to its "end-point" is equal to

$$E_{s\,qu}\ (\text{rad}) = \sum_{n=1}^{n_s} E_p/2\sqrt{n}\ , \tag{41}$$

$$E_{s\,gr}\ (\text{rad}) = \sum_{n=1}^{n_s} E_p \left(\sqrt{n} - \sqrt{n-1} - \frac{1}{2\sqrt{n}}\right) = E_p\sqrt{n_s} - \sum_{n=1}^{n_s} \frac{E_p}{2\sqrt{n_s}}\ , \tag{42}$$

$$E_s\ (\text{total rad.}) = E_{s\,qu}\ (\text{rad}) + E_{s\,gr}\ (\text{rad}) = E\sqrt{n_s} = E_s\ . \tag{43}$$

Note that with increase of n_s the total gravitational radiation quickly tends to its maximal value E_p. As we see, the proportionality

$$^{E_{s\,gr}\ (\text{rad})}\!/_{E_{s\,qu}\ (\text{rad})} = {}^{1}\!/_{4n_s} + {}^{1}\!/_{8n_s^2} + ... \tag{44}$$

clearly shows the great importance of gravitational radiance when the temperatures of black holes are near to Planckian scale.

7. Real Mechanism of Quantum-Gravitational Radiation and Removal of "Information Loss" Problem

Above we have showed that, in accordance with the V. Mukhanov's degeneracy effect, the strong equilibrium of quantum black hole can be broken by quantum jump from n_s state to the $n_s - 1$ one. We have found, in Eq. (36), that each of the two emitted particles have the energy equal to $E_{sm}/2$. From this, we can easily calculate their non-reduced Compton wavelength:

$$\lambda_c\,(X_s) = \lambda_c\left(\bar{X}_s\right) = \frac{2\pi\hbar c}{E_{sm}/2} = 4\pi R_s\ . \tag{45}$$

If we compare this value with quantum black hole gravitational radius R_s, we find that these two particles will immediately "escape" from tremendous gravitational "well" of quantum black hole via the V. Gribov–S. Hawking tunneling effect. However, the "breaking news" is: this quantum tunneling effect of two emitted particles is accompanied with radiation of gravitational waves that play an important role in the Planck Scale Physics. Note that quantum black hole radiates two bit of quantum information during "jumping" process:

$$\Delta I_{s,s-1\,qu} = I_s - I_{s-1} = 2n_s - 2(n_s - 1) = 2\ (\text{bit})\ , \tag{46}$$

and these two bits were carried away by two "escaped" particles.

As we see above Eq. (52), the last, "remnant" Planck hole collapsed emitting the last two photons carrying the last two bits of quantum information. These

conclusions can represented by the strict mathematical relation:

$$I_s \text{ (radiated)} = \sum_{n=1}^{n_s} \Delta I_{n,n-1\,qu} = 2n_s = I_s \ , \tag{47}$$

that confirms the unitarity principle of quantum physics in the quantum black hole theory in the form of the law of quantum information conservation, that definitely solves the so-called "information loss" problem.

8. Entropy Production by Radiation

In conformity with Clausius relation, we can easily find the entropy production by quantum black hole radiation:

$$\begin{aligned} \Delta S_{s,s-1} = \frac{\Delta E_{s,s-1}}{T_s} = \frac{\Delta E_{s,s-1\,qu}}{T_s} + \frac{\Delta E_{s,s-1\,gr}}{T_s} = \\ = \Delta S_{s,s-1\,qu} + \Delta S_{s,s-1\,gr} = 2k + 2k\left(\frac{1}{4n_s} + \frac{1}{8n_s} + ...\right) \ . \end{aligned} \tag{48}$$

The quantum entropy term

$$\Delta S_{s,s-1\,qu} = 2k = k\Delta I_{s,s-1} \tag{49}$$

is closely connected with two bit of radiated information Eq. (46). But what represent the gravitational radiance term $\Delta S_{s,s-1\,gr}$? The form of the term

$$\Delta S_{s,s-1\,gr} = 2k\left(\frac{1}{4n_s} + \frac{1}{8n_s^2} + ...\right) \tag{50}$$

suggests that it is closely connected with quadrupolar, octupolar etc. modes of gravitational radiation that is the source of a dissipative and irreversible dark energy. We may call this term "gravitational waves entropy production".

It is interesting that famous physicist T. Jacobson in his important work "Non-equilibrium Thermodynamics of Spacetime" named a similar term "bulk viscosity entropy production term" and connected it with Ricci flow. But what is more fascinating: the famous mathematician Grisha Perelman presented his extraordinary work "The entropy formula for Ricci flow and its geometric application", in which argue that the entropy is an effective tool for mathematical investigation.

9. Dynamics: Radiance Power and Lifetime

Before the V. Mukhanov's "degeneracy" jump, quantum black hole must relax to gain the spherical form. Note that inside the 2-d photon condensate the "time flow" is the same as the "time flow" for external observer. This is not a deliberative assumption but a result of LIGO measurement in which the duration of ring-down phase is only a small part of a second. This is because in each point of the 2-d photon condensate all the tangential forces are equilibrated. The "stopped time-flow" effect take place only in the nearest vicinity, but not inside the "stretched horizon".

It is clear that the relaxation process needs a causal synchronism, which means that all the pairs of points located, one from another, at a distance of half a circle (πR_s) must be casually connected. This requires fulfillment of a lot of time at n_s state

$$\Delta t_s = \frac{\pi R_s}{c} = 2\pi t_p \sqrt{n_s} \; . \tag{51}$$

From this formula, we can easily calculate the lifetime of an "evaporated" quantum black hole:

$$\tau_s = \sum_{n=1}^{n_s} 2\pi t_p \sqrt{n} \; . \tag{52}$$

Using Bohr's correspondence principle, a very simple relation is found:

$$\tau_s = \int_0^{n_s} 2\pi t_p \sqrt{n} \, \mathrm{d}n = \frac{4\pi}{3} t_p n_s^{3/2} = \frac{4\pi}{3} t_p \left(\frac{E_s}{E_p} \right)^3 \; . \tag{53}$$

If we compare it with the S. Hawking's formula, we can see that

$$\tau_s = \frac{1}{3840} \tau_s \text{ (Hawking)} \; . \tag{54}$$

This big difference appears because S. Hawking associated black hole radiation with the blackbody radiation and with the Stefan-Boltzmann law, which means a continuous thermal spectrum. In contrast to this, following J. Bekenstein and V. Mukhanov, we have showed that this spectrum is discrete. Hence such a strong difference occurs.

Let's find the radiance power:

$$P_s = \frac{\Delta E_{s,s-1}}{\Delta t_s} \cong \frac{E_p}{4\pi t_p n_s} = \frac{\hbar c^6}{4\pi G^2 M_s^2} \; . \tag{55}$$

Comparing this with the S. Hawking's result, we find, respectively

$$P_s = 3840 P_s \text{ (Hawking)} \; . \tag{56}$$

The reason for such a large difference is the same.

We have a rare opportunity to qualitatively compare our results. It is known that the "baryonic epoch" lasted for about 400 thousand years. According to our calculations, in conformity with Eq. (53), the lifetime of the black hole, able of generating baryons, is about 240 thousand years, that quite "fits" into the mentioned interval of 400 thousand years. Whereas by S. Hawking model Eq. (54) it take as long as 920 millions (!) years, which is completely inconsistent with the data of observational cosmology. In what follows, we can find more details.

Moreover, such quantum black holes can produce pairs of ordinary neutrons via broken chiral symmetry that may solve the "old" problems of baryogenesis (followed by nucleosynthesis and leptogenesis) and matter–antimatter asymmetry in the Universe.

10. Dynamical Parameters of Particle Production

Whereas with him, the results obtained above can be easily extended to the processes of pair-production of any kind. To do this, it is enough to implement the condition for their generation

$$E_{s,s-1\,qu} \geqslant 2E_x \ , \tag{57}$$

where $E_x = m_x c^2$ is the rest energy of each particle, m_x being the rest mass. This condition is easily transformed into

$$E_s \leqslant \frac{E_p^2}{4E_x} \ . \tag{58}$$

The main result can be obtained by substituting Eq. (58) into Eq. (53):

$$\tau_s(x) \leqslant \frac{\pi}{48} t_p \left(\frac{E_p}{E_x}\right)^3 \ . \tag{59}$$

Condition Eq. (58) is easily modified into

$$M_s(x) \leqslant \frac{M_p^2}{4m_x} \ , \tag{60}$$

which determines the extremely large mass of a black hole able to produce a pair of particles $\left(X_s, \bar{X}_s\right)$ of a given type.

If it is known that, in the table of rest masses, a particle of type X_1 of mass m_{X1} is immediately followed by a particle of type X_2 of a larger mass m_{X2}, then we can determine the generation time of a particle of type X_1 by a black hole using the formula

$$\Delta\tau_1(X_1) = \tau_s(X_1) - \tau_s(X_2) \ , \tag{61}$$

whereas the total number of generated particles and antiparticles of the type X_1 is easily found from relation

$$N_s(X_1) = \frac{M_p^2}{8}\left(\frac{1}{m_{X1}^2} - \frac{1}{m_{X2}^2}\right) \ . \tag{62}$$

11. Birth and Rise of Quantum Black Holes at The Beginning of the Universe and at the Gravitational Collapse of Astrophysical Objects

"What I cannot create, I do not understand."
(R. Feynman)

The natural "suppression" of the Higgs field at the energies well above 246 GeV exclude all Feynman's diagrams that describe scattering processes in Standard Model. Even two photon scattering "box-diagram" do not work because it needs the presence of a non-zero Higgs field. Despite that quantum electromagnetic field do not

depends on Higgs field, two-photon scattering require intermediate virtual particle-antiparticle pair that is impossible when Higgs field is suppressed by energies of photons. Note that photons do not interact directly. Only gravitational field may save this situation but photons are massless particles. With one notable exception: photons do have rest masses in 2-d and 3-d photon condensates.

With these arguments, we conclude that Planckian black hole may be created only through the mediation of the gravitational field that acted in the 3-d Planck photon condensate. Note that a minimal photon condensate is represented by binary Planck system, (γ_p, γ_p), with two Planck photons in a close contact. These distinct binary Planck systems were formed when local homogeneity and isotropy were broken through the Planckian fluctuations The distance between the "centers" of this "fuzzballs" is equal to Planck length l_p. The total mass of Planck binary system is $2M_p$ and its rest energy is $2E_p$. The initial internal gravitational force is equal to the Planckian one:

$$F(\gamma_p, \gamma_p) = G\frac{M_p M_p}{l_p^2} = F_p \ . \tag{63}$$

This tremendous gravitational force provokes coalescence of this binary Planckian system. This tremendous Planckian coalescence inevitably generates a Planckian gravitational wave Γ_p that break the continuity of spacetime and forms a two-photon spacetime "buble". The energy of this Planckian gravitational wave is equal to Planckian work W_p:

$$E(\Gamma_p) = W_p = F_p l_p = E_p \ . \tag{64}$$

But what is the rest energy of this "buble"? This rest energy is equal to difference between initial rest energy of binary Planck system and energy of radiated Planck gravitational wave:

$$E(\gamma_p, \gamma_p) - E(\Gamma_p) = 2E_p - E_p = E_p \ .$$

In Sec. "2. Basic Relations" we have found that a minimal spherical 2-d photon condensate with two photons have Planck rest mass M_p and Planck rest energy E_p, Eq. (6). Note that this result was obtained without any presumptions and hypotheses about the importance of the Planckian Units System. We may say that it emerged in natural way starting from basic system of relations Eqs. (1)–(5) for quantum black holes. This means that the produced spacetime "buble" is nothing but the Planck black hole BH_p.

Thus, we can write the following fundamental scheme (diagram) of the birth of Planck black hole accompanied by Planck gravitational wave:

$$(\gamma_p, \gamma_p) \longrightarrow BH_p + \Gamma_p \tag{65}$$

with

$$E(BH_p) = E(\gamma_p, \gamma_p) - E(\Gamma_p) = E_p \ . \tag{66}$$

Expressions Eqs. (65) and (66) represent the fundamental conditions for the nucleation of Planck black holes, which, through accretion, can reach very significant sizes.

A very important question arises: where and when conditions of formation of Planck binary systems (γ_p, γ_p) could exist?

There are only two mutually reinforcing answers to this question:

- at the Beginning of the Universe, when *primordial* quantum black holes were created;
- in the nuclei of gravitationally collapsed astrophysical objects, such as neutron stars, where did the *secondary* quantum black holes emerged from.

Let us define the natural condition for accretion in the general form

$$\lambda_\gamma \leqslant \lambda_{sm} = 2\pi R_s \ , \tag{67}$$

which is equivalent to the condition

$$E_\gamma \geqslant E_{sm} \ . \tag{68}$$

Here E_γ is the energy of the absorbed photon, γ, and λ_γ is its wavelength.

Note that the velocity of accretion can be well above velocity of emission because it depends only on the intensity of captured photons flow.

Note one more very important circumstance: black holes consist of light and "feed" only on light. A clear understanding of the function of accretion disks and jets accompanying black holes immediately follows from this. Accretion discs perform the function of "thermal extraction" of light from the ordinary matter, while jets perform the functions of "evacuators" of rested plasma as a sort of "production wast". The tremendous two jets from *Sagittarius A**, which is called "Fermi bubbles", are the good illustrations and demonstration of these statements.

12. Cosmogenesis: Hot Big Bang and Pre-Inflation Stage

According to the law of conservation of energy, it accounts for an energy equal to the value of the energy of the modern Universe of the order of $10^{61}\, E_p$. Since in the future we will operate with energy densities, the exact value of this quantity is not important for us, only important being the fact that the total number of Planck photons in this condensate is tremendous large and has a value of the order of 10^{61}, that allows us to use in the following the theory of probabilities and the law of large numbers. At the same time, we will consider our diagrams as probabilistic events which should be connected in the casual and energetical sense.

Remark 12.1. Considering primordial Planck photon condensate trapped in its gravitational field as a *"prima materia"* at the "beginning of times" we automatically remove the synchronization problem, since the speed of physical processes

is the same in all domains of primordial condensate. Also, we are removing the homogeneity and isotropy problems due to the fact that the 3-d Planck condensate has the densest possible packing, close to the fuzzy spherical one, in which each Planck photon is densely "covered" by 12 other ones (interference is impossible due to the impossibility of exceeding the Planck energy density E_p/l_p^3). The "time flow" was homogenic and was determined by the Planckian time t_p. Note that it was this fact that caused the initial synchronization of all processes that occurred at the beginning of Hot Bing Bang.

Remark 12.2. The law of conservation of energy in the observable Universe guarantees us that it is the energy of primordial Planckian 3-d photon condensate trapped in its own gravitational field that cause all physical processes that occurred and will occur in the Universe.

Vacuum cannot serve as a *"perpetuum mobile"* of the Universe. All attempts to explain the so called "cosmology constant problem" by the cosmic vacuum energy was failed. However, it is the Planckian quantum fluctuations of vacuum in the primordial 3-d condensate that are the natural sources of "breaking" of its gravitational homogeneity and anisotropy.

We must consider one very important problem: not all Planckian photons in the primordial 3-d condensate can form the primordial binary Planckian systems (γ_p, γ_p). A part becames free.

The probability of such event to occur, due to its exceptional importance for cosmology, we will note as $\aleph$ (*alef*: "divine"). This probability can be computed using the relation

$$\aleph = (1 - \aleph)^{12} \ , \tag{69}$$

where $(1 - \aleph)^{12}$ is the probability for all its twelve surrounding photons to become non-free, *i.e.* to take part at events of the type Eq. (65). Solving the Eq. (69) we obtain

$$\aleph = 0.14745 \ldots . \tag{70}$$

If we use the presented above diagrams Eq. (65) as events from the point of view of probability theory and laws of large numbers we can easily find the following numbers at the beginning of the Universe as a beginning of the Hot Big Bang:

$$\Omega_L = \aleph \cong 0.1474 \ , \qquad \Omega_{BH} = \Omega_{GR} = \frac{(1 - \aleph)}{2} \cong 0.4263 \ , \tag{71}$$

where Ω_L — energy density of free light (free Planck photons, γ_p), Ω_{BH} — rest energy density of Planck black holes (BH_p), Ω_{GR} — energy density of Planck gravitational waves (Γ_p).

After about $50\pi t_p$ (*i.e.* $\sim 10^{-41}$ sec) the preinflation stage of Hot Big Bang is finished with following results:

$$\Omega_L \ = (7\aleph - 1)\sum_{n=1}^{7}\frac{1}{2\sqrt{n}} + (1 - 6\aleph)\sum_{n=1}^{9}\frac{1}{2\sqrt{n}} \cong 0.3358\,, \tag{72}$$

$$\Omega_{BH} \cong 0 \text{ (a very small value)}\,, \tag{73}$$

$$\Omega_{GR} = 1 - \Omega_L - \Omega_{BH} \cong 0.6642\ (66.42\%)\ . \tag{74}$$

Note that this irreversible density of energy (66.42%) remains practically unchanged till the beginning of II stage of inflation, when the binary collisions of black holes will become the source of the increase of this density (as we can see below).

From Eqs. (72)–(74) we find the strongest inequality

$$\Omega_{BH} \ll \Omega_L + \Omega_{GR}\ , \tag{75}$$

that denote the end of the pre-inflation stage of the Hot Big Bang and the beginning of the hyperinflation stage of the Universe.

The strong inequality Eq. (75) shows that at the end of the pre-inflation stage the weak energy of the squeezed gravitational forces were totally suppressed by the tremendous common energy of the quantum electromagnetic and gravitational radiation stretched forces (close to the whole energy of the Universe!).

Moreover, the very small value of Ω_{BH} is backed by the enormous absolute number of primordial black holes that were the "seeds" of the modern Cosmic Web.

As far as we know, all these results are the only physically substantiated confirmation of Hot Bing Bang and inflation theories.

In conformity with "Planck-2018" observational data[14] the energy density of dark energy Ω_Λ represents 0.6847 (68.47%) of the total energy of the Universe. This means that the relic gravitational waves emitted in the pre-inflation phases of Hot Big Bang represent

$$\frac{\Omega_{GR}}{\Omega_\Lambda} \times 100\% = \frac{0.6642}{0.6847} \times 100\% \cong 97\%\ (sic!) \tag{76}$$

of the nowadays dark energy.

Note that the only two kinds of primordial gravitational waves Γ_p and $\Gamma_{p,0}$ with E_p and $E_p/2$ energies that accompanied birth and death of Planck black holes taken together represents 93.39% of the nowadays dark energy.

These and others relic gravitational waves form the homogenic and anisotropic relic Cosmic Gravitational Waves Background (CGWsB) manifested only as the most of the irreversible and omnipresent dark energy shown in the "Planck-2018" data. Now these waves are of infinitesimal amplitudes and of frequency range of few kilohertz.

In fact, these results represent the veritable solutions of so called "cosmological constant problem",[15] dark matter and dark energy problems.

13. Two-stage Inflation

At the end of the baryogenesis, leptogenesis and nucleosynthesis epoch, when the stage I of inflation was ended, the remaining energy of ordinary matter reached the 4.96% of the total energy of the observable Universe (note that this value presented by "Planck-2018" data is unchanged in time). If we neglect the small energy density of light, we can determine the remaining energy density of black holes (dark matter) at the end of I-st stage of inflation:

$$\Omega_{BH}(\%) = 100\% - 4.96\% - 66.42\% = 28.62\% \, .$$

After this epoch, there came the non-accelerated stage of the expanse of the Universe. But 6–8 billions of years ago, the II-nd stage of small inflation began. Now, from "Planck-2018" data we know that the distribution of the energy in the nowadays Universe is roughly represented by the following numbers:

$$\begin{aligned} 4.96\% \quad & \text{(for baryonic matter)}, \\ 26.57\% \quad & \text{(for dark matter)}, \\ 68.47\% \quad & \text{(for dark energy)}. \end{aligned}$$

As we can see, a comparison with the end of the I stage of inflation clearly shows that the increase in the dark energy is caused by the decrease of the energy associated to dark matter. This leads to the unambiguous conclusion that the stage II of inflation is provided by the binary coalescences of black holes.

Conclusions

Presented approach to the Planck scale physics that governed the cosmological processes at the beginning of the Universe is based on the simple but consistent algebraic relations and schemes (diagrams) with such specific terms as Planck binary systems (γ_p, γ_p) quantum black holes BH_s, gravitational waves Γ_s *etc.* These physico-mathematical tools work in the area where the tools of standard models of physics and cosmology do not work because of tremendous temperatures and pressures that blocked the Higgs field activity. In a such terrible environment only 3-d photon condensates and 2-d spherical photon condensates (quantum black holes) are unique sources of gravity at the beginning of the Universe.

As it was showed above, presented results elucidate the decisive role of primordial black holes (as a dominated part of dark matter) in the generation of gravitational waves (a dominant part of dark energy) and clearly explain the physical background of Hot Big Bang and two-stage inflation. Moreover, these results solve the "old" unsolved problem of physics and cosmology such as "cosmic censure" problem, information loss paradox, black hole "end-point" problem, so called "cosmological constant" problem and so on.

From the theoretical point of view, presented approach derive from the last A. Einstein's conjecture about algebraic combined quantum and continuum description of reality and from the deepest principles and conjectures of such

distinguished physicists and cosmologists as J. Bekenstein, S. Weinberg, S. Hawking, V. Mukhanov, L. Susskind, G. 't Hooft, W. Unruh, T. Jacobson, K. S. Thorne, F. Wilczek, M. Maggiore., J. Peebles, B. Carr, P. W. Anderson, L. Smolin, C. Rovelly, F. Vidotto ("Planck Star" concept), A. Kashlinsky, S. Hossenfelder and many other eminent theorists. But the decisive role was played the theoretical consequences from the last fundamental discoveries of experimental physics and observational cosmology.

Acknowledgments

The author expresses his sincere gratitude to prof. Gr. Vereshchagin, prof. S. Ansoldi and prof. A. Pittelli for the opportunity to present these results at the "Early Universe" session of the 16-th Marcel Grossmann Meeting (Rome, 2021).

Helical magnetic fields lead to baryogenesis

Ashu Kushwaha and S. Shankaranarayanan

E-mail: ashu712@iitb.ac.in, shanki@phy.iitb.ac.in

The origin of primordial magnetic fields and baryon asymmetry of the Universe are still unresolved issues and require physics beyond the standard models of cosmology and particle physics. Since both require physics beyond the standard model, there is a possibility that the same new physics can solve both. In this talk, I will discuss our model, where non-minimal coupling to the Riemann tensor generates sufficient primordial helical magnetic fields at all observable scales during inflation. Interestingly, the generation of helical magnetic fields leads to baryogenesis, and the model predicts the observed amount of baryon asymmetry of the Universe for a range of reheating temperatures consistent with the observations.

Keywords: Helical magnetic fields, baryogenesis, based on the works[1,2]

1. Introduction

The present Universe contains only matter and no antimatter, except for the rare antiparticles produced by cosmic rays. This asymmetry between baryons and antibaryons, also known as Baryon Asymmetry of the Universe (BAU), is characterized by the parameter $\eta_B \sim 10^{-10}$. Yet, we still do not completely understand the genesis of this asymmetry. However, in a remarkable paper in 1967, Sakharov[4] pointed out that to have observed baryon asymmetry following conditions must be satisfied by any theory: (1) baryon number violation (2) charge (C) and charge parity (CP) violation and (3) departure from thermal equilibrium.[6]

Observations from Faraday rotation and synchrotron radiation show the presence of micro-Gauss strength magnetic fields in the galaxies and the clusters of galaxies.[8] While the magnetic field measurements from Faraday rotation and synchrotron radiation provide upper bounds of the magnetic fields, the FERMI measurement of gamma-rays emitted by blazars provides a lower bound of the order of 10^{-15} G in intergalactic voids.[9] The origin of the magnetic field in these regions is still an open problem in modern cosmology; there is no compelling theoretical model to explain the generation of these large-scale magnetic fields.

The origin of primordial magnetic fields and the origin of the baryon asymmetry of the Universe are the unresolved issues in modern cosmology and particle physics models. Both require physics beyond the standard model and pose an exciting question— are these processes cosmological or particle physics or both? It seems impossible to generate the observed amount of baryon asymmetry within the Standard Model of particle physics framework. Since both require physics beyond the

standard model, there is a possibility that the same physics can solve both problems. This talk discusses a mechanism that leads to the generation of primordial helical magnetic fields and baryon asymmetry at the beginning of the radiation-dominated epoch.

The electromagnetic field has two transverse degrees of freedom, i.e., left and right circular polarization, associated with the left and right-handed helicity modes. Furthermore, modes with the same evolution (or dispersion relation) lead to the non-helical electromagnetic field. In contrast, differently propagating modes with non-zero net helicity imbalance give a helical magnetic field. In order to create this helicity imbalance we consider the following scenario: under parity transformation electric and magnetic fields transform as $\mathbf{E} \longrightarrow -\mathbf{E}, \mathbf{B} \longrightarrow \mathbf{B}$, since standard electromagnetic action, $F_{\mu\nu}F^{\mu\nu} = (B^2 - E^2)/2$ is parity invariant, but the Chern-Simon term $F_{\mu\nu}\tilde{F}^{\mu\nu} = -4\mathbf{E}\cdot\mathbf{B}$ is parity non-invariant. Therefore, introducing this term in the action will lead to the different evolution of the modes. There is an interesting quantity related to the $F_{\mu\nu}\tilde{F}^{\mu\nu}$ called magnetic helicity density, which in a given volume, is proportional to the difference between the number of left and right-handed photons, and is given by: $\mathcal{H}_M = \frac{1}{V}\int_V d^3x \mathbf{A}\cdot\mathbf{B}$, where $\mathbf{A}$ is electromagnetic vector potential. Helical magnetic fields are very interesting for the following reasons: (1) the decay rate to energy density and coherence length is slow for these fields, which differs from the non-helical, (2) helical magnetic fields leave a very distinct signature as they violate parity symmetry which leads to observable effects, for example, correlations between the anisotropies in the temperature and B-polarisation or the E- and the B-polarisations in the CMB, and (3) if we could measure helical magnetic fields, it would provide evidence of CP violation in the early Universe.

It is important to note that both kinds of magnetogenesis models, i.e., early time and late time models, have problems. Inflation provides a causal mechanism to generate the magnetic fields of large coherence length. The problem with magnetic field generation during inflation is that standard electromagnetic action is conformally flat. Hence, the inflationary mechanism can not amplify quantum fluctuations of electromagnetic fields. Therefore one needs to break the conformal symmetry of the action. In the literature, models breaking conformal invariance by introducing non-minimal coupling terms in the electromagnetic action are proposed or by the time-dependent coupling with the gauge field.[8] These models produce non-helical magnetic fields. On the other hand, the generation of helical magnetic fields baryogenesis in the early Universe requires a parity-violating source.

A more popular scenario of helical field generation (and baryogenesis) is by adding the interaction term $f(\phi)F_{\mu\nu}\tilde{F}^{\mu\nu}$ which is responsible for creating the imbalance between left-handed and right-handed photons.[10] However, these scalar field coupled models suffer from strong coupling and backreaction problems and sensitivity to the reheating dynamics. In this talk, I will discuss our model where the electromagnetic field is coupled to the Riemann curvature, which breaks the conformal invariance and parity symmetry of the theory and leads to the production

of primordial helical fields at all length scales. Interestingly, as we will see that the same helical modes will give a non-zero contribution to Chern-Simon (CS) number density and hence lead to the baryogenesis.

1.1. *Baryogenesis in the presence of primordial helical magnetic field*

Almost two decades back, Davidson[3] pointed out some very interesting relation between primordial magnetic field and Sakharov's conditions of the baryon asymmetry of the Universe. The presence of background magnetic fields in the early Universe may break the $C, CP, SO(3)$ and thermal equilibrium. Specifically, she argued that there are symmetries that are broken due to the presence of magnetic field: (1) there should be some kind of out-of- thermal-equilibrium dynamics because in equilibrium, the photon distribution is thermal, and there are no particle currents to sustain a "long-range" field, (2) because $\mathbf{B}$ is odd (changes sign) under CP, the presence of magnetic field will lead to CP violation, (3) since the magnetic field is a vector quantity, it chooses a particular direction hence breaks the isotropy (rotational invariance). This implies that one could see the presence of a magnetic field to provide the CP violation and out of thermal equilibrium conditions required in baryogenesis models. However, Davidson's conditions are necessary but not sufficient. One key missing ingredient is the requirement of *primordial helical magnetic fields* which can provide evidence of CP violation in the early Universe if we could measure them. Interestingly, as we show next, the presence of primordial helical fields leads to the non-zero Chern-Simons number and, eventually, the change in the Fermion number.

In the early Universe, the generation of the non-zero primordial helical magnetic fields leads to a chiral anomaly resulting from the imbalance between left and right-handed fermions. In the presence of an electromagnetic field in curved space-time, the chiral anomaly is given by the following equation[5]:

$$\nabla_\mu J^\mu_A = -\frac{1}{384\pi^2}\epsilon^{\mu\nu\rho\sigma} R_{\mu\nu\alpha\beta} R^{\alpha\beta}{}_{\rho\sigma} + \frac{e^2}{16\pi^2}\epsilon^{\mu\nu\alpha\beta} F_{\mu\nu} F_{\alpha\beta} \tag{1}$$

where J^μ_A is the chiral current, $R_{\rho\sigma}{}^{\alpha\beta}$ is the Riemann tensor and A_μ is the four-vector potential of the electromagnetic field, $F_{\mu\nu} = \nabla_\mu A_\nu - \nabla_\nu A_\mu$ and $\epsilon^{\mu\nu\rho\sigma} = \frac{1}{\sqrt{-g}}\eta^{\mu\nu\rho\sigma}$ is a fully antisymmetric tensor, and we set $\eta^{0123} = 1 = -\eta_{0123}$.

In the case of flat FRW background in conformal time (η):

$$ds^2 = a^2(\eta)\left(d\eta^2 - \delta_{ij} dx^i dx^j\right), \tag{2}$$

the first non-zero contribution of the first term in the RHS of Eq. (1) comes only at second order and hence will not play any role in our analysis. However, due to the presence of the magnetic fields, the second term in the RHS of Eq.(1) is the non-zero only and hence leads to a net chiral current. Thus, if we consider only

up to the first-order in perturbations, *only* the second term in the RHS of Eq. (1) contributes, and the chiral anomaly equation reduces to:

$$\partial_\mu \left(\sqrt{-g} J^\mu_A\right) = \frac{e^2}{4\pi^2} \partial_\mu \left(\sqrt{-g} K^\mu\right) \tag{3}$$

where

$$K^\mu = \frac{\eta^{\mu\nu\alpha\beta}}{\sqrt{-g}} A_\nu \partial_\alpha A_\beta$$

is the topological current. Using Eq. (6), the net baryon number density, $n_B = a(\eta)\langle 0|J^0_A|0\rangle$ is related to Chern-Simon number density $n_{CS} = \langle 0|K^0|0\rangle$ as,[7]

$$n_B \equiv \frac{e^2}{4\pi^2} a(\eta) n_{CS}\,, \tag{4}$$

where

$$n_{CS} = \frac{1}{a^4} \epsilon_{ijk} \langle 0|A_i\, \partial_j A_k|0\rangle = \frac{1}{a^4} \int_\mu^\Lambda \frac{dk}{k} \frac{k^4}{2\pi^2} \left(|A_+|^2 - |A_-|^2\right)\,, \tag{5}$$

where Λ, and μ set the possible energy range (or epoch) of the baryogenesis after inflation, and $A_\pm$ refer to the positive and negative modes of the helical magnetic fields which are generated during inflation. Note that due to the absence of standard model particles $n_B = 0$ during inflation. As we can see from Eq.(8) that all the modes re-entering the horizon at the beginning of the radiation-dominated epoch contribute significantly, and hence the value of n_{CS} depends on the upper cut-off Λ. It is important to note that n_{CS} vanishes if the primordial magnetic fields are non-helical, i. e. $|A_+| = |A_-|$, and hence will not lead to baryogenesis. Thus, the key missing ingredient of Davidson's conditions is the requirement of helical magnetic fields. non-zero only and hence leads to a net chiral current. Thus, if we consider only up to the first-order in perturbations, *only* the second term in the RHS of Eq. (1) contributes, and the chiral anomaly equation reduces to:

$$\partial_\mu \left(\sqrt{-g} J^\mu_A\right) = \frac{e^2}{4\pi^2} \partial_\mu \left(\sqrt{-g} K^\mu\right) \tag{6}$$

where

$$K^\mu = \frac{\eta^{\mu\nu\alpha\beta}}{\sqrt{-g}} A_\nu \partial_\alpha A_\beta$$

is the topological current. Using Eq. (6), the net baryon number density, $n_B = a(\eta)\langle 0|J^0_A|0\rangle$ is related to Chern-Simon number density $n_{CS} = \langle 0|K^0|0\rangle$ as,[7]

$$n_B \equiv \frac{e^2}{4\pi^2} a(\eta) n_{CS}. \tag{7}$$

where

$$n_{CS} = \frac{1}{a^4} \epsilon_{ijk} \langle 0|A_i\, \partial_j A_k|0\rangle = \frac{1}{a^4} \int_\mu^\Lambda \frac{dk}{k} \frac{k^4}{2\pi^2} \left(|A_+|^2 - |A_-|^2\right)\,, \tag{8}$$

where Λ, and μ set the possible energy range (or epoch) of the baryogenesis after inflation, and $A_\pm$ refer to the positive and negative modes of the helical magnetic fields which are generated during inflation. Note that due to the absence of standard model particles $n_B = 0$ during inflation. As we can see from Eq.(8) that all the modes re-entering the horizon at the beginning of the radiation-dominated epoch contribute significantly, and hence the value of n_{CS} depends on the upper cut-off Λ. It is important to note that n_{CS} vanishes if the primordial magnetic fields are non-helical, i. e. $|A_+| = |A_-|$, and hence will not lead to baryogenesis. Thus, the key missing ingredient of Davidson's conditions is the requirement of helical magnetic fields.

2. Generation and evolution of primordial helical magnetic field

We consider the following action:

$$S = -\frac{M_{\rm P}^2}{2}\int d^4x\sqrt{-g}\,R + \int d^4x\sqrt{-g}\left[\frac{1}{2}\partial_\mu\phi\partial^\mu\phi - V(\phi)\right] - \frac{1}{4}\int d^4x\,\sqrt{-g}\,F_{\mu\nu}F^{\mu\nu} - \frac{\sigma}{M^2}\int d^4x\,\sqrt{-g}\,R_{\rho\sigma}{}^{\alpha\beta}F_{\alpha\beta}\,\tilde{F}^{\rho\sigma} \tag{9}$$

where $R_{\rho\sigma}{}^{\alpha\beta}$ is the Riemann tensor, A_μ is the four-vector potential of the electromagnetic field, $F_{\mu\nu} = \nabla_\mu A_\nu - \nabla_\nu A_\mu$ and $\tilde{F}^{\rho\sigma} = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}$ is the dual of $F_{\mu\nu}$. $\epsilon^{\mu\nu\rho\sigma} = \frac{1}{\sqrt{-g}}\,\eta^{\mu\nu\rho\sigma}$ is fully antisymmetric tensor, $\eta^{\mu\nu\rho\sigma}$ is Levi-Civita symbol whose values are ±1 and we set $\eta^{0123} = 1 = -\eta_{0123}$.

Note that in Eq. (9), the first three terms are the standard terms (the Einstein-Hilbert action, scalar field action, and standard electrodynamics, respectively). However, the presence of the Riemann tensor term breaks the conformal (and parity) invariance of the action. We assume that the scalar field (ϕ) dominates the energy density in the early Universe (during inflation) and leads to $60 - 70$ e-foldings of inflation with $H \simeq 10^{14}$GeV. M is the energy scale, which sets the scale for the breaking of conformal invariance. We assume that $10^{-3} \leq (H_{\rm Inf}/M) \leq 1$ where $H_{\rm Inf} \sim 10^{14}$ GeV is the Hubble scale during inflation. It is important to note that due to Riemann coupling, M appears as a time-dependent coupling in the FRW background i.e. $\frac{1}{M_{\rm eff}} \sim \frac{1}{M}\frac{a'}{a^2} = \frac{H}{M}$. Using $H_0 \approx 10^{-44}$GeV and $M \approx 10^{17}$GeV, we can see that at current epcoh $\frac{H_0}{M} \sim 10^{-59}$. Therefore, the Riemann coupling is tiny, and the non-minimal coupling term in the electromagnetic action will have a significant contribution only in the early Universe.

Our model has the following salient features: First, our model does not require the coupling of the electromagnetic field with the scalar field. Hence, there are no extra degrees of freedom, which will not lead to a strong-coupling problem. Second, the conformal invariance is broken due to the coupling to the Riemann tensor. Since the curvature is significant in the early Universe, the coupling term will introduce non-trivial corrections to the electromagnetic action. However, as mentioned above, the Riemann coupling term will not contribute at late-times, and the model is

identical to standard electrodynamics. Third, as we show explicitly, our model is free from backreaction for a range of scale-factor during inflation. This is different from other models where a specific coupling function is chosen to avoid any back-reaction.[10]

2.1. *Estimating the strength of the helical magnetic fields*

We estimate the total electromagnetic energy density at the horizon exit and to identify whether the modes lead to back-reaction on the metric, we define the quantity, $R = \frac{(\rho_B+\rho_E)|_{\mathcal{H}\sim k_*}}{6H^2M_{\rm Pl}}$, which is the ratio of the total energy density of the fluctuations at horizon exit and background energy density during inflation. Since $R << 1$ for any $\alpha \leq -\frac{1}{2}$ ($\alpha = -1/2$ corresponds to de-Sitter universe), the model does not have back-reaction.

α	$\rho_{\rm total}$ (in GeV^4)	R
$-\frac{1}{2}-\epsilon$	$\sim 10^{64}$	$\sim 10^{-4}$
$-\frac{3}{4}$	$\sim 10^{62}$	$\sim 10^{-6}$
-1	$\sim 10^{61}$	$\sim 10^{-7}$
-3	$\sim 10^{59}$	$\sim 10^{-9}$

To estimate the current value of the helical fields, we assume instantaneous reheating and the fact that Universe becomes radiation-dominated after inflation. Due to flux conservation, the magnetic energy density will decay as $1/a^4$, i.e. $\rho_B(0) = \rho_B^{(f)}\left(\frac{a_f}{a_0}\right)^4$ where a_0 is the present day scale-factor, $\rho_B^{(f)}$ and a_f refer to the magnetic energy density and the scale-factor at the end of inflation, respectively. Using the fact that the relevant modes exited Hubble radius around 30 e-foldings of inflation, with energy density $\rho_B \approx 10^{64}$GeV^4, the primordial helical fields at GPc scales is: $B_0 \approx 10^{-20}$G where we have used $1G = 1.95 \times 10^{-20}$GeV^2. Our model predicts the following primordial helical fields that re-entered the horizon at two different epochs: $B|_{50\ \rm MPc} \sim 10^{-18}\ G$ ($z \sim 20$) and $B|_{1\ \rm MPc} \sim 10^{-14}\ G$ ($z \sim 1000$). Thus, the model generates sufficient primordial helical magnetic fields at all observable scales. Also, our model predicts the present-day helical magnetic field of strength 10^{-15}G on Mpc scales.

3. Baryon asymmetry of the Universe

Now, we compute the baryon asymmetry created by the helical modes generated during inflation. To do that, we need to obtain the ranges of Λ and μ. The largest scales observed in the CMB are produced around 40 - 60 e-foldings before the end of inflation, and hence we have considered these modes for the generation of the helical magnetic field. However, taking advantage that modes are generated at all length scales in our model, we focus on the helical fields that renter the horizon very early

(at the beginning of the radiation-dominated epoch) to generate the required BAU. This means that the modes that left the horizon around the last 5 to 10 e-foldings of inflation are only relevant.

Since the entropy density per comoving volume is conserved, the quantity n_B/s is better suited for theoretical calculations. Assuming that there was no significant entropy production after reheating phase, entropy density in the radiation-dominated epoch is:

$$s \simeq \frac{2\pi^2}{45} g\, T_{\rm RH}^3\,, \tag{10}$$

where $T_{\rm RH}$ is the reheating temperature and the effective relativistic degrees of freedom $g \sim 100$ at reheating. The BAU parameter is given by:

$$\eta_B = \frac{n_B}{s} \approx 10^{-29}|C|^2 \frac{\Lambda^3}{T_{\rm RH}^3} \approx 10^{-2} \left(\frac{M}{M_{\rm Pl}}\right)^3 \left(\frac{\Lambda}{T_{\rm RH}}\right)^3 \tag{11}$$

where $|C| \approx \frac{M^{3/2}\eta_0}{\sqrt[4]{\eta_{end}10^{45}GeV^3}}$ and $M_{\rm Pl} \approx 10^{19}$GeV. Assuming the exit of inflation at 10^{14}GeV, and for the observed baryon asymmetry 10^{-10}, the reheating temperature $T_{\rm RH}$ is in the range 10^{12}—10^{14} GeV, which is is consistent with the constraints on the reheating temperature. This suggests that our model does not prefer a very low-energy reheating temperature

4. Conclusions

This talk focuses on a viable scenario for the generation of helical magnetic fields during inflation which lead to the baryogenesis in the early Universe. The model does not require coupling to the scalar field and hence does not lead to a strong coupling problem, and also, there is no backreaction on the background dynamics. The generation of the helical fields is due to the coupling of the electromagnetic fields with the dual of the Riemann tensor, which breaks the parity symmetry of the action. Interestingly, our model generates the present-day magnetic field of strength $10^{-15}G$ Mpc scales.

We have explicitly shown that Davidson's conditions are necessary *but not* sufficient. The key missing ingredient is the requirement of *primordial helical magnetic fields*. We have shown that the BAU parameter predicted by our model is independent of any specific inflation model and reheating dynamics; however, it depends on the scale at which inflation ends and reheating temperature. Furthermore, focussing on the modes that leave the horizon around 5 to 10 e-foldings the BAU parameter obtained in our model is inversely proportional to reheating temperature. Assuming the exit of inflation at 10^{14} GeV, for the observed amount of baryon asymmetry $\eta_B \sim 10^{-10}$, we obtained that the reheating temperature should be in the range $10^{12} - 10^{14}$ GeV, which is consistent with the constraints on the reheating temperature.

We implement Polymer Quantum Mechanics on the Hamiltonian formulation of the isotropic Universe in both the representations of the standard Ashtekar-Barbero-Immirzi connection and of a new generalized coordinate conjugate to the Universe volume. The resulting dynamics is a bouncing cosmology; when quantizing the volume-like variable the Big Bounce is an intrinsic cut-off on the cosmological dynamics, while when using the standard connection the Bounce density results to be dependent on the initial conditions of the prepared wave packet. Then we compare the nature of the resulting Bounce with what emerges in Loop Quantum Cosmology, where the dependence of the critical density on the initial conditions is present when the minimum area eigenvalue is implemented in a comoving representation instead of the physical one. We conclude that, if one hand the preferable scenario should be a Big Bounce whose density depends on initial conditions in view of the privileged SU(2) character that the Ashtekar-Barbero-Immirzi connection possesses in the full Loop Quantum Gravity, on the other hand the equivalence demonstrated in the context of polymer cosmology can be a hint in favour of the viability of the improved scheme of Loop Quantum Cosmology even though it is not expressed through the privileged set of variables.

Keywords: Quantum Cosmology; Polymer Quantum Mechanics; Early Universe.

1. Introduction

Loop Quantum Cosmology (LQC)[1–5] is the implementation of Loop Quantum Gravity (LQG)[6] in the symmetry-reduced cosmological minisuperspaces. It predicts the emergence of a Bouncing scenario that removes the classical singularity, but has the intrinsic limitation that the $SU(2)$ symmetry of LQG is lost.

Here we address the nature of the Bounce through the implementation of Polymer Quantum Mechanics (PQM)[7] on the flat isotropic Friedmann-Lemaître-Robertson-Walker (FLRW) model in two different representations: the Ashtekar-Barbero-Immirzi variables (the basic $SU(2)$ variables of LQG and LQC) and the volume variables.[8] Then, we compare our results with LQC in order to gain some insight on both frameworks. A more detailed analysis is presented in Ref. 9.

This work is organized as follows: in section 2 we introduce the framework of PQM; then we implement PQM on the FLRW model firstly expressed in the Ashtekar variables in section 3, and then in the volume variables in section 4; in

section 5 we compare our results with LQC; finally in section 6 we summarize our work. We use the natural units $\hbar = c = 8\pi G = 1$.

2. Polymer Quantum Mechanics

PQM[7] is an alternative representation that is non-unitarily connected to the standard Schrödinger representation. It implements a fundamental scale in the Hilbert space through the introduction of a lattice structure. Its aim is to reproduce effects similar to those of LQG through an independent framework that allows for more freedom in the choice of the preferred configurational variable and that is easily and reliably applicable to many Hamiltonian systems.

Let us consider a generic Hamiltonian system with canonical variables (Q, P). The kinematical framework of PQM consists in assigning to one of the variables, usually the position Q, a discrete character. As a consequence, in the quantization procedure, the conjugate momentum P cannot be promoted to a well-defined operator because the translational operator $\hat{T}(\lambda) = e^{i\lambda P}$ is not weakly continuous.

The procedure to regularize the momentum P and to construct a well-defined operator consists in the introduction of a lattice on position Q with constant spacing $\beta_0 \in \mathbb{R}$. The Hilbert space is then constructed as the one that contains all those states $|\psi\rangle = \sum_i b_i \, |\beta_n\rangle$, with $\beta_n = n\beta_0$ and $\sum_i |b_i|^2 < \infty$. Now the translational operator must be restricted to act only by discrete steps to remain on γ_{β_0}: this is achieved simply by setting $\zeta = \beta_0$ in order to obtain $\hat{T}(\beta_0) \, |\beta_n\rangle = |\beta_{n+1}\rangle$.

When the condition $P\beta_0 \ll 1$ is satisfied, we can approximate P with a sine function, so that the regulated momentum operator can be constructed as the incremental ratio of the translational operator on the lattice:

$$P \approx \frac{\sin(\beta_0 P)}{\beta_0} = \frac{e^{i\beta_0 P} - e^{-i\beta_0 P}}{2i\beta_0}, \tag{1a}$$

$$\widehat{P_{\beta_0}} \, |\beta_n\rangle = \frac{\hat{T}(\beta_0) - \hat{T}(-\beta_0)}{2i\beta_0} \, |\beta_n\rangle = \frac{|\beta_{n+1}\rangle - |\beta_{n-1}\rangle}{2i\beta_0}. \tag{1b}$$

For the squared momentum operator there are infinitely many approximations, but they usually amount to just a rescaling of the lattice parameter β_0; the simplest one in order to avoid discrepancies is obtained by composing the operator (1b) with itself, corresponding to the approximation $P^2 \approx \sin^2(\beta_0 P)/\beta_0^2$.

When performing the quantization of a system using the momentum polarization of the polymer representation, the regulated momentum operator must be used together with the differential coordinate operator. Alternatively, it is possible to perform a semiclassical analysis by using the formal substitution (1a) in the classical Hamiltonian, thus including quantum modifications in the classical dynamics.[8,10,11]

3. Polymer FLRW Dynamics in Ashtekar Variables

We will now show the dynamics of the flat isotropic FLRW model expressed in the Ashtekar variables. Given the symmetries of the model, the connection and

the triads reduce to a very simple form: $A^i_a \to c = \gamma\dot{a}$, $E^a_i \to p$, with $|p| = a^2$, $\{c, p\} = \gamma/3$, where $a = a(t)$ is the scale factor of the Universe, the dot represents a derivative with respect to time t and γ is the Immirzi parameter.

3.1. *Semiclassical Dynamics*

We consider the FLRW model filled with a free massless scalar field ϕ; we discretize the area p, so we use the sine substitution (1a) on the connection c. We have a four-dimensional phase space $(c, p; \phi, P_\phi)$, where P_ϕ is the momentum conjugate to the scalar field. The modified Hamiltonian constraint for this model is

$$\mathcal{C}_{\text{poly}} = -\frac{3}{\gamma^2\beta_0^2}\sqrt{p}\,\sin^2(\beta_0 c) + \rho_\phi\, p^{\frac{3}{2}} = 0. \tag{2}$$

Then the dynamics is derived through the standard Hamilton's equations.

Through the constraint, we obtain a modified Friedmann equation:

$$H^2 = \left(\frac{\dot{a}}{a}\right)^2 = \left(\frac{\dot{p}}{2p}\right)^2 = \frac{\rho_\phi}{3}\left(1 - \frac{\rho_\phi}{\rho_\beta}\right), \quad \rho_\beta = \frac{3}{\gamma^2\beta_0^2 p}; \tag{3}$$

the correction factor in parentheses contains a regularizing density ρ_β that depends on time through p; the minus sign introduces a critical point for the dynamics.

Since P_ϕ is a constant of motion, it is possible to use the scalar field as internal time; this makes the Friedmann equation easily solvable, and its solution $p(\phi)$ is

$$p(\phi) = \frac{\gamma\beta_0 P_\phi}{\sqrt{6}}\,\cosh\left(\sqrt{\frac{2}{3}}\,\phi\right). \tag{4}$$

The hyperbolic cosine has a non-zero minimum: the singularity is avoided and the Big Bang is replaced by a Big Bounce. However, the critical density, i.e. the energy density at the Bounce, is $\rho_{\text{crit}} = \rho_\beta(p|_{\phi_B}) = 3^{\frac{3}{2}}\sqrt{2}\,/P_\phi\gamma\beta_0$: it is dependent on the constant of motion P_ϕ that must be therefore set through initial conditions.

3.2. *Quantum Dynamics*

In the quantum picture, the fundamental variables are promoted to operators so that the quantum Hamiltonian constraint yields a Wheeler–De Witt (WDW) equation:

$$\hat{c} = \frac{\sin(\beta_0 c)}{\beta_0}, \quad \hat{p} = -i\frac{\gamma}{3}\frac{\mathrm{d}}{\mathrm{d}c}, \quad \widehat{P_\phi} = -i\frac{\mathrm{d}}{\mathrm{d}\phi}, \tag{5a}$$

$$\hat{\mathcal{C}}_{\text{poly}}\Psi(c,\phi) = \left[-\frac{2}{3\beta_0^2}\left(\sin(\beta_0 c)\,\frac{\mathrm{d}}{\mathrm{d}c}\right)^2 + \frac{\mathrm{d}^2}{\mathrm{d}\phi^2}\right]\Psi(c,\phi) = 0; \tag{5b}$$

through a substitution, the latter is recast as a Klein-Gordon-like (KG) equation:

$$x = \sqrt{\frac{3}{2}}\,\ln\left[\tan\left(\frac{\beta_0 c}{2}\right)\right] + x_0 \quad \Longrightarrow \quad \frac{\mathrm{d}^2}{\mathrm{d}x^2}\Psi(x,\phi) = \frac{\mathrm{d}^2}{\mathrm{d}\phi^2}\Psi(x,\phi). \tag{6}$$

We construct its solution as a Gaussian-like wavepacket over eigenvalues k_ϕ of $\hat{P}_\phi$:

$$\Psi(x,\phi) = \int_0^\infty \frac{\mathrm{d}k_\phi}{\sqrt{4\pi\sigma}}\, e^{-\frac{(k_\phi-\overline{k}_\phi)^2}{2\sigma^2}}\, k_\phi\, e^{ik_\phi x}\, e^{ik_\phi \phi}; \tag{7}$$

then we evolve it backwards in time, and study the behaviour of the expectation value of the energy density operator through a KG scalar product of the form

$$\langle\widehat{\rho_\phi}\rangle = \int_{-\infty}^{\infty} \mathrm{d}x \left(\Psi^* \partial_\phi(\widehat{\rho_\phi}\Psi) - (\widehat{\rho_\phi}\Psi)\partial_\phi\Psi^*\right), \quad \widehat{\rho_\phi} = \frac{\hat{P}_\phi^2}{2|\hat{p}|^3}. \tag{8}$$

The result is a function of time ϕ. Figure 1 shows the energy density increasing towards the singularity, reaching a finite maximum and then decreasing again; in view of its scalar nature, this behaviour confirms the presence of a Big Bounce also at the quantum level. However, the critical density at the Bounce (i.e. the value of the peak) is dependent on the initial condition $\overline{k}_\phi$, as in the semiclassical dynamics.

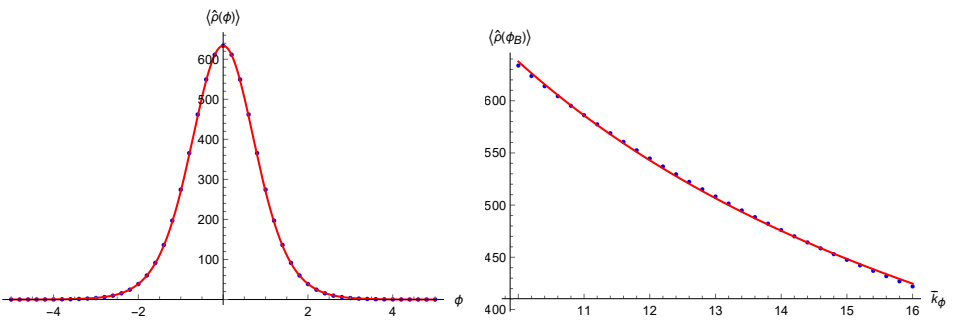

Fig. 1. Behaviour of the expected value of the energy density operator $\langle\widehat{\rho_\phi}\rangle$ as function of time ϕ (left panel) and dependence of the value of the energy density at the Bounce $\langle\widehat{\rho_\phi}\rangle\big|_{\phi_B}$ on the initial condition for the wavepacket $\overline{k}_\phi$ (right panel). The blue dots are the quantum expectation values, fitted with red continuous functions in accordance with semiclassical evolution.

4. Polymer FLRW Dynamics in Volume Variables

4.1. *Specialization of Polymer Cosmology*

In order to find the suitable variable to obtain a fixed Bounce density,[8] we perform a canonical transformation on the classical Hamiltonian to a generic function F of the scale factor: $p \to F(a)$, $c \to P_F = 2\sqrt{p}\, c\, /F'(a)$ with $F'(a) = \partial F/\partial a$. By using the polymer substitution (1a) on the new momentum P_F, we obtain a modified Hamiltonian constraint and a corresponding modified Friedmann equation:

$$\mathcal{C}_{\mathrm{poly}} = -\frac{3}{4\gamma^2\beta_0^2}\frac{\left(F'(a)\right)^2}{\sqrt{p}}\sin^2(\beta_0 P_F) + \rho_\phi\, p^{\frac{3}{2}} = 0, \quad \rho_\phi = \frac{P_\phi^2}{2p^3}, \tag{9a}$$

$$H^2 = \frac{\rho_\phi}{3}\left(1 - \frac{\rho_\phi}{\tilde{\rho}_\beta}\right), \quad \tilde{\rho}_\beta = \frac{3}{4\gamma^2\beta_0^2}\frac{\left(F'(a)\right)^2}{p^2} \propto \left(\frac{F'(a)}{p}\right)^2. \tag{9b}$$

To obtain a universal regularizing density $\tilde{\rho}_\beta$, we must have $F(a) \propto a^3$; we choose to use as new fundamental variables $v = a^3$ and $\tilde{c} = 2c/3\sqrt{p} \propto \dot{a}/a$.

4.2. *Semiclassical Dynamics*

We implement PQM on the system by considering v as discrete and using the formal substitution (1a) on the new generalized coordinate $\tilde{c}$:

$$\mathcal{C}_{\text{poly}} = -\frac{27}{4\gamma^2\beta_0^2}\, v\, \sin^2(\beta_0\tilde{c}) + \rho_\phi\, v = 0, \quad \rho_\phi = \frac{P_\phi^2}{2v^2}. \tag{10}$$

This new representation yields a modified Friedmann equation with a fixed regularizing density, as expected:

$$H^2 = \left(\frac{\dot{a}}{a}\right)^2 = \left(\frac{\dot{v}}{3v}\right)^2 = \frac{\rho_\phi}{3}\left(1 - \frac{\rho_\phi}{\tilde{\rho}_\beta}\right), \quad \tilde{\rho}_\beta = \frac{27}{4\gamma^2\beta_0^2} = \tilde{\rho}_{\text{crit}}. \tag{11}$$

The quantity $\tilde{\rho}_\beta = \tilde{\rho}_{\text{crit}}$ depends only on fundamental constants and the Immirzi parameter, and can therefore be already considered a critical density. Using ϕ as time, the new modified Friedmann equation is easily solvable for $v(\phi)$:

$$v(\phi) = \frac{2\gamma\beta_0}{\sqrt{54}}\, P_\phi \cosh\left(\sqrt{\frac{3}{2}}\,\phi\right). \tag{12}$$

We still have a hyperbolic cosine, indicating a Bounce that replaces the Big Bang, but this time the value of the energy density at which this happens is universal.

4.3. *Quantum Dynamics*

In the quantization procedure the fundamental variables are promoted to operators and the quantum Hamiltonian constraint yields a WDW equation:

$$\hat{v} = -i\,\frac{\mathrm{d}}{\mathrm{d}\tilde{c}}, \quad \hat{\tilde{c}} = \frac{\sin(\beta_0\tilde{c})}{\beta_0}, \quad \hat{P}_\phi = -i\,\frac{\mathrm{d}}{\mathrm{d}\phi}; \tag{13}$$

$$\hat{\tilde{\mathcal{C}}}_{\text{poly}}\Psi(\tilde{c},\phi) = \left[-\frac{3}{2\beta_0^2}\left(\sin(\beta_0\tilde{c})\,\frac{\mathrm{d}}{\mathrm{d}\tilde{c}}\right)^2 + \frac{\mathrm{d}^2}{\mathrm{d}\phi^2}\right]\Psi(\tilde{c},\phi) = 0. \tag{14}$$

Through a suitable substitution, the latter is recast as a KG-like equation in the variable $\tilde{x}$ where ϕ plays the role of time:

$$\tilde{x} = \sqrt{\frac{2}{3}}\,\ln\left[\tan\left(\frac{\beta_0\tilde{c}}{2}\right)\right] + \tilde{x}_0 \quad \Longrightarrow \quad \frac{\mathrm{d}^2}{\mathrm{d}\tilde{x}^2}\Psi(\tilde{x},\phi) = \frac{\mathrm{d}^2}{\mathrm{d}\phi^2}\Psi(\tilde{x},\phi). \tag{15}$$

We construct the solution as a Gaussian-like wavepacket of the form

$$\Psi(\tilde{x},\phi) = \int_0^\infty \frac{\mathrm{d}k_\phi}{\sqrt{4\pi\sigma}}\, e^{-\frac{(k_\phi - \overline{k}_\phi)^2}{2\sigma^2}}\, k_\phi\, e^{ik_\phi\tilde{x}}\, e^{ik_\phi\phi}. \tag{16}$$

Finally, we evolve it backwards in time and study the behaviour of the expected value of relevant operators (the volume $\hat{V} = \hat{v}$ and the energy density $\widehat{\rho_\phi} = \hat{P}_\phi^2/2\hat{v}^2$) through the same KG scalar product (8) in terms of $\tilde{x}$. The Bounce is present also

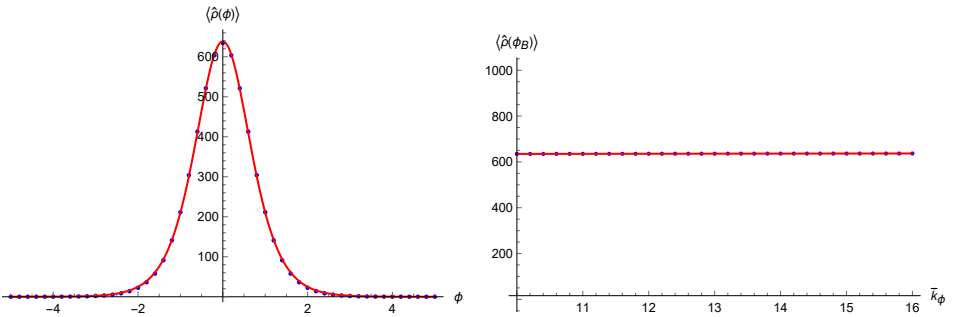

Fig. 2. Expected value of the energy density operator as function of time ϕ (left panel) and dependence of the critical density (the value of the energy density at the Bounce) on the initial condition for the wavepacket $\overline{k}_\phi$. The blue dots are the quantum expectation values that have been fitted with red continuous functions in accordance with semiclassical evolution.

in this quantum setting; however in this case the energy density, depicted in the left panel of figure 2, has a value at the Bounce that is constant and independent on $\overline{k}_\phi$, as shown in the right panel of the same figure.

5. Discussion of the Results

5.1. *The Nature of the Bounce in Polymer Cosmology*

The quantization procedure of PQM implements on a Hamiltonian system a lattice that has a constant step by construction. Therefore the canonical changes of variables must be performed on the classical Hamiltonian constraint before discretization. The nature of the resulting Bounce in the two pictures is not the same, and the two dynamics are inequivalent.

To recover the equivalence, we can perform the canonical transformation *after* the implementation of the lattice. We consider the system with the discretized volume and change the variables to Ashtekar ones; the canonical transformation must preserve the Poisson brackets and therefore must satisfy the condition $\beta_0 \tilde{c} = \beta' c$. We obtain a discretized system in the variables (c, p) that has a new lattice spacing β' dependent on the variable p. The new equation of motion for p is mapped to the original equation of motion in the Ashtekar variables, but the lattice parameter β_0 is replaced by the new one β'; the resulting dynamics is a Big Bounce scenario with a fixed, universal critical density, the same obtained by discretizing the volume with a constant lattice. Thus we conclude that the nature of the Bounce is decided by the variable to which a constant lattice spacing is assigned.

We stress that this result can be demonstrated only at a semiclassical level; on the quantum level this comparison is impossible, because a quantization procedure with a non-constant translational parameter has not been developed yet.

5.2. *Comparison with Loop Quantum Cosmology*

One of the most important results of LQG is the quantization of the kinematical geometrical operators of area and volume,[12] with the Area Gap Δ being the smallest non-zero area eigenvalue. In the construction of the quantum Hamiltonian constraint of LQC, the area gap is introduced from the full theory somewhat ad hoc, and the character of its implementation defines different schemes of LQC. In the first formulation, the area gap was implemented as a kinematical feature (as in full LQG) on the comoving area: this is equivalent to introducing a fixed lattice and yields the original μ_0 scheme of LQC, a scenario very similar to our polymer cosmology with the Ashtekar variables of section 3, that presents a Big Bounce dependent on initial conditions.[2,3] Then, in the improved dynamics, the area gap is implemented as a dynamical feature on the physical area, i.e. rescaled by the squared scale factor; this leads to a lattice with a non-constant spacing $\bar{\mu}(p)$, and prevents quantization. Therefore a change of basis is performed to a volume-like variable $\nu \propto v$ to make the lattice parameter constant (note how this is the inverse change of variables that we performed above). Now the quantization can be completed, and the resulting dynamics is a Big Bounce with a critical density that is a universal feature.[4,5] This scenario, dubbed $\bar{\mu}$ scheme, is analogous to the polymer FLRW cosmology in volume variables presented here in section 4.

The improved scheme avoids the dependence of quantum gravitational effects on initial conditions, a feature that does not have a very clear physical interpretation, and therefore seems to be more appealing than the original formulation. One criticism is that the new $\bar{\mu}$ scenario takes LQC further away from LQG because it does not use the Ashtekar variables anymore, that are privileged in the full theory in view of their $SU(2)$ character. However the dynamical similarities of PQM and LQC may justify the change of variables: at least on a semiclassical effective level, the dynamics of the model expressed in volume variables with a constant spacing is equivalent to that of the same model expressed in Ashtekar variables with a p-dependent lattice step.

6. Summary and Conclusions

We have shown how the implementation of PQM on the flat isotropic model solves the singularity by replacing the Big Bang with a Big Bounce, but its nature depends on the fundamental variable used to describe the model: with the area p from the Ashtekar variables the energy density at the Bounce is dependent on the initial conditions, while if the volume $v = a^3$ is used instead, the Bounce is a universal feature with a fixed energy density; therefore the two pictures yield two different

and inequivalent dynamics. A possibility to recover the equivalence is to perform the canonical transformation after the implementation of the lattice and to allow for a non-constant step; this does not affect the dynamics, meaning that the nature of the Bounce is decided by the variable that has a lattice with constant spacing.

In LQC two analogous pictures emerge: the original μ_0 scheme yields a Bounce dependent on initial conditions, while the improved $\bar{\mu}$ scheme prevents this feature through a change of basis and presents a universal Bounce. These similarities with polymer cosmology may be used to gain insight into the validity of the two scenarios: if on one hand the improved scheme, although physically more appealing, can be criticized for not using the privileged $SU(2)$ variables of LQG, on the other hand the parallelism with the minisuperspace implementation of PQM justifies the $\bar{\mu}$ scenario in view of the equivalence demonstrated in semiclassical polymer cosmology.

General relativistic evolution equations for density perturbations in open, flat and closed FLRW universes and the problem of structure formation

Pieter G. Miedema

Independent Scientist
Breda, The Netherlands
E-mail: PG.Miedema@ProtonMail.com

Due to the general covariance of the Einstein equations and conservation laws, the linearized equations have solutions which are gauge-dependent and have, therefore, no physical significance.

In this contribution I will show that the decomposition theorems for symmetric second-rank tensors of the maximally symmetric subspaces of constant time imply that there are exactly two, unique, gauge-invariant quantities which describe the true, physical perturbations to the energy density and particle number density. In the limit of zero spatial fluid velocity, and hence zero pressure, the set of linearized Einstein equations and conservation laws, combined with the new gauge-invariant quantities reduce to the Poisson equation of the Newtonian Theory of Gravity and the energy-mass relation of the Special Theory of Relativity. The relativistic gauge transformation reduces to the Newtonian gauge transformation in which time and space are decoupled.

The cosmological perturbation theory for open, flat and closed Friedmann-Lemaître-Robertson-Walker (FLRW) universes consists of a second-order ordinary differential equation (with source term entropy perturbations) which describes the evolution of perturbations in the total energy density, and a first-order ordinary differential equation which describes the evolution of entropy perturbations.

The cosmological perturbation theory is applied to a flat FLRW universe. For large-scale perturbations the outcome is in accordance with treatments in the literature. In the radiation-dominated era small-scale perturbations grew proportional to the square root of time and perturbations in the CDM particle number density were, due to gravitation, coupled to perturbations in the total energy density. Therefore, structure formation could have begun successfully only after decoupling of matter and radiation. After decoupling density perturbations exchanged heat with their environment. This heat exchange may have enhanced the growth rate of their mass sufficiently to explain structure formation in the early universe, a phenomenon which cannot be understood from adiabatic density perturbations.

Keywords: Cosmology; Perturbation Theory; Structure Formation.

1. Introduction

The theory related to the linearized Einstein equations and conservation laws is important in cosmology because it describes the growth of all kinds of structures in the expanding universe, such as stars, galaxies and microwave background fluctuations. Lifshitz[1] and Lifshitz and Khalatnikov[2] were the first researchers to derive a cosmological perturbation theory. They encountered the problem that the solutions of the linearized Einstein equations and conservation laws have no physical significance. Due to the linearity of the equations, the solutions can be changed

by a linear coordinate transformation, i.e., a gauge transformation. Therefore, the solutions are *gauge-dependent*. This is the well-known *gauge problem of cosmology* which is up till now not solved.

In this contribution I outline the solution of the gauge problem. Next, I briefly give the derivation of a new perturbation theory for cosmological perturbations in open, flat and closed FLRW universes. The perturbation theory is applied to a flat FLRW universe to study the evolution of density perturbations. The derivation of the perturbation theory is given in full detail in Ref. 3, whereas the problem of structure formation in a flat FLRW universe is discussed in detail in Ref. 4.

2. Cosmological Perturbation Theory

We consider FLRW universes filled with a perfect fluid. The energy momentum tensor is then given by

$$T^{\mu\nu} = (\varepsilon + p)u^\mu u^\nu - pg^{\mu\nu}. \tag{1}$$

From thermodynamics it is known that both the energy density ε and the pressure p depend on the particle number density n and the absolute temperature T, i.e.,

$$\varepsilon = \varepsilon(n, T), \quad p = p(n, T). \tag{2}$$

Since T can, in principle, be eliminated from these equations of state, a computationally more convenient equation of state for the pressure is used, namely

$$p = p(n, \varepsilon). \tag{3}$$

Using (1) and (3) one can write down the Einstein equations and conservation laws into a set of background equations

$$G^{\mu\nu}_{(0)} = \kappa T^{\mu\nu}_{(0)}, \quad T^{\mu\nu}_{(0)\,;\nu} = 0, \tag{4}$$

which govern the *global* evolution of FLRW universes, and a system of perturbation equations

$$G^{\mu\nu}_{(1)} = \kappa T^{\mu\nu}_{(1)}, \quad T^{\mu\nu}_{(1)\,;\nu} = 0. \tag{5}$$

These equations govern the evolution of *local* perturbations in FLRW universes.

2.1. *General Covariance*

It is well-known that the General Theory of Relativity is invariant under general coordinate transformations $x^\mu \to x'^\mu(x^\nu)$. In particular, the linearized Einstein equations and conservation laws are invariant under a general linear coordinate transformation, i.e., a gauge transformation

$$x^\mu \to x'^\mu = x^\mu - \xi^\mu(t, \boldsymbol{x}), \tag{6}$$

where $\xi^\mu(t, \boldsymbol{x})$ are four arbitrary infinitesimal functions of time, $x^0 = ct$, and space, $\boldsymbol{x} = (x^1, x^2, x^3)$, coordinates, the so-called gauge functions. As a consequence, there

are no preferred coordinate systems (see Weinberg,[5] Appendix B), so that one may choose any system of reference which makes the calculations tractable.

However, because of the linearity of the perturbation equations and conservation laws, the so-called gauge problem of cosmology emerges.

2.2. *Gauge Problem of Cosmology*

Consider a closed, flat or open FLRW universe filled with a perfect fluid, with an equation of state for the pressure (3). The evolution of the energy density $\varepsilon_{(0)}$, the particle number density $n_{(0)}$ and the expansion scalar $\theta_{(0)} = 3H$ of the background universe are governed by the usual Einstein equations and conservation laws for a FLRW universe

$$3H^2 = \tfrac{1}{2}R_{(0)} + \kappa\varepsilon_{(0)} + \Lambda, \quad \kappa = 8\pi G_{\mathrm{N}}/c^4, \tag{7a}$$

$$\dot{R}_{(0)} = -2HR_{(0)}, \tag{7b}$$

$$\dot{\varepsilon}_{(0)} = -3H\varepsilon_{(0)}(1+w), \qquad w := p_{(0)}/\varepsilon_{(0)}, \tag{7c}$$

$$\dot{n}_{(0)} = -3Hn_{(0)}. \tag{7d}$$

From this system of equations it follows that the evolution of FLRW universes is characterized by the three scalars $\varepsilon_{(0)}$, $n_{(0)}$ and $\theta_{(0)}$.

The general solution of the linearized Einstein equations and conservation laws contain, among other quantities, the perturbed quantities $\varepsilon_{(1)}$, $n_{(1)}$ and $\theta_{(1)}$. Since the linearized equations are invariant under linear coordinate transformations (6) one can generate new, equivalent, solutions $\varepsilon'_{(1)}$, $n'_{(1)}$ and $\theta'_{(1)}$, i.e.,

$$\varepsilon'_{(1)} = \varepsilon_{(1)} + \xi^0\dot{\varepsilon}_{(0)}, \quad n'_{(1)} = n_{(1)} + \xi^0\dot{n}_{(0)}, \quad \theta'_{(1)} = \theta_{(1)} + \xi^0\dot{\theta}_{(0)} \tag{8}$$

where $\xi^0\dot{\varepsilon}_{(0)}$, $\xi^0\dot{n}_{(0)}$ and $\xi^0\dot{\theta}_{(0)}$ are the so-called gauge modes. Therefore, $\varepsilon_{(1)}$, $n_{(1)}$ and $\theta_{(1)}$ are *gauge-dependent* and have, as a consequence, no physical significance.

3. Previous Attempts to Solve the Gauge Problem of Cosmology

Bardeen[6] was the first to demonstrate that, using gauge-invariant quantities, one can recast the linearized Einstein equations and conservation laws into a new set of evolution equations that are free of non-physical gauge modes. Bardeen's definition of a gauge-invariant density perturbation is such that it becomes equal to the gauge-dependent density perturbation in the limit of small scales. The underlying assumption is that on small scales the gauge modes vanish so that gauge-dependent quantities become gauge-independent. However, the physical quantities $\varepsilon^{\mathrm{phys}}_{(1)}$, $n^{\mathrm{phys}}_{(1)}$ and $\theta^{\mathrm{phys}}_{(1)}$ do not become equal to the gauge-dependent quantities $\varepsilon_{(1)}$, $n_{(1)}$ and $\theta_{(1)}$ in the non-relativistic limit, since the gauge modes $\hat{\varepsilon}_{(1)}$, $\hat{n}_{(1)}$ and $\hat{\theta}_{(1)}$ never become zero. This is a direct consequence of the facts that the universe is not static in the non-relativistic limit and that the relativistic space-time gauge transformations reduce in the non-relativistic limit to Newtonian gauge transformations with space

and time decoupled. Consequently, the quantities defined by Bardeen are not equal to the real physical energy density perturbation.

The article of Bardeen has inspired the pioneering works of Ellis *et al.*,[7–9] Mukhanov *et al.*[10,11] and Bruni *et al.*[12] These researchers proposed alternative perturbation theories using gauge-invariant quantities which differ from the ones used by Bardeen. The theory proposed by Mukhanov *et al.*[10,11] yields the Poisson equation of the Newtonian Theory of Gravity only if the Hubble function, i.e., the expansion scalar, vanishes. This, however, violates the background Friedmann equation. In fact, the background Friedmann equation is needed to derive the Poisson equation from the linearized Friedmann equation in the non-relativistic limit. Consequently, the gauge-invariant quantities defined in Refs. 10 and 11 are not equal to the true physical perturbations.

In the approach in Refs. 7–9 a density perturbation is defined using gradients, i.e., a gauge-invariant and covariant function is defined which 'closely corresponds to the intention of the usual gauge-dependent density contrast function'. However, a perturbation theory based on this definition does not yield the Poisson equation in the non-relativistic limit.

The above mentioned pioneering treatments caused an abundance of other important works, e.g., Refs. 13–18. In his review article, Ellis[19] discusses the work of Lifshitz and Khalatnikov, and also provides an overview of other research on the subject. From the vast literature on cosmological density perturbations, it must be concluded that there is still no agreement on which gauge-invariant quantities are the true energy density perturbation and particle number density perturbation. None of the cosmological perturbation theories in the literature has a correct non-relativistic limit, so that there is still no solution to the gauge problem of cosmology.

4. Real, Measurable Density Perturbations

In contrast to the gauge-dependent quantities $\varepsilon_{(1)}$, $n_{(1)}$ and $\theta_{(1)}$ the real, measurable density perturbations $\varepsilon^{\rm phys}_{(1)}$, $n^{\rm phys}_{(1)}$ and $\theta^{\rm phys}_{(1)}$ are independent of the choice of a coordinate system, i.e., are *gauge-invariant*. The physics of density perturbations is hidden in the general solution of the linearized Einstein equations and conservation laws. Therefore, the physical quantities $\varepsilon^{\rm phys}_{(1)}$, $n^{\rm phys}_{(1)}$ and $\theta^{\rm phys}_{(1)}$ can be expressed as linear combinations, with time-dependent coefficients, of gauge-dependent solutions of these equations, such that the gauge modes are eliminated. Furthermore, $\varepsilon^{\rm phys}_{(1)}$ and $n^{\rm phys}_{(1)}$ have the property that in the non-relativistic limit the linearized Einstein equations and conservation laws combined with expressions for $\varepsilon^{\rm phys}_{(1)}$and $n^{\rm phys}_{(1)}$ reduce, in a *non-static* flat FLRW universe, to the time-independent Poisson equation with $\varepsilon^{\rm phys}_{(1)}$ as source term, and the well-known Einstein mass-energy relation $\varepsilon^{\rm phys}_{(1)} = n^{\rm phys}_{(1)} mc^2$ of the Special Theory of Relativity. Finally, the relativistic gauge transformation (6) reduces in the non-relativistic limit to the Newtonian gauge transformation. Consequently, the gauge problem is, in fact, the problem of finding expressions for $\varepsilon^{\rm phys}_{(1)}$, $n^{\rm phys}_{(1)}$ and $\theta^{\rm phys}_{(1)}$.

5. Solution of the Gauge Problem

The gauge-dependent quantities $\varepsilon_{(1)}$, $n_{(1)}$ and $\theta_{(1)}$ transform under the gauge transformation (6) in exactly the same way, namely as (8). Therefore, one can combine two of these quantities such that the gauge modes are eliminated. We have three choices and in each choice one of the gauge-invariant quantities vanishes. The obvious, non-trivial choice is

$$\varepsilon^{\rm phys}_{(1)} := \varepsilon_{(1)} - \frac{\dot{\varepsilon}_{(0)}}{\dot{\theta}_{(0)}}\theta_{(1)}, \quad n^{\rm phys}_{(1)} := n_{(1)} - \frac{\dot{n}_{(0)}}{\dot{\theta}_{(0)}}\theta_{(1)}, \quad \theta^{\rm phys}_{(1)} := \theta_{(1)} - \frac{\dot{\theta}_{(0)}}{\dot{\theta}_{(0)}}\theta_{(1)} = 0, \tag{9}$$

where $\theta^{\rm phys}_{(1)} = 0$ implies that local density perturbations have no influence on the global expansion $\theta_{(0)} = 3H$ of the universe.

Now, the question arises, are $\varepsilon^{\rm phys}_{(1)}$, $n^{\rm phys}_{(1)}$ and $\theta^{\rm phys}_{(1)}$ the real, measurable perturbations? Since the linear combinations (9) are the only possible ones, it is plausible that this is indeed the case. However, to be sure, we have to study the quantities (9) together with the background equations (4) and the perturbation equations (5) in the non-relativistic limit. This is the subject of Sec. 8. To that end, we have to rewrite the linearized Einstein equations and conservation laws (5) into a more convenient form. This will be done in Sec. 7 with the help of the decomposition theorems in the next section.

6. Decomposition Theorems of Symmetric Second-rank 3-tensors

Since the General Theory of Relativity is invariant under coordinate transformations, we may choose our coordinates such that the calculations are tractable.

We choose a synchronous system of reference, since this facilitates the non-relativistic limit: in the Newtonian Theory of Gravity all coordinate systems are synchronous. A second reason is that in synchronous coordinates, the decomposition theorems in Refs. 20–22 for symmetric second rank tensors of the maximally symmetric three-spaces of constant time can be used.

In synchronous coordinates the metric tensor $g_{\mu\nu}(t, \boldsymbol{x})$ of FLRW universes has the form

$$g_{00} = 1, \quad g_{0i} = 0, \quad g_{ij} = -a^2(t)\tilde{g}_{ij}(\boldsymbol{x}), \tag{10}$$

where $a(t)$ is the scale factor of the universe, $g_{00} = 1$ indicates that coordinate time is equal to proper time, $g_{0i} = 0$ is the global synchronicity condition (see the textbook of Landau and Lifshitz,[23] § 84) and $\tilde{g}_{ij}$ is the metric tensor of the three-dimensional maximally symmetric sub-spaces of constant time[a]. From the Killing equations $\xi_{\mu;\nu} + \xi_{\nu;\mu} = 0$ and (10) it follows that the functions $\xi^\mu(t, \boldsymbol{x})$ in (6) become

$$\xi^0 = \psi(\boldsymbol{x}), \quad \xi^i = \tilde{g}^{ik}(\boldsymbol{x})\frac{\partial\psi(\boldsymbol{x})}{\partial x^k}\int^{ct}\frac{{\rm d}\tau}{a^2(\tau)} + \chi^i(\boldsymbol{x}), \tag{11}$$

[a]Quantities with a tilde, i.e., $\tilde{q}$, belong to the three-dimensional maximally symmetric subspaces of constant time.

if only transformations between synchronous coordinates are allowed. The four functions $\psi(\boldsymbol{x})$ and $\chi^i(\boldsymbol{x})$ cannot be fixed since the four coordinate conditions $g_{00} = 1$ and $g_{0i} = 0$ have already exhausted all four degrees of freedom (see Weinberg,[24] Section 7.4 on coordinate conditions).

In Refs. 20–22 it is shown that *any* symmetric second-rank three-tensor, and hence the perturbed metric tensor h_{ij} and the perturbed Ricci tensor $R_{(1)ij}$, can uniquely be decomposed into three parts. For the perturbed metric tensor, one has

$$h^i{}_j = h^i_{\parallel j} + h^i_{\perp j} + h^i_{*j}, \qquad h^k_{\perp k} = 0, \quad h^k_{*k} = 0, \quad h^k_{*i|k} = 0, \tag{12}$$

where tensor, vector and scalar perturbations are denoted by $*$, $\perp$ and $\parallel$, respectively. The perturbed Ricci tensor, $R_{(1)ij}$, being a symmetric second-rank three-tensor, can in the same way be decomposed

$$R^i_{(1)j} = R^i_{(1)\parallel j} + R^i_{(1)\perp j} + R^i_{(1)*j}, \qquad R^k_{(1)\perp k} = 0, \quad R^k_{(1)*k} = 0, \quad R^k_{(1)*i|k} = 0. \tag{13}$$

Finally, York and Stewart demonstrated that the components $h^i_{\parallel j}$ can be written in terms of two independent potentials $\phi(t, \boldsymbol{x})$ and $\zeta(t, \boldsymbol{x})$, namely

$$h^i_{\parallel j} = \frac{2}{c^2}(\phi\delta^i{}_j + \zeta^{|i}{}_{|j}). \tag{14}$$

The decompositions (12) and (13) and the expression (14) imply that the decomposition of the spatial part $\boldsymbol{u}_{(1)} = (u^1_{(1)}, u^2_{(1)}, u^3_{(1)})$ of the perturbed fluid four-velocity

$$\boldsymbol{u}_{(1)} = \boldsymbol{u}_{(1)\parallel} + \boldsymbol{u}_{(1)\perp}, \tag{15}$$

where the components $\boldsymbol{u}_{(1)\parallel}$ and $\boldsymbol{u}_{(1)\perp}$ have the properties

$$\tilde{\boldsymbol{\nabla}} \cdot \boldsymbol{u}_{(1)} = \tilde{\boldsymbol{\nabla}} \cdot \boldsymbol{u}_{(1)\parallel}, \quad \tilde{\boldsymbol{\nabla}} \times \boldsymbol{u}_{(1)} = \tilde{\boldsymbol{\nabla}} \times \boldsymbol{u}_{(1)\perp}, \tag{16}$$

is consistent with the three linearized momentum constraint equations $G^{0i}_{(1)} = \kappa T^{0i}_{(1)}$. In expressions (16) $\tilde{\boldsymbol{\nabla}}$ is the generalized vector differential operator, defined by $\tilde{\nabla}_i v^k := v^k{}_{|i}$.

7. Evolution Equations for Scalar Perturbations

The general solution of the linearized Einstein equations and conservation laws (5) is a linear combination of scalar, vector and tensor perturbations. From the decomposition theorems it follows that only the scalar perturbations are coupled to density perturbations. Therefore, in the linearized equations (5) we may replace $h^i{}_j$ by $h^i_{\parallel j}$ and $u^i_{(1)}$ by $u^i_{(1)\parallel}$, to obtain perturbation equations which exclusively describe the evolution of scalar perturbations. For the Ricci tensor we find $R^i_{(1)j} \to R^i_{(1)\parallel j}$, so that the local perturbation to the global spatial curvature $R_{(0)}$ due to local density perturbations is given by

$$R_{(1)} := R^k_{(1)k} = g^{ij}_{(0)}(h^k{}_{k|i|j} - h^k{}_{i|k|j}) + \tfrac{1}{3}R_{(0)}h^k{}_k. \tag{17}$$

Since the rotational part of the local spatial fluid velocity is not coupled to scalar perturbations we may for scalar perturbations replace the three components of the fluid velocity by its divergence, i.e.,

$$\vartheta_{(1)} := u^k_{(1)|k}. \tag{18}$$

Finally, the perturbation to the expansion is given by

$$\theta_{(1)} = \vartheta_{(1)} - \tfrac{1}{2}\dot{h}^k{}_k. \tag{19}$$

Using the substitutions given above, we can rewrite the full set of perturbed Einstein equations and conservation laws (5) in the form

$$2H(\theta_{(1)} - \vartheta_{(1)}) = \tfrac{1}{2}R_{(1)} + \kappa\varepsilon_{(1)}, \tag{20a}$$

$$\dot{R}_{(1)} = -2HR_{(1)} + 2\kappa\varepsilon_{(0)}(1+w)\vartheta_{(1)} - \tfrac{2}{3}R_{(0)}(\theta_{(1)} - \vartheta_{(1)}), \tag{20b}$$

$$\dot{\varepsilon}_{(1)} = -3H(\varepsilon_{(1)} + p_{(1)}) - \varepsilon_{(0)}(1+w)\theta_{(1)}, \tag{20c}$$

$$\dot{\vartheta}_{(1)} = -H(2-3\beta^2)\vartheta_{(1)} - \frac{1}{\varepsilon_{(0)}(1+w)}\frac{\tilde{\nabla}^2 p_{(1)}}{a^2}, \quad \beta^2 := \frac{\dot{p}_{(0)}}{\dot{\varepsilon}_{(0)}}, \tag{20d}$$

$$\dot{n}_{(1)} = -3Hn_{(1)} - n_{(0)}\theta_{(1)}, \tag{20e}$$

which describe exclusively scalar perturbations. The system (20) consists of the energy density constraint equation or linearized Friedmann equation (20a), the momentum constraint equation (20b), the energy density conservation law (20c), the momentum conservation law (20d) and the particle number density conservation law (20e). These equations are the perturbed counterparts of Eqs. (7). Since the system of equations (20) includes all constraint equations and conservation laws, the *dynamical* equations $G^{ij}_{(1)} = \kappa T^{ij}_{(1)}$ are automatically satisfied by the solution of the system (20).

The background equations (7) combined with the system (20) determines the evolution of $\varepsilon^{\text{phys}}_{(1)}$ and $n^{\text{phys}}_{(1)}$ given by (9). However, the system (20) has also gauge modes as solution, i.e.,

$$\hat{\varepsilon}_{(1)} = \psi\dot{\varepsilon}_{(0)}, \quad \hat{n}_{(1)} = \psi\dot{n}_{(0)}, \quad \hat{\theta}_{(1)} = \psi\dot{\theta}_{(0)}, \tag{21a}$$

$$\hat{\vartheta}_{(1)} = -\frac{\tilde{\nabla}^2\psi}{a^2}, \quad \hat{R}_{(1)} = 4H\left[\frac{\tilde{\nabla}^2\psi}{a^2} - \tfrac{1}{2}R_{(0)}\psi\right], \tag{21b}$$

where $\xi^0 = \psi(\boldsymbol{x})$ in synchronous coordinates, see (11). Therefore, I have derived a new system of equations which is free from the gauge modes and determines exclusively the evolution of $\varepsilon^{\text{phys}}_{(1)}$ and $n^{\text{phys}}_{(1)}$. This will be the subject of Sec. 9. First, we show in the next section that $\varepsilon^{\text{phys}}_{(1)}$ and $n^{\text{phys}}_{(1)}$ are the real, measurable density perturbations.

8. Non-relativistic Limit

The standard non-relativistic limit is defined by four requirements, see, e.g., the textbook of Carroll,[25] page 153:

(1) The gravitational field should be weak, i.e., can be considered as a perturbation of a flat, i.e., $R_{(0)} = 0$, FLRW universe.

(2) The particles are moving slowly with respect to the speed of light.

(3) The transformation (6) with (11) is reduced to transformations for which the Newtonian Theory of Gravity is invariant.

(4) The gravitational field of a density perturbation should be static, i.e., it does not change with time.

Requirement (3), which is not used in the literature, is needed because we have to deal with gauge transformations (6) with (11) in an expanding universe.

In the Newtonian Theory of Gravity space is flat. Therefore, we consider a flat, $R_{(0)} = 0$, FLRW universe, so that spatial covariant derivatives reduce to ordinary derivatives. Combining expressions (14) and (17), we get

$$R_{(1)} = \frac{4}{c^2}\phi^{|k}{}_{|k} = -\frac{4}{c^2}\frac{\nabla^2\phi}{a^2}, \tag{22}$$

where ∇^2 is the usual Laplace operator.

The non-relativistic limit follows from

$$u^i_{(1)\mathrm{phys}} \to 0, \quad \Leftrightarrow \quad p^{\mathrm{phys}}_{(1)} \to 0, \tag{23}$$

i.e., the *physical* part of the fluid velocity is small with respect to the speed of light. Note that non-zero pressure differences imply fluid flow and vice versa. Using the background equations (7), the quantities (9) and the perturbation equations (20) we can draw the following conclusions:

(1) The momentum constraint equation (20b) implies with (22) and (23) that $\dot{\phi} = 0$, i.e., in the non-relativistic limit the potential ϕ is independent of time.

(2) The perturbed Friedmann equation (20a) and the time-derivative of the background Friedmann equation (7a) imply the Poisson equation

$$\nabla^2\varphi(\boldsymbol{x}) = \frac{4\pi G_{\mathrm{N}}}{c^2}\varepsilon^{\mathrm{phys}}_{(1)}(\boldsymbol{x}), \tag{24}$$

where $\varphi(\boldsymbol{x}) := \phi(\boldsymbol{x})/a^2(t_0)$.

(3) In the limit (23) the masses of the particles in a density perturbation are equal to their rest masses, so that the definitions (9) imply with (20c) and (20e)

$$n^{\mathrm{gi}}_{(1)}(\boldsymbol{x}) = \frac{\varepsilon^{\mathrm{gi}}_{(1)}(\boldsymbol{x})}{mc^2}, \tag{25}$$

which is the well-known energy mass relation of the Special Theory of Relativity.

(4) The relativistic gauge transformation (6) reduces in the non-relativistic limit to the Newtonian gauge transformation

$$x^0 \to x'^0 = x^0 - C, \quad x^i \to x'^i = x^i - \chi^i(\boldsymbol{x}), \tag{26}$$

where $\chi^i(\boldsymbol{x})$ are three arbitrary functions of the spatial coordinates and C is an arbitrary constant. Thus, in the non-relativistic limit time and space transformations are decoupled: time coordinates may be shifted and spatial coordinates may be chosen arbitrarily.

(5) Finally, the perturbed conservation laws (20c) and (20e) have only the gauge modes as solutions. Therefore, these equations have no physical significance and need not be considered anymore.

We can now draw the conclusion that $\varepsilon^{\text{phys}}_{(1)}$, $n^{\text{phys}}_{(1)}$ and $\theta^{\text{phys}}_{(1)} = 0$ defined by the expressions (9) are the unique, measurable, physical perturbations to the energy density, the particle number density and the global expansion, respectively.

9. Evolution Equations for Density Perturbations

I have used the computer algebra system to rewrite the system (20) into a new system of equations for the density contrast functions $\delta_\varepsilon := \varepsilon^{\text{phys}}_{(1)}/\varepsilon_{(0)}$ and $\delta_n := n^{\text{phys}}_{(1)}/n_{(0)}$. The result is the system of evolution equations for density perturbations in an open, flat and closed FLRW universe:

$$\ddot{\delta}_\varepsilon + b_1\dot{\delta}_\varepsilon + b_2\delta_\varepsilon = b_3\left[\delta_n - \frac{\delta_\varepsilon}{1+w}\right], \tag{27a}$$

$$\frac{1}{c}\frac{\mathrm{d}}{\mathrm{d}t}\left[\delta_n - \frac{\delta_\varepsilon}{1+w}\right] = \frac{3Hn_{(0)}p_n}{\varepsilon_{(0)}(1+w)}\left[\delta_n - \frac{\delta_\varepsilon}{1+w}\right], \tag{27b}$$

where the coefficients b_1, b_2 and b_3 are determined by the background equations (7) and the equation of state for the pressure $p = p(n, \varepsilon)$.

9.1. *Diabatic Perturbations*

Density perturbations are diabatic ('non-adiabatic') if and only if the equation of state for the pressure depends on both the particle number density n and the energy density ε.

The combined First and Second Law of Thermodynamics is given by

$$T_{(0)}s^{\text{phys}}_{(1)} = -\frac{\varepsilon_{(0)}(1+w)}{n_{(0)}}\left[\delta_n - \frac{\delta_\varepsilon}{1+w}\right]. \tag{28}$$

Thus, the evolution of density perturbations is determined by both their internal gravity and heat exchange with their environment.

For diabatic perturbations the pressure perturbation is given by

$$p^{\text{phys}}_{(1)} = \beta^2\varepsilon_{(0)}\delta_\varepsilon + n_{(0)}p_n\left[\delta_n - \frac{\delta_\varepsilon}{1+w}\right], \tag{29}$$

where the first term is the *adiabatic* part of the pressure perturbation and the second term is the *diabatic* part.

9.2. *Adiabatic Perturbations*

For barotropic equations of state, i.e., $p = p(\varepsilon)$, we have $p_n := (\partial p/\partial n)_\varepsilon = 0$, implying that $b_3 = 0$. In this case Eq. (27a) is a homogeneous equation and, as a consequence, describes adiabatic perturbations. Since for adiabatic perturbations $T_{(0)}s^{\rm phys}_{(1)} = 0$, Eq. (27b) reduces in this case to an algebraic equation

$$\delta_n - \frac{\delta_\varepsilon}{1+w} = 0, \tag{30}$$

so that for adiabatic perturbations the perturbations in the energy density are coupled to perturbations in the particle number density. Adiabatic perturbations evolve only through their internal gravity.

10. Structure Formation in a Flat FLRW Universe

In this section we consider a flat FLRW universe. The coefficients of Eq. (27a) are in this case given by

$$b_1 = H(1-3w-3\beta^2) - 2\frac{\dot\beta}{\beta}, \tag{31a}$$

$$b_2 = \kappa\varepsilon_{(0)}\left[2\beta^2(2+3w) - \tfrac{1}{6}(1+18w+9w^2)\right] + 2H\frac{\dot\beta}{\beta}(1+3w) - \beta^2\frac{\nabla^2}{a^2}, \tag{31b}$$

$$b_3 = \left\{\frac{-2}{1+w}\left[\varepsilon_{(0)}p_{\varepsilon n}(1+w) + \frac{2p_n}{3H}\frac{\dot\beta}{\beta} + p_n(p_\varepsilon - \beta^2) + n_{(0)}p_{nn}\right] + p_n\right\}\frac{n_{(0)}}{\varepsilon_{(0)}}\frac{\nabla^2}{a^2}, \tag{31c}$$

where the partial derivatives of the equation of state for the pressure $p(n,\varepsilon)$ are given by

$$p_n := \left(\frac{\partial p}{\partial n}\right)_\varepsilon, \quad p_\varepsilon := \left(\frac{\partial p}{\partial \varepsilon}\right)_n, \quad p_{\varepsilon n} := \frac{\partial^2 p}{\partial\varepsilon\,\partial n}, \quad p_{nn} := \frac{\partial^2 p}{\partial n^2}. \tag{32}$$

The symbol ∇^2 denotes the Laplace operator. The quantity $\beta(t)$ is defined by $\beta^2 := \dot p_{(0)}/\dot\varepsilon_{(0)}$. Using that $\dot p_{(0)} = p_n\dot n_{(0)} + p_\varepsilon\dot\varepsilon_{(0)}$ and the conservation laws (7c) and (7d) one gets

$$\beta^2 = p_\varepsilon + \frac{n_{(0)}p_n}{\varepsilon_{(0)}(1+w)}. \tag{33}$$

From the definitions $w := p_{(0)}/\varepsilon_{(0)}$ and $\beta^2 := \dot p_{(0)}/\dot\varepsilon_{(0)}$ and the energy conservation law (7c), one finds for the time-derivative of w

$$\dot w = 3H(1+w)(w-\beta^2). \tag{34}$$

This expression holds true *independent* of the precise form of the equation of state.

10.1. *Radiation Dominated Universe*

In this era the primordial fluid can be treated as radiation-dominated with equations of state

$$\varepsilon = a_{\mathrm{B}} T_\gamma^4, \quad p = \tfrac{1}{3} a_{\mathrm{B}} T_\gamma^4, \tag{35}$$

where a_{B} is the black body constant and T_γ the radiation temperature. The equations of state (35) imply the equation of state for the pressure $p = \frac{1}{3}\varepsilon$, so that, with (32),

$$p_n = 0, \quad p_\varepsilon = \tfrac{1}{3}. \tag{36}$$

Therefore, one has from (33),

$$\beta^2 = w = \tfrac{1}{3}. \tag{37}$$

Using (36) and (37), the perturbation equations (27) reduce to

$$\ddot{\delta}_\varepsilon - H\dot{\delta}_\varepsilon - \left[\frac{1}{3}\frac{\nabla^2}{a^2} - \tfrac{2}{3}\kappa\varepsilon_{(0)}\right]\delta_\varepsilon = 0, \tag{38a}$$

$$\delta_n - \tfrac{3}{4}\delta_\varepsilon = 0. \tag{38b}$$

Using the solutions of the background equations (7) and using that $\delta_\varepsilon(t, \boldsymbol{x}) = \delta_\varepsilon(t, \boldsymbol{q}) \exp(\mathrm{i}\boldsymbol{q} \cdot \boldsymbol{x})$, with $|\boldsymbol{q}| = 2\pi/\lambda$, Eq. (38a) can be written in the form

$$\delta_\varepsilon'' - \frac{1}{2\tau}\delta_\varepsilon' + \left[\frac{\mu_{\mathrm{r}}^2}{4\tau} + \frac{1}{2\tau^2}\right]\delta_\varepsilon = 0, \quad \mu_{\mathrm{r}} := \frac{2\pi}{\lambda_0}\frac{1}{H(t_0)}\frac{1}{\sqrt{3}}, \quad \lambda_0 := \lambda a(t_0), \tag{39}$$

where a prime denotes differentiation with respect to the dimensionless time $\tau := t/t_0 \geq 1$. The general solution of Eq. (39) is

$$\delta_\varepsilon(\tau, \boldsymbol{q}) = \left[A_1(\boldsymbol{q}) \sin\left(\mu_{\mathrm{r}}\sqrt{\tau}\right) + A_2(\boldsymbol{q}) \cos\left(\mu_{\mathrm{r}}\sqrt{\tau}\right)\right]\sqrt{\tau}, \tag{40}$$

where $A_1(\boldsymbol{q})$ and $A_2(\boldsymbol{q})$ are the 'constants' of integration. For large-scale ($\lambda \to \infty$) perturbations, we find from Eq. (40) the well-known[2, 26–29] solution

$$\delta_\varepsilon = c_1\tau + c_2\tau^{1/2}. \tag{41}$$

We can now draw the following conclusions. From Eq. (40) it follows that density perturbations oscillate. However, in contrast to the outcome of the standard perturbation theory in the literature, density perturbations oscillate with an *increasing* amplitude. Moreover, baryons were tightly coupled to radiation through Thomson scattering, i.e., baryons obey $\delta_{n,\,\mathrm{baryon}} = \frac{3}{4}\delta_\varepsilon$. Thus, for baryons (38b) is identically satisfied. In contrast to baryons, CDM is *not* coupled to radiation through Thomson scattering. However, equation (38b) follows from the General Theory of Relativity. As a consequence, equation (38b) should be obeyed by *all* kinds of particles that interact through gravitation. In other words, equation (38b) holds true for baryons as well as CDM. Since CDM interacts only via gravity with baryons and radiation, the fluctuations in CDM are coupled through gravitation to fluctuations in the energy density.

10.2. *Era after Decoupling of Matter and Radiation*

Once protons and electrons combined to yield hydrogen, the radiation pressure was negligible, and the equations of state have become those of a non-relativistic monatomic perfect gas with three degrees of freedom

$$\varepsilon(n,T) = nmc^2 + \tfrac{3}{2}nk_{\mathrm{B}}T, \quad p(n,T) = nk_{\mathrm{B}}T, \tag{42}$$

where k_{B} is Boltzmann's constant, m the mean particle mass, and T the temperature of the matter. Eliminating T from (42) yields the equation of state for the pressure

$$p(n,\varepsilon) = \tfrac{2}{3}(\varepsilon - nmc^2), \tag{43}$$

so that with (32) one has

$$p_n = -\tfrac{2}{3}mc^2, \quad p_\varepsilon = \tfrac{2}{3}. \tag{44}$$

Substituting p_n, p_ε, and ε given by (42) into (33) on finds, using that $mc^2 \gg k_{\mathrm{B}}T$,

$$\beta \approx \frac{v_{\mathrm{s}}}{c} = \sqrt{\frac{5}{3}\frac{k_{\mathrm{B}}T_{(0)}}{mc^2}}, \quad w \approx \frac{k_{\mathrm{B}}T_{(0)}}{mc^2} \lesssim 2.7\times 10^{-10}, \tag{45}$$

with v_{s} the adiabatic speed of sound and $T_{(0)}$ the matter temperature. Using that $\beta^2 \approx \frac{5}{3}w$ and $w \ll 1$, expression (34) reduces to $\dot{w} \approx -2Hw$, so that with $H := \dot{a}/a$ one has $w \propto a^{-2}$. This implies with (45) that the matter temperature decays as

$$T_{(0)} \propto a^{-2}. \tag{46}$$

This, in turn, implies with (45) that $\dot{\beta}/\beta = -H$. The system (27) can now be rewritten as

$$\ddot{\delta}_\varepsilon + 3H\dot{\delta}_\varepsilon - \left[\beta^2\frac{\nabla^2}{a^2} + \tfrac{5}{6}\kappa\varepsilon_{(0)}\right]\delta_\varepsilon = -\frac{2}{3}\frac{\nabla^2}{a^2}\left(\delta_n - \delta_\varepsilon\right), \tag{47a}$$

$$\frac{1}{c}\frac{\mathrm{d}}{\mathrm{d}t}\left(\delta_n - \delta_\varepsilon\right) = -2H\left(\delta_n - \delta_\varepsilon\right), \tag{47b}$$

where $w \ll 1$ and $\beta^2 \ll 1$ have been neglected with respect to constants of order unity. From equation (47b) it follows with $H := \dot{a}/a$ that

$$\delta_n - \delta_\varepsilon \propto a^{-2}. \tag{48}$$

Combining (46) and (48) it follows that the fluctuation in the kinetic energy density is given by

$$\delta_{\mathrm{kin}}(t,\boldsymbol{x}) \approx \delta_\varepsilon(t,\boldsymbol{x}) - \delta_n(t,\boldsymbol{x}) \approx \frac{3}{2}\frac{k_{\mathrm{B}}T_{(0)}(t)}{mc^2}\delta_T(t_{\mathrm{dec}},\boldsymbol{x}), \tag{49}$$

where $\delta_T(t_{\mathrm{dec}},\boldsymbol{x})$ is a constant, i.e., a free parameter of the perturbation theory and t_{dec} is the time of decoupling of matter and radiation. Moreover, it is found for the entropy perturbation and the fluctuation in the pressure, respectively,

$$s^{\mathrm{phys}}_{(1)} \approx \tfrac{3}{2}k_{\mathrm{B}}\delta_T, \quad \delta_p \approx \tfrac{5}{3}\delta_\varepsilon + \delta_T, \tag{50}$$

as follows from (28), (29) and (42).

Using that $\delta_\varepsilon(t,\boldsymbol{x}) = \delta_\varepsilon(t,\boldsymbol{q})\exp(\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{x})$, $\delta_n(t,\boldsymbol{x}) = \delta_n(t,\boldsymbol{q})\exp(\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{x})$ with $|\boldsymbol{q}| = 2\pi/\lambda$ and the solutions of the background equations (7), the system (47) can be rewritten as one ordinary differential equation

$$\delta_\varepsilon'' + \frac{2}{\tau}\delta_\varepsilon' + \left[\frac{4}{9}\frac{\mu_\mathrm{m}^2}{\tau^{8/3}} - \frac{10}{9\tau^2}\right]\delta_\varepsilon = -\frac{4}{15}\frac{\mu_\mathrm{m}^2}{\tau^{8/3}}\delta_T(t_\mathrm{dec},\boldsymbol{q}), \quad \tau \geq 1, \tag{51}$$

where a prime denotes differentiation with respect to the dimensionless time $\tau := t/t_\mathrm{dec}$. The parameter μ_m is expressed in observable quantities at the present time t_p

$$\mu_\mathrm{m} = \frac{2\pi}{\lambda_\mathrm{dec}}\frac{1}{cH(t_\mathrm{p})}\frac{1}{\left[z(t_\mathrm{dec})+1\right]}\sqrt{\frac{5}{3}\frac{k_\mathrm{B}T_{(0)\gamma}(t_\mathrm{p})}{m}} = \frac{16.48}{\lambda_\mathrm{dec}}, \tag{52}$$

where λ_dec is expressed in parsec.

For large scales $\lambda_\mathrm{dec} \to \infty$, the solution of Eq. (51) is given by

$$\delta_\varepsilon = c_1\tau^{2/3} + c_2\tau^{-5/3}. \tag{53}$$

The first term is a well-known solution, whereas the gauge mode τ^{-1} is absent.

In order to solve Eq. (51) for all finite scales λ_dec, we have to specify the initial values $\delta(t_\mathrm{dec},\boldsymbol{q})$ and its derivative $\delta'(t_\mathrm{dec},\boldsymbol{q})$. From measurements of the Planck satellite[30] it is found that for $\tau = 1$, i.e., at $t = t_\mathrm{dec}$,

$$|\delta_\varepsilon(t_\mathrm{dec},\boldsymbol{q})| \lesssim 10^{-5}. \tag{54}$$

The initial growth rate is unknown. Therefore, we assume that there is initially no growth at all, i.e., we take

$$\delta_\varepsilon'(t_\mathrm{dec},\boldsymbol{q}) \approx 0. \tag{55}$$

The initial value of the entropy perturbation (50) is a random variable and depends on how a density perturbation undergoes the very fast transition from a very high pressure epoch just before decoupling to the very low pressure era just after decoupling. Some small areas end up with positive entropy perturbations and others with negative entropy perturbations. In fact, it is found that

(1) $s_{(1)}^\mathrm{phys} \approx \frac{3}{2}k_\mathrm{B}\delta_T > 0 \;\Rightarrow$ large voids

(2) $s_{(1)}^\mathrm{phys} \approx \frac{3}{2}k_\mathrm{B}\delta_T < 0 \;\Rightarrow$ structure formation

The results of the integration of Eq. (51) are depicted in Fig. 1. The curves are labeled by the diabatic pressure perturbation δ_T (50). Density perturbations start to grow at the time of decoupling. Each curve shows the time (or, equivalently, the redshift) when a density perturbation becomes non-linear, i.e., $\delta_\varepsilon = 1$. The growth of density perturbations is governed by both gravity and heat exchange. At a scale of 6.5 pc = 21 ly (the peak value) gravity and heat exchange work perfectly together, resulting in very early star formation. Because of the steepness of the curves to the left of the peak, I will refer to this value as the *relativistic* Jeans scale. The corresponding relativistic Jeans mass is $4.3\times10^3\,M_\odot$. For scales larger than the relativistic Jeans scale, gravity is strong but heat exchange is low because of the large

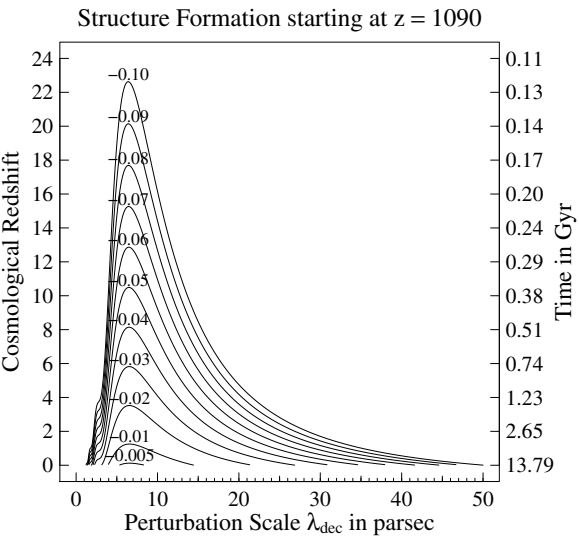

Fig. 1. The curves give the redshift and time, as a function of $\lambda_{\rm dec}$, when a linear perturbation in the energy density with initial values $\delta_\varepsilon(t_{\rm dec}, \boldsymbol{q}) \lesssim 10^{-5}$ and $\delta'_\varepsilon(t_{\rm dec}, \boldsymbol{q}) \approx 0$ starting to grow at an initial redshift of $z(t_{\rm dec}) = 1090$ has become non-linear, i.e., $\delta_\varepsilon(t, \boldsymbol{q}) = 1$. The curves are labeled with the initial values of the relative perturbations $\delta_T(t_{\rm dec}, \boldsymbol{q})$ in the diabatic part of the pressure. For each curve, the Jeans scale, i.e., the peak value, is at 6.5 pc.

scale, resulting in a later collapse time. The larger the scale, the later the collapse time. For very large scales the collapse time is proportional to $\tau^{2/3}$, the classic result for adiabatic density perturbations. On the other hand, for scales smaller than the relativistic Jeans scale, gravity becomes rapidly very weak, resulting also in a much later collapse time.

Figure 2 shows the growth rates of density perturbations as a function of their initial scale $\lambda_{\rm dec}$ at decoupling. The fastest growth occurs within the first 16 Myr. Density perturbations at the relativistic Jeans scale of 6.5 pc grow fast until non-linearity. Density perturbations with initial scale 4.1 pc grow initially faster than perturbations at the relativistic Jeans scale. Eventually, the rapid growth slows down and the perturbations grow slowly into the non-linear phase. Density perturbations which are initially smaller than 4.1 pc oscillate towards non-linearity. Finally, perturbations smaller than approximately 1 pc and larger than 50 pc do not become non-linear within the age of the universe.

11. Standard Perturbation Theory

The standard equation which is supposed to describe the evolution of density perturbations $\delta := \varepsilon_{(1)}/\varepsilon_{(0)}$ and which is ubiquitous in the literature reads

$$\ddot{\delta} + 2H\dot{\delta} - \left[\beta^2 \frac{\nabla^2}{a^2} + \tfrac{1}{2}\kappa\varepsilon_{(0)}(1+w)(1+3w)\right]\delta = 0. \tag{56}$$

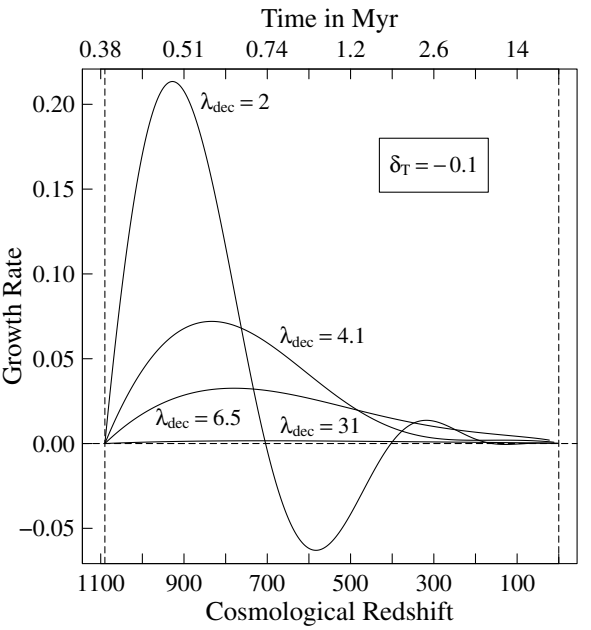

Fig. 2. The curves give the growth rates δ'_ε, as function of the redshift z, or time in million of years. The evolution of perturbations started at $z = 1090$. The initial dimensions λ_{dec} of the perturbations are measured in parsec.

See, for example, the classic article of Bonnor.[31] In this equation $\beta^2 = w = \frac{1}{3}$, (37), in the radiation-dominated universe, whereas $\beta = v_{\mathrm{s}}/c$ and $w = 0$, (45), after decoupling of matter and radiation. The standard equation (56) differs substantially from the new equations (38) and (47), since the latter two equations determine the evolution of the true, measurable energy density fluctuation $\delta_\varepsilon := \varepsilon_{(1)}^{\mathrm{phys}}/\varepsilon_{(0)}$. In this section we briefly explain why the standard equation differs from the new equations.

Since equations (38) and (47) are derived from the system (20), we try to derive Eq. (56) also from the system of equations (20), this time not using the definitions (9). In this procedure Eq. (20e) is not needed, since the equation of state for the pressure in Eq. (56) is of the form $p = p(\varepsilon)$.

11.1. *Radiation-dominated Universe*

The result for the radiation-dominated era is

$$\ddot{\delta} + 2H\dot{\delta} - \left[\frac{1}{3}\frac{\nabla^2}{a^2} + \tfrac{4}{3}\kappa\varepsilon_{(0)}\right]\delta = -\tfrac{4}{3}H\vartheta_{(1)}, \tag{57a}$$

$$\dot{\vartheta}_{(1)} + H\vartheta_{(1)} + \frac{1}{4}\frac{\nabla^2\delta}{a^2} = 0. \tag{57b}$$

The problem with this system is that it admits, next to physical solutions, also the gauge modes

$$\hat{\delta}(t,\boldsymbol{x}) := -4H(t)\psi(\boldsymbol{x}), \quad \hat{\vartheta}(t,\boldsymbol{x}) := -\frac{\nabla^2\psi(\boldsymbol{x})}{a^2(t)}. \tag{58}$$

Since these solutions have no physical significance, one cannot impose *physical* initial conditions to solve the system (57) since that would imply that the arbitrary gauge function $\psi(\boldsymbol{x})$ could be fixed by physical conditions, which is impossible. Furthermore, the gauge modes displace the divergence $\vartheta_{(1)}$ of the fluid velocity to the right-hand side, Eq. (57a). Since $\vartheta_{(1)}$ is an intrinsic property of an evolving density perturbation, it should be incorporated in the left-hand side of the evolution equation, as is the case for Eq. (38a). That is why Eq. (38a) predicts oscillating density perturbations with an *increasing* amplitude, whereas the standard equation (56) yields oscillating perturbations with a *constant* amplitude. Because of the presence of gauge modes in its solution, the system (57) is inadequate to study the evolution of density perturbations in the universe. In contrast to the system (57) the standard equation (56) lacks the divergence $\vartheta_{(1)}$. Since, in addition, the gauge mode $\hat{\delta}$ is a solution of Equation (56), the standard equation is simply useless.

11.2. *Era after Decoupling of Matter and Radiation*

In the era after decoupling we find

$$\ddot{\delta} + 2H\dot{\delta} - \left[\beta^2\frac{\nabla^2}{a^2} + \tfrac{1}{2}\kappa\varepsilon_{(0)}\right]\delta = -3H\beta^2\vartheta_{(1)}, \tag{59a}$$

$$\dot{\vartheta}_{(1)} + 2H\vartheta_{(1)} + \beta^2\frac{\nabla^2\delta}{a^2} = 0. \tag{59b}$$

In this case the gauge function $\psi(\boldsymbol{x})$ reduces to a constant C, (26), in accordance with the fact that after decoupling the cosmological fluid is described by a non-relativistic fluid (42). Therefore, the only surviving gauge mode is given by

$$\hat{\delta}(t,\boldsymbol{x}) := -3H(t)C, \tag{60}$$

and $\vartheta_{(1)} = \vartheta_{(1)}^{\text{phys}}$ is a physical quantity. Due to the presence of a gauge mode, the system (59) is still inadequate to study the evolution of density perturbations.

Finally, we consider a pressure-less fluid, also known as 'dust'. Substituting $p = 0$, i.e., $\beta = 0$, into the system (59) we find

$$\ddot{\delta} + 2H\dot{\delta} - \tfrac{1}{2}\kappa\varepsilon_{(0)}\delta = 0, \tag{61a}$$

$$\dot{\vartheta}_{(1)} + 2H\vartheta_{(1)} = 0. \tag{61b}$$

These equations are decoupled, implying that the divergence of the fluid velocity has no influence whatsoever on the growth of a perturbation. However, if there are no pressure differences in a fluid, then there is no fluid flow, $\vartheta_{(1)}^{\text{phys}} = 0$, so that density perturbations do not evolve. Since Eq. (61b) has only the gauge mode $\hat{\vartheta}_{(1)}$ as solution this equation is not needed anymore.

Equation (61a) follows also from the Newtonian Theory of Gravity if one takes the expansion into account. Since it has next to the gauge mode $\propto t^{-1}$ also a physical solution $\propto t^{2/3}$ regardless of the fact that there is no fluid flow, it should be clear that the Newtonian perturbation theory is inadequate to describe the evolution of density perturbations in the universe.

12. Conclusion

In this article I have sketched the derivation of a perturbation theory for open, flat and closed FLRW universes filled with perfect fluid described by a non-barotropic equation of state for the pressure $p(n, \varepsilon)$. The new theory has a Newtonian limit in a non-static universe. As a consequence, the gauge problem of cosmology is finally solved. The new perturbation theory consists of a second-order ordinary differential equation for the density contrast $\delta_\varepsilon := \varepsilon^{\text{phys}}_{(1)}/\varepsilon_{(0)}$, and a first-order ordinary differential equation for $\delta_n - \delta_\varepsilon/(1+w)$, where the latter expression is proportional to entropy perturbations. A first conclusion that can be drawn from the new perturbation theory is that local density perturbations do not affect the global expansion of the universe.

The new perturbation theory has been applied to a flat FLRW universe. The results are as follows. In the radiation-dominated universe density perturbations oscillate with an amplitude which is proportional to the square root of time. Both CDM as well as ordinary matter are coupled to perturbations in the radiation. As a consequence, structure formation can start only after decoupling of matter and radiation. After decoupling the growth of structure depends on both its internal gravity and its heat exchange with its environment. Heat exchange depends on the initial value of the entropy perturbation as well as the initial scale of a density perturbation. The entropy perturbation is a free parameter of the perturbation theory and can, therefore, take on random values. For sufficiently large negative values of the entropy perturbation I have found that the first stars are formed at $z \approx 24$–12, or, equivalently 110–300 Myr after the Big Bang. The relativistic Jeans scale is $6.5\,\text{pc} \approx 21\,\text{ly}$, and the corresponding relativistic Jeans mass is $4.3 \times 10^3\, M_\odot$.

The research in Refs. 3 and 4 has revealed that the General Relativistic perturbation theory explains structure formation in the early universe, without the need of CDM. The standard equation (56) of cosmology should not be used anymore.

Observations of the 21cm signal through intensity mapping techniques are expected in the near future. This new observable will allow probing the evolution of the Universe in a very wide redshift range, from the dark ages, through the epoch of reionization up to the present time. We constrain cosmological parameters from forecast measurements of the 21 cm signal power spectrum $P_{21}(k, z)$ combined with the latest CMB data from Planck 2018 observations. In the same framework, we test also modified gravity models to unveil beyond ΛCDM features coupling information from primordial probes, such as the CMB, to lower redshift ones. We extend the codes EFTCAMB/EFTCosmoMC to compute the likelihood function for $P_{21}(k, z)$ and we construct a mock data set of forecast intensity mapping observations. At the time being, we are bound by the experimental state-of-the-art to consider the redshift bin $z = 0.39$. However, in the future, it may be possible to study also wider redshift ranges. We describe our likelihood implementation and present the results we obtained from the statistical Monte-Carlo Markov-Chain analysis we conducted.

Keywords: Cosmology; 21cm Intensity Mapping; Dark Energy; Modified Gravity; Forecast constraints.

1. Introduction

According to the Standard Model of Cosmology, the Λ - Cold Dark Matter (ΛCDM) model, the Universe we live in is currently going to a phase of accelerated expansion. The cause of acceleration is assigned to an enigmatic component, called Dark Energy (DE), which constitutes $\sim 70\%$ of the Universe. From the birth of the precision cosmology era, the ΛCDM model has been extensively tested and it proved to be in remarkable agreement with several, independent observations.[1–4] Despite its success, tensions on cosmological parameters[5–8] and open theoretical problems, regarding the nature of the Cosmological Constant (Λ),[9–11] motivated the emergence of a plethora of models alternative to ΛCDM.[12,13]

At the state-of-the-art, constraints on Modified Gravity (MG) or DE models are all broadly compatible with ΛCDM. However, observations from future experiments,

such as Euclid[a] and the Square Kilometer Array Observatory (SKAO),[b] are expected to be crucial in the quest for selecting the correct model.

In this work, we test the effect of the detection on the 21cm signal on beyond ΛCDM models, i.e. $P_{21}(k)$. We forecast intensity mapping observations of $P_{21}(k)$, as it will be measured by the MeerKAT radio-telescope,[c] the SKAO precursor and pathfinder in South Africa.[14–16] We build a realistic mock data set for $P_{21}(k)$ at redshift $z = 0.39$ and conduct a Monte Carlo Markov Chain (MCMC) analysis to constrain beyond ΛCDM theories. We adopt a model-independent approach by studying MG/DE within the Effective Field Theory (EFT) formalism for Cosmic Acceleration.[17,18] To this end we modify the codes `EFTCAMB/EFTCosmoMC`,[19–21] to include a new module for the $P_{21}(k)$ likelihood computation. We compute constraints on cosmological and EFT parameters from $P_{21}(k)$ alone and combined with the latest Planck 2018 CMB data.[1]

This work is intended as an introduction to a more extensive analysis, that can be found in Ref.[22]. The structure of the paper is the following. First, we review general aspects of the theoretical and experimental framework in section 1.1. We outline the main aspects of our methodology in section 2. Results are presented in section 3 and summarized in section 4.

1.1. *Theoretical and experimental framework*

The Effective Field Theory (EFT) technique was first used in a cosmological scenario to describe inflation[23,24] and then applied to the description of Cosmic Acceleration.[17,18] The idea behind EFT for DE is to construct the most general action to be *effective*, i.e. easily interfaced with data, and *unifying*, in order to include as many DE/MG models as special cases. Up to second order in perturbation theory and in the Jordan frame, the resulting action is

$$\begin{aligned} S = \int \mathrm{d}^4x\sqrt{-g}\Bigg\{ & \frac{m_0^2}{2}\left[1+\Omega^{\rm EFT}(\tau)\right]R + \Lambda(\tau) - c(\tau)a^2\delta g^{00} \\ & + \frac{M_2^4(\tau)}{2}\left(a^2\delta g^{00}\right)^2 - \frac{\bar{M}_1^3(\tau)}{2}a^2\delta g^{00}\delta K \\ & - \frac{\bar{M}_2^2(\tau)}{2}\left(\delta K\right)^2 - \frac{\bar{M}_3^2(\tau)}{2}\delta K^\mu_\nu \delta K^\nu_\mu \\ & + m_2^2(\tau)(g^{\mu\nu}+n^\mu n^\nu)\partial_\mu\left(a^2g^{00}\right)\partial_\nu\left(a^2g^{00}\right) \\ & + \frac{\hat{M}^2(\tau)}{2}a^2\delta g^{00}\delta R^{(3)} + \dots \Bigg\} + S_m, \end{aligned} \tag{1}$$

where the nine functions of the conformal time τ, $\{\Omega^{\rm EFT}, \Lambda, c\}$ and $\{M_2^4, \bar{M}_1^3, \bar{M}_2^2, \bar{M}_3^2, m_2^2, \hat{M}^2\}$, are referred to as EFT functions. We recover the

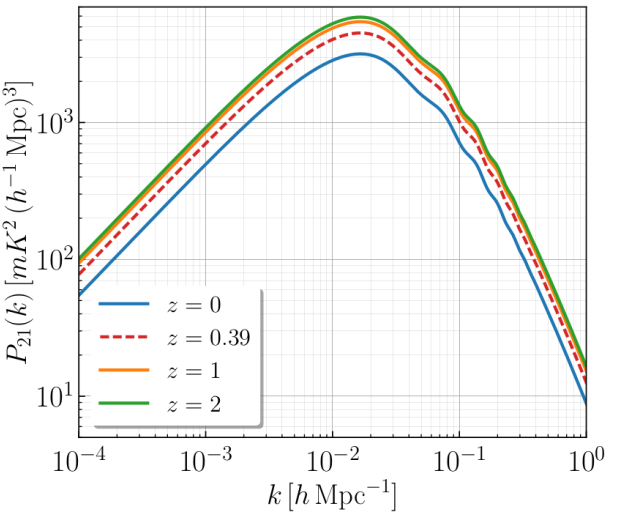

Fig. 1. Linear power spectra for the 21cm signal at different redshifts. Results are computed with the model in Eq. (2) for a ΛCDM fiducial cosmology, i.e. Planck 2018 best fit results.[1]

ΛCDM limit when all the EFT functions are set to zero. By choosing the evolution of each EFT function one can either test the specific effect of the single operators on observables (*pure* EFT approach) or map the EFT functions into well known DE/MG models. We will adopt the *pure* EFT approach and we will study a subset of models described by the functions $\{\Omega^{\rm EFT}, \Lambda, c\}$ on a ΛCDM background.

EFT models can be studied numerically by means of the Einstein-Boltzmann solver `EFTCAMB`,[19,21] an extension of the code `CAMB`,[25] and the MCMC sampler `EFTCosmoMC`,[20] an extension of `CosmoMC`.[26,27] *Pure* EFT models have been studied in the literature,[1,20,28] however, at the state-of-the-art, all the models are compatible with ΛCDM. For a complete review on EFT for DE and the latest constraints, we refer to Ref.[29].

Although no significant proof supporting a specific beyond ΛCDM model has yet been found, in this work we quantify the impact of future observations on EFT models. We focus on the 21cm signal detection through line intensity mapping techniques, which allows sampling the neutral hydrogen (HI) distribution in a wide redshift range.[30–35] These observations will open an important window on DE/MG theories.[36–42] Currently, several purpose-built radio-telescopes, such as the Canadian Hydrogen Intensity Mapping Experiment (CHIME),[d] the Hydrogen Intensity and Real-Time Analysis experiment (HIRAX),[e] the Five-hundred-meter Aperture Spherical Telescope (FAST),[f] are already taking data or are under construction.

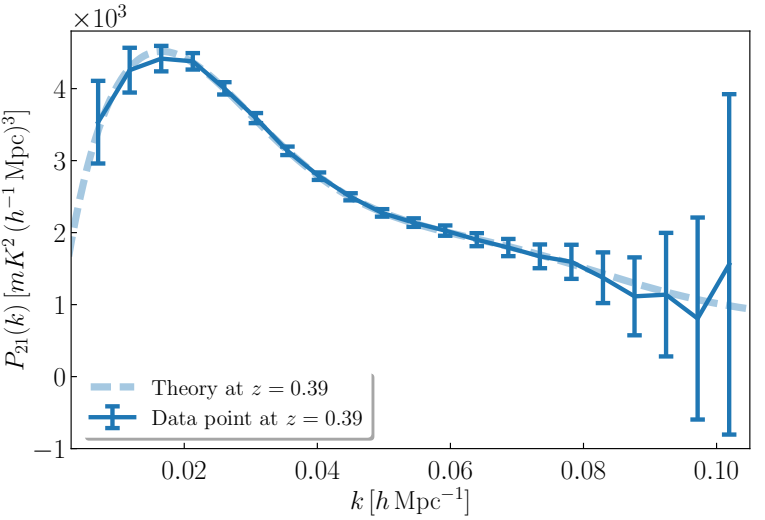

Fig. 2. Mock data set observations and theory prediction at $z = 0.39$ for the 21cm signal power spectrum. Error bars are generated considering a realistic intensity mapping survey with the MeerKAT telescope. Central values are instead obtained from points predicted by the theory for ΛCDM and the fiducial cosmology we assume. Each point from the theory is then displaced randomly according to a gaussian distribution with a fifth of the error on that point as standard deviation.

Moreover, radio cosmology and the study of DE/MG theories is one of the main science goals of the world's largest interferometer, the Square Kilometer Array Observatory (SKAO),[g] in particular with intensity mapping techniques.[43]

The MeerKAT telescope,[h] the SKAO precursor in South Africa, can be successfully exploited for 21cm intensity mapping[14,15] and has attained encouraging results.[16] In this work, we mimick observations with the MeerKAT telescope, which operates at an interesting redshift range for DE and for which real data will be available in the near future.

2. Likelihood implementation

To compute the likelihood function $\mathcal{L}(D|\boldsymbol{\alpha})$, which we assume to be a multivariate Gaussian, we need the theoretical expectations for the set of parameters $\boldsymbol{\alpha}$, describing the considered model, and the observed set of data D. To compute $\boldsymbol{\alpha}$ we extend the codes `EFCAMB/ETCosmoMC` and model the linear power spectrum of the 21cm signal as[35,43,44]

$$P_{21}(z,\,k) = \bar{T}_b^2(z)(b_{\mathrm{HI}}(z) + f(z))^2 P_{\mathrm{m}}(z,k), \tag{2}$$

[g]See `https://www.skatelescope.org/`.
[h]See `https://www.sarao.ac.za/gallery/meerkat/`.

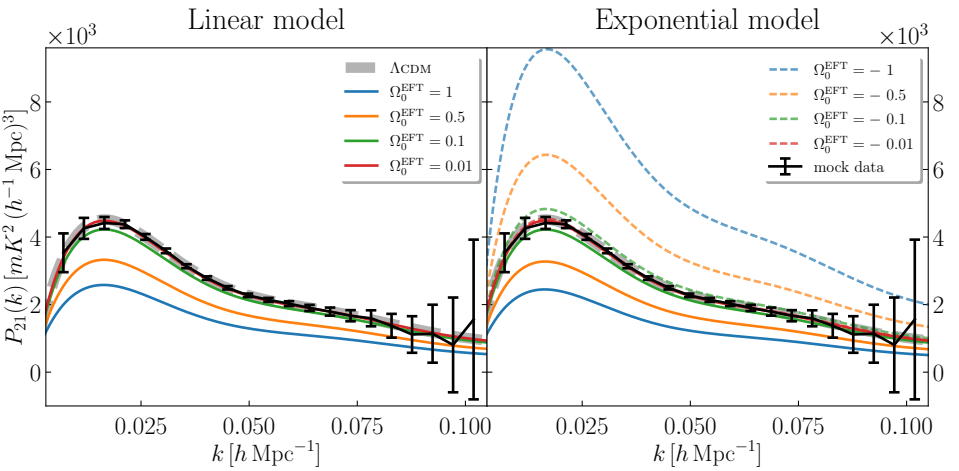

Fig. 3. Linear power spectra for the 21cm signal for ΛCDM and several *pure* EFT models, described by different values of the parameter $\Omega_0^{\rm EFT}$. We show theoretical predictions at redshift $z = 0.39$ for a linear (left panel) and an exponential (right panel) evolution of the function $\Omega_0^{\rm EFT}$. For the linear case we consider $\Omega_0^{\rm EFT} = 0.01, 0.1, 0.5, 1$, while for the exponential $\Omega_0^{\rm EFT} = \pm 0.01, \pm 0.1, \pm 0.5, \pm 1$. Black points with errorbars are the mock data set we construct in this work, as described in Sec. 2.

where T_b is the brightness temperature, $b_{\rm HI}$ is the HI bias, f is the linear growth rate and $P_{\rm m}$ is the linear matter power spectrum. We stress that the model dependence here enters through f and $P_{\rm m}$. Our predictions for $P_{21}(z, k)$ at different redshifts are shown in Fig. 1.

Given that real data are not available yet, we construct a mock data set of forecast observations of $P_{21}(k)$. We model the errors taking into account the technical specifications of the MeerKAT telescope, while we generate central points from the theory. Our mock data set is presented in Fig. 2. Here we focus on the redshift bin $z = 0.39$, which will be measured by MeerKAT. We explore also the effects of tomography in Ref.[22].

3. Results

In this section, we present our main results. We begin by studying a ΛCDM reference scenario. Then, we study a *pure* EFT model on a ΛCDM background, where the function $\Omega^{\rm EFT}(a)$ evolves as a linear function of the scale factor a, i.e. $\Omega^{\rm EFT}(a) = \Omega_0^{\rm EFT}\, a$. In Fig. 3, we compare theoretical predictions of $P_{21}(k)$ for different values of $\Omega_0^{\rm EFT}$ with the mock data set we constructed. One can see that the $P_{21}(k)$ observable is sensitive to variations in $\Omega_0^{\rm EFT}$, thus we expect that the $P_{21}(k)$ likelihood could help in constraining such model. However, we anticipate that this single data set alone is still not powerful enough to constrain $\Omega^{\rm EFT}$ alone. When combined with CMB data, instead, $\Omega_0^{\rm EFT}$ is already constrained by CMB to be < 0.1 (green line),

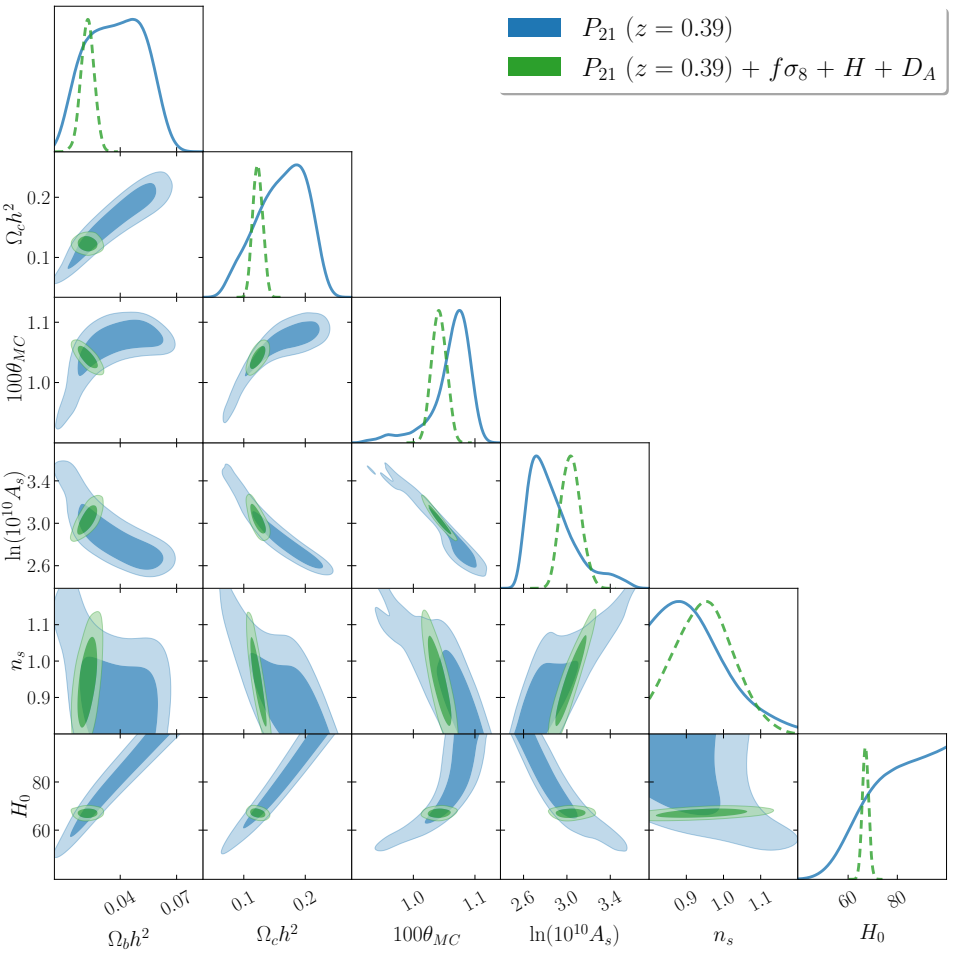

Fig. 4. Joint constraints (68% and 95% confidence regions) and marginalized posterior distributions on cosmological parameters for a ΛCDM model. Here the label $P_{21}(z = 0.39)$ stands for the 21cm power spectrum likelihood at redshift $z = 0.39$, while $f\sigma_8 + H + D_A$ represents the additional *background* likelihood computed at the same redshift $z = 0.39$. We consider the parameter τ fixed to a Planck 2018 fiducial cosmology value,[1] i.e. $\tau = 0.0543$.

therefore we will observe a small improvement in the constraining power when adding $P_{21}(k)$.

We analyse the effect of the $P_{21}(k)$ likelihood both alone and combined with CMB data. We consider the following data sets:

- *Planck 2018*: CMB data from Ref.[1], i.e. TT, TE, EE power spectra + low polarization (lowE) data + lensing;[i]

[i]See `http://pla.esac.esa.int/pla/\#home`.

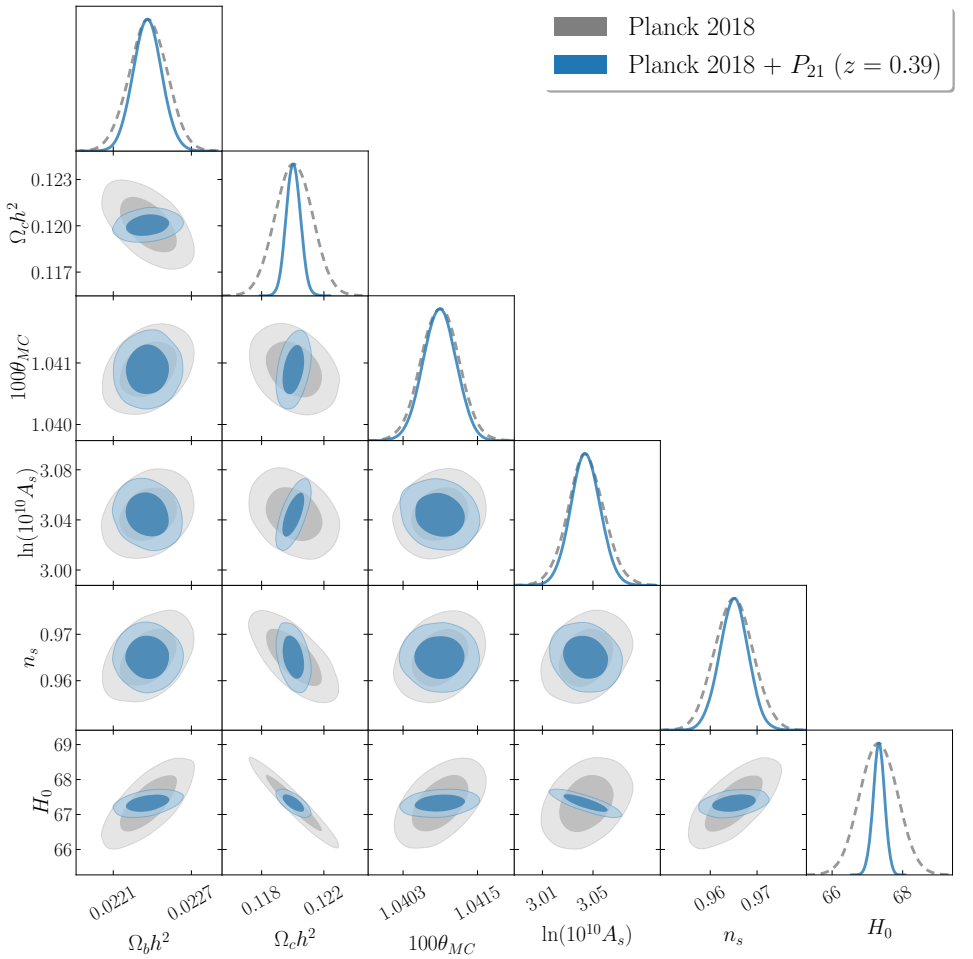

Fig. 5. Joint constraints (68% and 95% confidence regions) and marginalized posterior distributions on cosmological parameters for a ΛCDM model. Here the label Planck 2018 stands for TT, TE, EE + lowE + lensing while the label $P_{21}(z = 0.39)$ stands for the 21cm power spectrum likelihood at redshift $z = 0.39$.

Table 1. Marginalized constraints on cosmological parameters at the 68% confidence level for a ΛCDM model. Deviations in the error with respect to Planck 2018 results are shown in brackets.

Parameter	Planck 2018	$+ P_{21}(z = 0.39)$	$P_{21}(z = 0.39)$	$+ f\sigma_8 + H + D_A$
$\Omega_b h^2$	0.02237 ± 0.00014	0.02236 ± 0.00011 (−24%)	0.038 ± 0.015	0.0226 ± 0.0035
$\Omega_c h^2$	0.1201 ± 0.0012	0.12004 ± 0.00046 (−61%)	$0.162^{+0.050}_{-0.033}$	0.1227 ± 0.0081
n_s	0.9650 ± 0.0041	0.9651 ± 0.0031 (−25%)	< 0.959	$0.951^{+0.072}_{-0.085}$
H_0	67.32 ± 0.53	67.32 ± 0.16(−69%)	> 73.6	67.1 ± 1.3

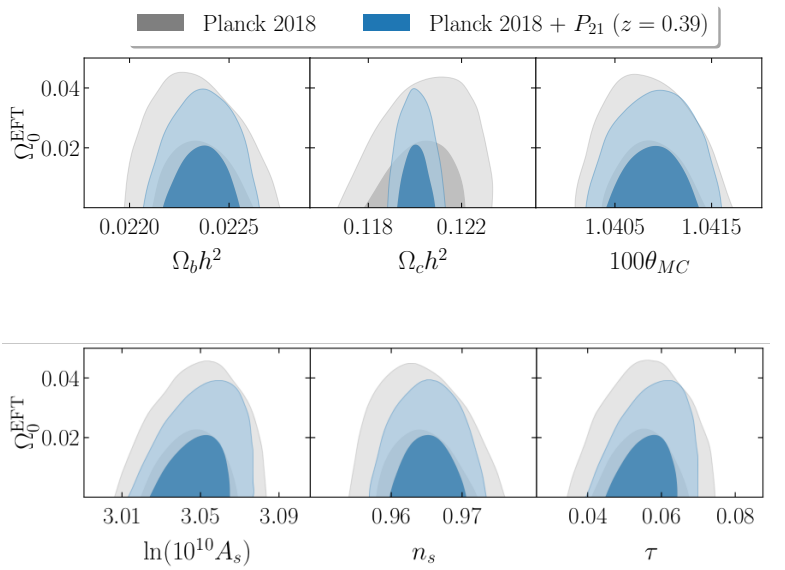

Fig. 6. Joint constraints (68% and 95% confidence regions) on cosmological and EFT parameters for a *pure* linear EFT model on a ΛCDM background. Here the label Planck 2018 stands for TT, TE, EE + lowE + lensing while the label $P_{21}(z = 0.39)$ stands for the 21cm power spectrum likelihood at redshift $z = 0.39$.

- $P_{21}(k)(z = 0.39)$: mock data set of MeerKAT forecast observations at redshift $z = 0.39$, constructed as described in Sec. 2;
- *background*: additional background and structure formation mock data sets for $f\sigma_8$, H, D_A at $z = 0.39$, inferred from higher redshift intensity mapping forecasts.[45]

For the ΛCDM case, we observe that the $P_{21}(k)$ likelihood alone has a weak constraining power on the cosmological parameters, as shown in Fig. 4. We find a strong correlation between H_0 and $\Omega_c h^2$, a feature that results to be pivotal when combining the 21cm signal data set with CMB data. The constraining power is significantly improved when we add the *background* data set. With $P_{21}(k)$ + *background* we are able to constrain the Hubble constant to $H_0 = 67.1 \pm 1.3$ km s^{-1}Mpc^{-1}, with a competitive error compared with results from other probes.[8] Combining CMB data with $P_{21}(k)$, we obtain an improvement on the errors on the cosmological parameters, as shown in Fig. 5 and Table 1. The effect is maximized for H_0 and $\Omega_c h^2$, for which we obtain a reduction on the error with respect to Planck estimate at the level of $\sim 60-70\%$. The correlation between H_0 and $\Omega_c h^2$ obtained with CMB data alone is perpendicular to the one found with $P_{21}(k)$. Therefore, combining the two data sets removes the correlation almost completely, thus significantly improving the constraints on H_0 and $\Omega_c h^2$.

Table 2. Marginalized constraints on cosmological parameters at the 68% confidence level for a *pure* linear EFT model on a ΛCDM background. Deviations in the error with respect to Planck 2018 results are shown in brackets.

Parameter	Planck 2018	$+ P_{21}(z = 0.39)$
$\Omega_b h^2$	0.02234 ± 0.00015	0.02237 ± 0.00011 (-26%)
$\Omega_c h^2$	0.1203 ± 0.0012	0.12003 ± 0.00046 (-63%)
H_0	67.21 ± 0.55	67.33 ± 0.17 (-70%)
$\Omega_0^{\rm EFT}$ ...	< 0.0147	< 0.0135 (-11%)

As anticipated, for the beyond ΛCDM case, we find that $P_{21}(k)$ alone has a weak constraining power on the EFT parameters. Thus, here we discuss only the results for $P_{21}(k)$ combined with CMB data, which are presented in Fig. 6 and Table 2. We find that adding $P_{21}(k)$ to CMB data reduces the error on the EFT parameter $\Omega_0^{\rm EFT}$ at the level of 11%. From the 2D contours, we observe that $P_{21}(k)$ also helps in removing some of the correlation between $\Omega_0^{\rm EFT}$ and the other cosmological parameters. Moreover, the constraints we obtain are comparable with results in the literature.[20,28] We stress that opening the parameter space to EFT models does not spoil the results on the cosmological parameters described above.

4. Conclusions

In this work we extended the `EFTCAMB/EFTCosmoMC` codes by implementing a new likelihood module fully integrated with original codes, to test forecast 21cm Intensity Mapping observations. We constructed a realistic data set at $z = 0.39$ from future MeerKAT-like observation settings. We tested the impact of the $P_{21}(k)$ likelihood on DE/MG models in the EFT framework.

We find a significant improvement on the $\Omega_c h^2$, H_0 constraints, from P_{21} combined with Early Universe probes, i.e. Planck 2018 CMB data.[1] The impact of $P_{21}(k)$ on beyond ΛCDM models is at the level of 11%. Thus, from this analysis, we conclude that 21cm power spectrum observations could help in increasing our knowledge of DE. However, we believe that adding tomographic data set of $P_{21}(k)$ observations could significantly improve the constraining power on EFT parameters. We investigate this claim and further expand this analysis in Ref.[22].

Acknowledgments

The author would like to thank her supervisor Prof. Matteo Viel and her collaborators Marta Spinelli, Sandeep B. Haridasu, and Alessandra Silvestri. We thank José Fonseca, for his valuable help in the construction of the MeerKAT-like $P_{21}(k)$ mock data, and Marco Raveri for useful discussions and technical help. This work is supported by the INFN INDARK grant.

General Relativity is *a priori* a theory invariant under time reversal. Its integration with the laws of thermodynamics allows for a formulation of non-equilibrium phenomena in gravity and the introduction of an arrow of time, i.e. the the breaking of such invariance. Even though most of the evolution of the universe takes place in local thermal equilibrium, the effects of irreversible processes on the expansion via entropic forces may be phenomenologically relevant. We review our previous work on the covariant formulation of non-equilibrium thermodynamics in General Relativity and the proposal to explain the recent cosmic acceleration from it.

Keywords: General Relativity, thermodynamics, non-equilibrium phenomena, entropic forces, cosmic acceleration.

1. Introduction

General Relativity is an extremely successful physical theory. More than a century after its formulation, its predictions continue to be valid at all probed scales, albeit an extension at short scales will be required in order to obtain a UV-complete quantum theory of gravity and resolve space-time singularities.

Thermodynamics is an even older discipline. Its fundamental laws seem to resist the passage of time and are still of great relevance today. On the one hand, thermodynamics may help in building the bridge between classical and quantum gravity, as the laws of black hole thermodynamics point towards the existence of a microphysical description of gravity yet to be understood.

On the other hand, the second law of thermodynamics, i.e. the growth of entropy, dictates the sign of the arrow of time. Physical laws are usually invariant under time inversion. The increase in entropy with time in out-of-equilibrium phenomena, however, allows one to distinguish the future-directed from the past directed description of a physical process.

There lacks a consistent and rigorous integration between General Relativity and the laws of thermodynamics. Understanding the very notion of the arrow of time is of particular interest for cosmology. In section 2 we argue for the need of going beyond reversible cosmology. This can be achieved for any space-time metric using variational techniques.[1] We review our main results in this new approach to non-equilibrium thermodynamics in General Relativity and present them in sections 3 to 6.

The growth of entropy associated to the causal horizon in open inflation scenarios may explain the current accelerated expansion of the universe within the general relativistic entropic acceleration (GREA) theory.[2] We briefly describe how this mechanism works in section 7 and finish with our conclusions.

2. Reversible cosmology

Let us begin the study of the problem of reversibility in gravity and cosmology by reviewing a prototypic case of reversible gravitational system: a homogeneous and isotropic universe. It is described by the Friedmann-Lemaître-Robertson-Walker (FLRW) metric

$$ds^2 = -dt^2 + a(t)^2 \left(\frac{dr^2}{1-kr^2} + r^2 d\Omega_2^2 \right) , \tag{1}$$

where $a(t)$ is the scale factor, $k = -1, 0, 1$ is the curvature parameter corresponding to, respectively, an open, flat and closed universe; and $d\Omega_2^2$ is the solid angle element. This space-time is filled with a perfect fluid, described by the stress-energy tensor

$$T_{\mu\nu} = (\rho + p) u_\mu u_\nu + p g_{\mu\nu} , \tag{2}$$

where ρ and p are, respectively, the density and pressure of the fluid. The Einstein field equations for this metric and matter content deliver the dynamics for the scale factor, the well-known Friedmann equations

$$H^2 + \frac{k}{a^2} = \frac{8\pi G}{3}\rho , \quad \frac{\ddot{a}}{a} = -\frac{4\pi G}{3}(\rho + 3p) , \tag{3}$$

where $H = \dot{a}/a$ is the Hubble parameter. There is a constraint on the stress-energy tensor due to the Einstein field equations and the Bianchi identities, namely its covariant conservation $D_\mu T^{\mu\nu} = 0$. From this constraint one can derive the continuity equation

$$\dot{\rho} + 3H(\rho + p) = 0 . \tag{4}$$

However, one can also derive this equation from the second law of thermodynamics. Indeed, changes in entropy are related to changes in internal energy and work $TdS = \delta U + \delta W$. If we apply this to a region of fixed comoving volume $a(t)^3$ we get

$$T\frac{dS}{dt} = \frac{d}{dt}\left(\rho a^3\right) + p\frac{d}{dt}\left(a^3\right) . \tag{5}$$

If the expansion of the universe is reversible, we can set the LHS to 0 and recover the continuity equation. However, this is only true in thermodynamical equilibrium and, in general, entropy is a monotonically increasing function of time. Most of the expansion history of the universe is indeed adiabatic. However, it is out-of-equilibrium at certain key points such as (p)reheating, phase transitions or gravitational collapse. Allowing for a time-varying entropy implies the addition of a term in the continuity equation

$$\dot{\rho} + 3H(\rho + p) = \frac{T\dot{S}}{a^3} . \tag{6}$$

Combining this with the first Friedmann equation we obtain a modified, non-equilibrium second Friedmann equation

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}\left(\rho + 3p - \frac{T\dot{S}}{a^3 H}\right) . \tag{7}$$

In principle, this evolution equation does not seem to be compatible with the Einstein field equations. In order to achieve that, the laws of thermodynamics need to be rigorously incorporated into the computation of the equations of motion. This can be achieved by applying the variational formalism of non-equilibrium thermodynamics, developed in another context by Gay-Balmaz and Yoshimura,[3,4] to General Relativity.

3. Entropic forces in mechanics and field theory

Entropic forces emerge naturally in any physical system out of equilibrium. They are a consequence of the coarse-graining of physical degrees of freedom and the laws of thermodynamics, which impose entropy to be a monotonically increasing function of time. This breaks time reversibility.

The dynamics of the coarse-grained degrees of freedom is unknown or ignored and so they do not appear in the action of the physical system. It would seem that a variational treatment of an out-of-equilibrium system is not possible. However, both the extremal-action principle and the second law of thermodynamics can be merged consistently by imposing the latter as a constrain on the variational problem defined by the action.[3,4] On the other hand, the first law of thermodynamics is obtained from the symmetries of the problem.

3.1. *Entropic forces in mechanics*

Let us start by reviewing the emergence of entropic forces in a mechanical system. Consider the action

$$\mathcal{S} = \int dt L(q, \dot{q}, S) , \tag{8}$$

where the Lagrangian depends on the generalized coordinate $q(t)$, its time derivative $\dot{q}(t)$ and the entropy $S(t)$. The variation of the action gives

$$\delta\mathcal{S} = \int dt \left(\frac{\delta L}{\delta q}\delta q + \frac{\partial L}{\partial S}\delta S\right) . \tag{9}$$

Setting $\delta\mathcal{S} = 0$ defines the variational problem. In order to enforce the second law of thermodynamics, we need to impose the variational constraint

$$\frac{\partial L}{\partial S}\delta S = f\delta q , \tag{10}$$

which simply states the relationship between variations of the entropy and the generalized coordinate. If we plug this in the variation of the action, then we can

readily obtain the equations of motion

$$\frac{\delta L}{\delta q} = \frac{\partial L}{\partial q} - \frac{d}{dt}\left(\frac{\partial L}{\partial \dot{q}}\right) = -f\,, \tag{11}$$

which is the Euler-Lagrange equation modified by the addition of the entropic force f. In order to know its precise form, we need to impose as well the phenomenological constraint, which is obtained by formally replacing the variations with time derivatives

$$\frac{\partial L}{\partial S}\dot{S} = f\dot{q}\,. \tag{12}$$

Note that usually temperature can be introduced as

$$T = -\frac{\partial L}{\partial S} > 0 \tag{13}$$

providing a clearer meaning to the variational and phenomenological constraint.

The imposition of the constraints and the emergence of an entropic force break the symmetry under time inversion. First, note that formally the Euler-Lagrange equation is invariant under the $t \to -t$ transformation, even with a non-vanishing entropic force. Next, the positiveness of the temperature and the change of entropy imposes $f\dot{q} < 0$. The entropic force has qualities of a generalized friction, as it opposes the coordinate velocity. Now, if one performs time inversion, this sign constraint becomes $f\dot{q} > 0$, as the temperature remains positive but entropy decreases with time. Before solving the equations of motion, $\dot{q}$ is still a degree of freedom and, thus, one must conclude a flip in the sign of f, which flips the overall sign of the Euler-Lagrange equation. Hence, one concludes that the emergence of an entropic force breaks symmetry under time reversal. The evolution of the system becomes irreversible.

3.2. *Entropic forces in classical field theory*

The extension of the variational formalism of non-equilibrium thermodynamics to the continuum is somewhat involved. We present a short-cut derivation that relies on the introduction of an additional constraint. We refer the reader to the appendix of Ref. 1 to check its equivalence with the full variational derivation originally presented in Ref. 4.

The action of a scalar field on Minkowski space-time contains now a dependency on a scalar function $s(t, \vec{x})$ that encodes information related to coarse-grained degrees of freedom

$$\mathcal{S} = \int d^4x \mathcal{L}\left(\phi, \partial_\mu \phi, s\right)\,. \tag{14}$$

In a similar fashion as before, the extremal-action principle needs to be supplemented by a variational constraint

$$\frac{\partial \mathcal{L}}{\partial s}\delta s = f\delta\phi\,, \tag{15}$$

so that the equation of motion becomes

$$\frac{\delta\mathcal{L}}{\delta\phi} = \frac{\partial\mathcal{L}}{\partial\phi} - \partial_\mu \frac{\partial\mathcal{L}}{\partial\partial_\mu\phi} = -f\,, \tag{16}$$

which is nothing but the Euler-Lagrange equation of a scalar field with a new term of entropic origin. As before, one can usually introduce a temperature as

$$T = -\frac{\partial\mathcal{L}}{\partial s} > 0 \tag{17}$$

and we would like to interpret s as the entropy density. However, due to spatial fluxes entropy does not need to necessarily increase locally and, thus, the constraint would not have a fixed sign. Before proceeding, we inspect the corresponding phenomenological constraint

$$\frac{\partial\mathcal{L}}{\partial s}\partial_0 s = f\partial_0\phi\,. \tag{18}$$

Instead, we interpret δs and $\partial_0 s$ as local entropy production and introduce a new function $s_{\rm tot}$ which is the actual entropy density and whose changes $\delta s_{\rm tot}$ and $\partial_0 s_{\rm tot}$ are indeed total local changes of the entropy density. Both are related as

$$\partial_0 s = \partial_0 s_{\rm tot} - \partial_i j_s^i\,, \tag{19}$$

where j_s^i is the entropy flux. This latter equation is an additional constraint we impose for the variational formalism to be consistent. Now one can check that $f\partial_0\phi < 0$ and time reversibility is broken by the same argument used in the mechanics example.

3.3. *Entropic forces in presence of additional symmetries*

The generalization of the above formalism to higher order tensors or to representations of some internal symmetry group is straightforward. Let us consider a field tensor z of contravariant rank r, which is also in some representation of an internal symmetry labelled by an index A. Then one builds the variational constraint as

$$\frac{\partial\mathcal{L}}{\partial s}\delta s = f_{A;\mu_1,\ldots\mu_r}\delta z_A^{\mu_1,\ldots\mu_r}\,, \tag{20}$$

which delivers the equation of motion

$$\frac{\delta\mathcal{L}}{\delta z_A^{\mu_1,\ldots\mu_r}}, = -f_{A;\mu_1,\ldots\mu_r}\,. \tag{21}$$

4. Entropic forces in General Relativity

The previous discussion makes us ready to study entropic forces in General Relativity. However, with the introduction of a dynamical space-time the very notion of time evolution becomes non-trivial. As we will see shortly, it is possible to obtain a modification of entropic origin to Einstein's field equation in the Lagrangian formulation of General Relativity. Its proper interpretation will require, nevertheless, the use of the Hamiltonian formalism.

4.1. *Lagrangian formulation*

Let us consider the Einstein-Hilbert action plus a matter term

$$\mathcal{S} = \frac{1}{2\kappa}\int d^4x\sqrt{-g}R + \int d^4x\mathcal{L}_m(g_{\mu\nu}, s)\,, \tag{22}$$

where $\kappa = 8\pi G$ is the gravitational coupling and we allow for the dependence of the matter Lagrangian on a function $s(t, \vec{x})$, which will have a similar interpretation to the one presented in the previous section. The extremal-action principle is supplemented by the variational constraint.

$$\frac{\partial\mathcal{L}_m}{\partial s} = \frac{1}{2}\sqrt{-g}f_{\mu\nu}\delta g^{\mu\nu}\,. \tag{23}$$

From the extremal-action principle and the variational constraint we obtain the modified Einstein's field equations

$$R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R = \kappa\left(T_{\mu\nu} - f_{\mu\nu}\right)\,, \tag{24}$$

where there is an additional term $f_{\mu\nu}$ of entropic origin. In order to obtain an expression for this term and to check the breaking of symmetry under time inversion we need to work in the Hamiltonian formulation of General Relativity.

4.2. *Hamiltonian formulation*

General Relativity admits a Hamiltonian formulation in the Arnowitt-Deser-Misner (ADM) formalism. Space-time is foliated in constant time hypersurfaces with normal unit vector n^μ, being the 4-metric split as

$$g_{\mu\nu} = h_{\mu\nu} - n_\mu n_\nu\,, \tag{25}$$

where $h_{\mu\nu}$ is the 3-metric induced on the hypersurfaces. Analogously, one can parametrize the 4-metric in terms of the 3-metric h_{ij} and the lapse and shift functions N and N^i

$$ds^2 = -(Ndt)^2 + h_{ij}(dx^i + N^i dt)(dx^j + N^j dt)\,. \tag{26}$$

Greek indices run from 0 to 3, while Latin ones do from 1 to 3 and are raised and lowered by h_{ij}. The normal vector can be written as

$$n_\mu = (-N, 0, 0, 0)\,. \tag{27}$$

Note that h_{ij} is the purely spatial part of $h_{\mu\nu}$ and is also the pull-back of $g_{\mu\nu}$ onto the hypersurface.

The Einstein-Hilbert action for this parametrization of the metric is given by the following gravitational Lagrangian:

$$\mathcal{L}_G = \sqrt{-g}R = \frac{1}{2\kappa}N\sqrt{h}\left({}^{(3)}R + K_{ij}K^{ij} - K^2\right)\,, \tag{28}$$

where K_{ij} is the extrinsic curvature of the 3-hypersurface Σ and is given by the Lie derivative along the normal vector n

$$K_{ij} = \frac{1}{2}\pounds_n h_{ij} = \frac{1}{2N}\left(\partial_0 h_{ij} - \nabla_i N_j - \nabla_j N_i\right) , \tag{29}$$

where ∇ denotes the covariant derivative on Σ with respect to the 3-metric h_{ij}. Its trace and traceless part are:

$$\begin{aligned} K &= h^{ij}K_{ij} = \frac{1}{N}\left(\partial_0 \ln\sqrt{h} - \nabla_i N^i\right) \\ \bar{K}_{ij} &= K_{ij} - \frac{1}{3}K h_{ij} . \end{aligned} \tag{30}$$

Unlike the intrinsic curvature, described by the Riemann tensor $R^{\rho}_{\mu\nu\lambda}$ and its contractions, the extrinsic curvature is a quantity that depends on the embedding of a surface in a larger manifold.

We are now ready to introduce the Hamiltonian formulation of the theory. Note that the only quantity whose time derivative appears in the gravitational Lagrangian is the 3-spatial metric h_{ij} and, thus, it is the only dynamical or propagating d.o.f. Correspondingly, one defines its conjugate momentum as:

$$\Pi^{ij} = \frac{\partial \mathcal{L}_G}{\partial \dot{h}_{ij}} = \sqrt{h}\left(K^{ij} - K h^{ij}\right) . \tag{31}$$

With this, the gravitational Lagrangian can be rewritten as

$$\begin{aligned} \mathcal{L}_G &= N\sqrt{h}^{(3)}R - \frac{N}{\sqrt{h}}\left(\Pi_{ij}\Pi^{ij} - \frac{1}{2}\Pi^2\right) - 2\Pi^{ij}\nabla_i N_j \\ &= \Pi^{ij}\dot{h}_{ij} - N\mathcal{H} - N_i\mathcal{H}^i - 2\nabla_i\left(\Pi^{ij}N_j\right) , \end{aligned} \tag{32}$$

where $\Pi = h_{ij}\Pi^{ij}$ and we introduced the functions:

$$\begin{aligned} \mathcal{H} &= -\sqrt{h}^{(3)}R + \frac{1}{\sqrt{h}}\left(\Pi_{ij}\Pi^{ij} - \frac{1}{2}\Pi^2\right) \\ \mathcal{H}^i &= -2\nabla_j\left(h^{-1/2}\Pi^{ij}\right) . \end{aligned} \tag{33}$$

Since N and N_i are not dynamical variables, they merely enter the gravitational Lagrangian as Lagrange multipliers. One defines the gravitational Hamiltonian as:

$$\begin{aligned} \mathcal{H}_G &= \Pi^{ij}\dot{h}_{ij} - \mathcal{L}_G \\ &= N\mathcal{H} + N_i\mathcal{H}^i + \nabla_i\left(\Pi^{ij}N_j\right) , \end{aligned} \tag{34}$$

with the Hamiltonian and momentum constraints:

$$\begin{aligned} \frac{\delta\mathcal{H}_G}{\delta N} &= \mathcal{H} = 0 \\ \frac{\delta\mathcal{H}_G}{\delta N_i} &= \mathcal{H}^i = 0 . \end{aligned} \tag{35}$$

The Hamiltonian evolution equations are obtained from the variations of the action with respect to the metric and conjugate momentum

$$\delta\mathcal{S} = \int d^4x \left[\left(-\dot{\Pi}^{ij} - \frac{\delta\mathcal{H}_G}{\delta h_{ij}} - \kappa N\sqrt{h}\tilde{f}^{ij} + 2\kappa\frac{\partial\mathcal{L}_m}{\partial h_{ij}} \right)\delta h_{ij} + \left(\dot{h}_{ij} - \frac{\delta\mathcal{H}_G}{\delta\Pi^{ij}} \right)\delta\Pi^{ij} \right], \tag{36}$$

where the variational constraint

$$\frac{\partial\mathcal{L}_m}{\partial s}\delta s = -\frac{1}{2}N\sqrt{h}\tilde{f}^{ij}\delta h_{ij} \tag{37}$$

was already implemented. Note that the minus sign arises from

$$\frac{\partial h_{ij}}{\partial h^{kl}} = -\frac{1}{2}\left(h_{ik}h_{jl} + h_{il}h_{jk}\right) \tag{38}$$

and that $\tilde{f}_{ij}$ is the pull-back of $f_{\mu\nu}$ onto the hypersurfaces. By setting the variation to 0 we obtain the two Hamilton equations

$$\begin{aligned} \frac{\delta\mathcal{H}_G}{\delta h_{ij}} &= -\dot{\Pi}^{ij} - \kappa N\sqrt{h}f^{ij} + 2\kappa\frac{\partial\mathcal{L}_m}{\partial h_{ij}} \\ \frac{\delta\mathcal{H}_G}{\delta\Pi^{ij}} &= \dot{h}_{ij}\,, \end{aligned} \tag{39}$$

which completes the derivation of the entropic modification to the gravitational equations of motion in the Hamiltonian formulation.

The tensor $\tilde{f}_{ij}$ can be obtained from the phenomenological constraint, which can now be stated rigorously. In the ADM formalism, a well-defined notion of time evolution is given by the flow along the normal vector n^μ. Hence, the time derivative is generalized to the Lie derivative along n^μ. Then the phenomenological constraint is given by

$$\frac{\partial\mathcal{L}}{\partial s}\pounds_n s = \frac{1}{2}N\sqrt{h}\tilde{f}_{ij}\pounds_n h^{ij}\,, \tag{40}$$

where growth in entropy by local processes is related to total entropy density growth by

$$\pounds_n s = \pounds_n s^{tot} - \nabla_i j_s^i\,. \tag{41}$$

Entropy produced locally is expected to grow over time, i.e. with the flow along the hypersurfaces, in compliance with the second law of thermodynamics. This completes the variational formulation of entropic forces in General Relativity.

4.3. *The Raychauduri equation*

Let us explore an immediate dynamical consequence of the inclusion of entropic forces, namely its effect on a congruence of worldlines with tangent vector n^μ. The congruence is then characterized by the tensor

$$\Theta_{\mu\nu} = D_\nu n_\mu = \frac{1}{3}\Theta h_{\mu\nu} + \sigma_{\mu\nu} + \omega_{\mu\nu} - a_\mu n_\nu\,, \tag{42}$$

where θ is the expansion rate of the congruence, $\sigma_{\mu\nu}$ is its shear or symmetric traceless part and $\omega_{\mu\nu}$ is its vorticity or antisymmetric part. If the worldline is not a geodesic, then the congruence suffers an acceleration given by:

$$a_\mu = n^\nu D_\nu n_\mu \,. \tag{43}$$

One can compute the Lie derivative of the expansion of the congruence along its tangent vector and find the Raychauduri equation[5]:

$$\pounds_n \Theta = -\frac{1}{3}\Theta^2 - \sigma_{\mu\nu}\sigma^{\mu\nu} + \omega_{\mu\nu}\omega^{\mu\nu} - R_{\mu\nu}n^\mu n^\nu + D_\mu a^\mu \,. \tag{44}$$

Let us perform the standard analysis of the sign of this equation. It is clear that $\sigma_{\mu\nu}\sigma^{\mu\nu} > 0$ and $\Theta^2 > 0$. On the other hand, if the congruence is chosen to be orthogonal to the spatial hypersurfaces, as we have been considering, then the vorticity vanishes $\omega_{\mu\nu} = 0$. Lastly, it is left to consider the term $R_{\mu\nu}n^\nu n^\nu$, which we can rewrite with the help of the field equations:

$$R_{\mu\nu}n^\mu n^\nu = 8\pi G\left(T_{\mu\nu}n^\mu n^\nu + \frac{1}{2}T - f_{\mu\nu}n^\mu n^\nu - \frac{1}{2}f\right) . \tag{45}$$

If the strong energy condition is satisfied, then

$$T_{\mu\nu}n^\mu n^\nu \geq -\frac{1}{2}T \tag{46}$$

and, in the absence of intrinsic acceleration, $a_\mu = 0$, we can establish the bound:

$$\pounds_n \Theta + \frac{1}{3}\Theta^2 \leq 8\pi G\left(f_{\mu\nu}n^\mu n^\nu + \frac{1}{2}f\right) . \tag{47}$$

For a vanishing entropic force $f_{\mu\nu} = 0$, this means that an expanding congruence cannot indefinitely sustain its divergence and will eventually recollapse. On the contrary, a positive and sufficiently large entropic contribution can avoid such recollapse. This may become relevant for an expanding universe, but also to generic gravitational collapse and the singularity theorems.[6–8]

5. Sources of entropy

A main ingredient in the variational formulation of non-equilibrium thermodynamics in General Relativity is the inclusion of entropy at the Lagrangian level and the derivation of a notion of temperature from it. In this section we present two relevant examples: hydrodynamical matter, which is a prototypical case, and horizons.

5.1. *Entropy from hydrodynamical matter*

A classical fluid is the simplest matter content that can be considered in General Relativity and it is of particular relevance in Cosmology. Without paying attention to microphysical details, the Lagrangian of hydrodynamical matter can be written as

$$\mathcal{L}_m = -\sqrt{-g}\rho(g_{\mu\nu}, s) \,, \tag{48}$$

the temperature being then simply given by

$$T = -\frac{1}{\sqrt{-g}}\frac{\partial \mathcal{L}_m}{\partial s} = \frac{\partial \rho}{\partial s}\,. \tag{49}$$

This is analogous to the case of a mechanical system, where the Lagrangian is generically given by a kinetic and a potential energy

$$L = E_K(q, \dot{q}) - U(q, S) \tag{50}$$

and temperature can be defined as

$$T = \frac{\partial L}{\partial S} = -\frac{\partial U}{\partial S}\,. \tag{51}$$

Thus, the energy density of a fluid can be readily interpreted as the thermodynamic internal energy.

5.2. *Entropy from gravity and horizons*

Gravity itself has thermodynamical features. It is known since the discovery of the laws of black hole mechanics and their promotion to laws of black hole thermodynamics, allowed by the introduction of Bekenstein entropy and Hawking temperature. We propose to include the entropy associated with a horizon $\mathcal{H}$ by extending the Einstein-Hilbert actions with surface terms of Gibbons-Hawking-York (GHY) type

$$S_{GHY} = \frac{1}{8\pi G}\int_{\mathcal{H}} d^3y\sqrt{h}K\,, \tag{52}$$

where h is the determinant of the induced 3-metric on the horizon and K is the trace of its extrinsic curvature. Definitions are analogous to the ones used in the ADM formalism, but we stress that here the hypersurface of interest is a horizon and not constant-time hypersurfaces.

From the thermodynamic point of view, the GHY term contributes to the internal energy of the system. Hence, it can be rewritten as a function of the temperature and entropy of the horizon

$$S_{GHY} = -\int dt\, N(t)\, TS\,. \tag{53}$$

We have kept the lapse function $N(t)$, to indicate that the variation of the total action with respect to it will generate a Hamiltonian constraint with an entropy term together with the ordinary matter/energy terms. In order to illustrate this, let us now compute the GHY for the event horizon of a Schwarzschild black hole.

The space-time of a Schwarzschild black hole of mass M is described by the static metric

$$ds^2 = -\left(1 - \frac{2GM}{r}\right)dt^2 + \left(1 - \frac{2GM}{r}\right)^{-1} dr^2 + r^2 d\Omega_2^2\,. \tag{54}$$

We foliate it with spherical hypersurfaces, i.e. their intersection with constant time hypersurfaces is a 2-sphere around the origin of coordinates. The corresponding normal vector is

$$n = -\sqrt{1 - \frac{2GM}{r}}\partial_r \,. \tag{55}$$

With this, the trace of the extrinsic curvature for such a sphere scaled by the metric determinant is

$$\sqrt{h}K = (3GM - 2r)\sin\theta \,. \tag{56}$$

Integrating over the angular coordinates and setting the 2-sphere at the event horizon, i.e. $r = 2GM$, and restoring for a moment $\hbar$ and c, the GHY becomes

$$S_{GHY} = -\frac{1}{2}\int dt Mc^2 = -\int dt T_{BH} S_{BH} \,, \tag{57}$$

where T_{BH} is the Hawking temperature and S_{BH} is the Bekenstein entropy of the Schwarzschild black hole:

$$T_{BH} = \frac{\hbar c^3}{8\pi GM} \,, \quad S_{BH} = \frac{Ac^3}{4G\hbar} = \frac{4\pi GM^2}{\hbar c} \,. \tag{58}$$

This favors the interpretation of the GHY term of a horizon as a contribution to the internal energy in the thermodynamic sense.

6. Irreversible cosmology

We derived in section 4 a powerful, generic tool to describe non-equilibrium thermodynamic effects in gravity. In the Hamiltonian formulation of General Relativity it is possible to obtain the modified equations of motion and rigorously impose the time-evolution of the entropy as dictated by the second law of thermodynamics.

In section 2 we motivated the study of these phenomena by our interest in understanding the dynamics of irreversible cosmology and justifying its equations of motion. One can obtain them using the Hamilton equations.[1] Here, however, we present a slightly different approach. Due to the symmetries of the FLRW universe, homogeneity and isotropy, there is a preferred slicing and time evolution is well-defined even at the Lagrangian level. Therefore, we can obtain the equations of non-equilibrium cosmology by imposing these symmetries, i.e. making an ansatz for the metric

$$ds^2 = -N(t)^2 dt^2 + a(t)^2\left(\frac{dr^2}{1-kr^2} + r^2 d\Omega_2^2\right) \,, \tag{59}$$

where the lapse function $N(t)$ accounts for the freedom in choosing the time coordinate, i.e. the symmetry under $t \to f(t)$. The Ricci scalar associated to this metric is

$$R = \frac{6}{a^2}\left(\frac{a\ddot{a}}{N^2} + \frac{\dot{a}^2}{N^2} + k\right) \,. \tag{60}$$

Let us stress that this result is imposed by symmetry, not dynamics. Without loss of generality, we can restrict the action to a region of comoving volume 1 and write it as

$$S = \int dtL = \frac{3}{8\pi G}\int dtNa\left(\frac{a\ddot{a}}{N^2} + \frac{\dot{a}^2}{N^2} + k\right) + \int dtNa^3\mathcal{L}_m(N,a,S)\,. \tag{61}$$

Effectively, this action describes a mechanical system, for the scale factor $a(t)$ has no spatial dependency and we got rid of the integral over spatial coordinates. The first term can be rewritten using integration by parts in order to get only terms with at most the first derivative of a

$$S = \frac{3}{8\pi G}\int dtNa\left(-\frac{\dot{a}^2}{N^2} + k\right) + \int dtNa^3\mathcal{L}_m(N,a,S)\,. \tag{62}$$

The variational constraint is here given by the usual expression for a mechanical system

$$\frac{\partial L}{\partial S}\delta S = f\delta a\,. \tag{63}$$

The Hamiltonian of the system is

$$H = \dot{a}\frac{\partial L}{\partial \dot{a}} - L = \frac{3}{8\pi G}\left(-\frac{\dot{a}^2 a}{N} - kaN\right) - Na^3\mathcal{L}_m\,. \tag{64}$$

For an arbitrary lapse function $N(t)$ this can be rewritten as

$$H = N^2a^3\frac{\partial \mathcal{L}_m}{\partial N}\,, \tag{65}$$

which gives the Hamiltonian constraint of the system. On the other hand, the dynamics is obtained from the equation of motion for a

$$\frac{\delta L}{\delta a} = -f\,. \tag{66}$$

Let us now consider the matter Lagrangian to be that of a perfect fluid, i.e.

$$\mathcal{L}_m = -\rho(a,S)\,. \tag{67}$$

Its stress-energy tensor is given in terms of the density ρ and pressure p by

$$T^{\mu\nu} = (\rho + p)u^{\mu\nu} + pg^{\mu\nu} \tag{68}$$

and $u^m u = (N,0,0,0)$ is the unit vector tangent to a comoving observer. Pressure is then obtained as

$$p = \frac{a^2}{3}T^{ij}\delta_{ij} = -\frac{1}{2a^4}\frac{\partial a^3\rho}{\partial a}\,. \tag{69}$$

Using the expressions for ρ and p and rearranging the terms in the Hamiltonian constraint and the equation of motion for $a(t)$ we arrive at the modified Friedmann

equations

$$\left(\frac{\dot{a}}{a}\right)^2 + \frac{k}{a^2} = \frac{8\pi G}{3}\rho$$
$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}\left(\rho + 3p + \frac{f}{a^2}\right). \tag{70}$$

The expression for the entropic force F is obtained from the phenomenological constraint

$$\left(\frac{\partial L}{\partial S}\right)\dot{S} = -T\dot{S} = f\dot{a} < 0\,, \tag{71}$$

which determines the sign $f < 0$ whenever dealing with an expanding universe $\dot{a} > 0$. We express finally the second Friedmann equation as

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}\left(\rho + 3p - \frac{T\dot{S}}{a^2\dot{a}}\right). \tag{72}$$

From this equation we can conclude that entropic forces generally drive an acceleration of the expansion of the universe. Whether this can dominate the dynamics of the scale factor will depend on the particular thermodynamic process. Most of the expansion history of the universe takes place in equilibrium. Out of equilibrium processes, such as (p)reheating, phase transitions or gravitational collapse are short-lived. Should their associated entropic force dominate, we still only expect a short period of accelerated expansion.

Symmetry under time inversion is broken by the same arguments presented in section 3. Hence, the Friedmann equations together with the phenomenological constraint, i.e. the second law of thermodynamics, describe cosmic irreversible dynamics.

We currently live in a universe that is undergoing an accelerated expansion. The possibility of explaining this by means of an entropic force is fascinating. In the next section we review our proposal to achieve this by means of the sustained growth of the entropy associated to a causal horizon.

7. Cosmic acceleration as an entropic force

The growth of entropy associated to the cosmic horizon may be responsible for the current observed accelerated expansion of the universe. The choice of horizon is in principle not unique. The only available one which can be defined locally in time is the cosmic apparent horizon, but it fails to significantly affect the expansion.[2]

There is another option in the framework of eternal inflation, according to which we live in an open universe nucleated by quantum tunneling from a false to a true vacuum. After nucleation the bubble universe undergoes its own inflationary era, which renders the local metric almost flat. However, due to the presence of the

bubble wall, the true causal horizon is located at a finite distance. It induces an entropic fluid via GHY term with energy density

$$\rho_H\, a^2 = \frac{T_H S_H}{a} = \frac{x_0}{2G}\,\sinh(2a_0 H_0 \eta)\,, \quad x_0 \equiv \frac{1-\Omega_0}{\Omega_0} = e^{-2N}\left(\frac{T_{\rm rh}}{T_{\rm eq}}\right)^2 (1+z_{\rm eq})\,, \tag{73}$$

where η is the conformal time, Ω_0 is the density parameter, $T_{\rm rh}$ is the reheating temperature, $T_{\rm eq}$ and $z_{\rm eq}$ are, respectively, the temperature and redshift at matter-radiation equality. Introducing $\tau = a_0 H_0 \eta$ one can write the second Friedmann equation in conformal time as

$$\left(\frac{a'}{a_0}\right)^2 = \Omega_M \left(\frac{a}{a_0}\right) + \Omega_K \left(\frac{a}{a_0}\right)^2 + \frac{4\pi}{3}\Omega_K \left(\frac{a}{a_0}\right)^2 \sinh(2\tau)\,, \tag{74}$$

where Ω_M is the matter density paremeter and Ω_K is the curvature parameter. We call this the general relatvistic entropic acceleration (GREA) theory.

By solving this equation with cosmological parameters consistent with the CMB values (Planck 2018: $\Omega_M \simeq 0.31$, $\Omega_K \simeq 0.0006$, $h_0 \simeq 0.68$) and initial conditions deep in the matter era, $a_i(\tau) = a_0\,\Omega_M \tau^2/4$, we find generic accelerating behaviour beyond the scale factor $a \sim 1/2$ (*i.e.* $z \sim 1$), see Fig. 1. This is consistent with the current observed acceleration of the universe and may even resolve the Hubble tension,[9] providing a way to obtain from the CMB a present value of H_0 that is consistent with late-universe observations, see Fig. 2.

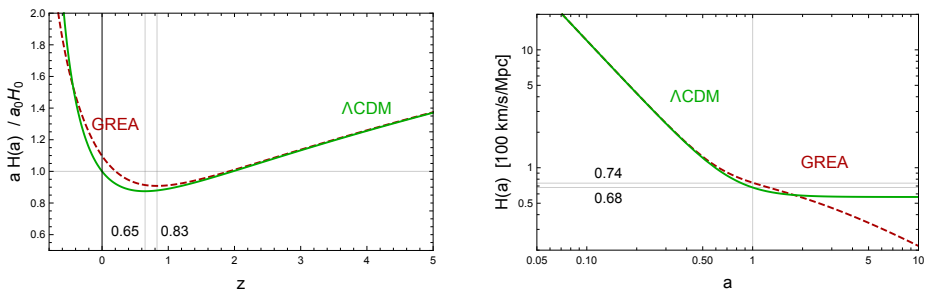

Fig. 1. The left plot shows the evolution of the inverse comoving horizon with the coasting point for each model, at $z \simeq 0.65$ for ΛCDM (in green) and $z \simeq 0.83$ for GREA (in red). The right plot shows the evolution of the rate of expansion. For GREA the present rate of expansion is approximately 74 km/s/Mpc, compared with the value of 68 km/s/Mpc predicted by ΛCDM, in agreement with the asymptotic value at the CMB.

8. Conclusions

The consistent inclusion of non-equilibrium phenomena in General Relativity leads to the modification of the Einstein field equations, as can be checked both in the Lagrangian and Hamiltonian formulations of the theory. This breaks symmetry under time inversion and allows for the introduction of an arrow of time.

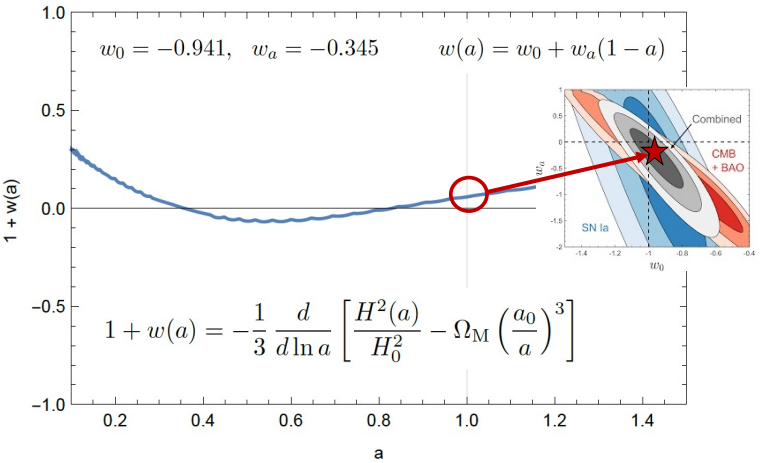

Fig. 2. The effective equation of state of the non-matter component of the GREA theory, as a function of thee sale factor. Note that the predicted effective PCL parameters (w_o, w_a) agree remarkably well with present observations.

In cosmology this implies the appearance of a term of entropic origin in the second Friedmann equation, which tends to accelerate the expansion of the universe as a result of the increase in entropy. Some physical processes such as (p)reheating, phase transitions or gravitational collapse may lead to phenomenologically relevant applications of this formalism. We look forward to further developments.

The sustained entropy growth associated to a causal horizon in the open universe scenario leads to an acceleration consistent with current observations and it may even solve the H_0 tension. Further research will be required to establish the full viability of the GREA theory.

The Borexino has recently reported the first experimental evidence of neutrinos from the CNO cycle. Since this process accounts only for about 1% of the total energy production in the Sun, the associated neutrino flux is extremely low as compared with the one from the pp-chain, the dominant process of hydrogen burning. This experimental evidence of the CNO neutrinos was obtained using the highly radio-pure liquid scintillator of Borexino. Improvements in the thermal stabilization of the detector over the last five years enabled us to exploit a method to constrain the rate of ^{210}Bi background. Since the CNO cycle is dominant in massive stars, this result gives the first experimental proof of the primary mechanism for stellar conversion of hydrogen into helium in the Universe.

Keywords: Solar neutrinos, CNO cycle, Liquid organic scintillators, solar models

Introduction

Stars are fuelled by nuclear fusion of light elements with a release of an enormous amount of energy. In particular the *pp* chain and the CNO cycle, active also in the Sun, produces a rich spectrum of electron-flavour neutrinos detectable on the Earth.[1,2] Those two mechanisms basically converts four hydrogen nuclei into a helium nucleus: the first using direct process throughout a big variety of branches, while the second using a closed loop starting and ending with ^{12}C acting as catalyst.

The contribution of these two mechanisms in the energy production is related to mass, and then to the core temperature, of the stars and to abundance of elements heavier than helium in the core (in jargon, "metallicity").

For stars heavier than 1.3 $M_{\odot}$ the CNO cycle is the dominant process of hydrogen fusion,[3] while in the Sun, with a core temperature of about 15×10^6K, the CNO accounts only for 1% of the total luminosity, with a large uncertainty related to poorly known metallicity.[4] The Borexino experiment, starting from mid-2007, has published a comprehensive study of the neutrino from the *pp* chain [5] and recently has reported the first direct detection of the CNO.[26] The CNO quest, started by Borexino, could in principle create a situation that makes it possible the solution of the long standing "solar metallicity problem" ,[2] i.e. the disagreement between the metallicity predicted by solar models using updated (low) metal abundances from spectroscopy (SSM-LZ) [6] and the one obtained from the helioseismology, which foresees a higher metal content (SSM-HZ).

In Sec. 1 a description of the detector and the main physics results of Borexino are reported. At the end of the section the hardware improvement for the CNO detection in Phase-III is also reported. In Sec. 2 the main strategy for the CNO detection is described and in Sec. 3 the independent constraint of the ^{210}Bi (the main background for the CNO neutrino interaction rate) is largely detailed. Finally, in Sec. 4 the spectral analysis for the extraction of the CNO rate in Borexino is presented.

1. The Borexino detector

Borexino experiment is the only experiment capable to detect solar neutrinos with a threshold as low as about 150 keV and to reconstruct the position and the energy of each event in real-time.

Borexino is located in the Hall C of Laboratori Nazionali Gran Sasso (INFN).[12] The detector is made of concentric shells with increasing radiopurity (see e.g. Ref.[13]): the innermost core, enclosed in a 125 μm thick ultra-pure nylon vessel of radius 4.25 m, is made of 300 tons of liquid scintillator (1,2,4-Trimethylbenzene with 1.5 g/l of PPO wavelength shifter). The active core is contained by a stainless steel sphere filled up with $\sim$ 1000 of buffer liquid (1,2,4-Trimethylbenzene with DMP quencher), whose internal surface is instrumented with more than 2000 PMTs for detecting the scintillation light. Finally, the SSS is located inside a 2000 ton water Cherenkov detector, equipped with about 200 PMTs. In Fig. 1 all the parts described above are represented in a graphical scheme. Thanks to an intense calibration campaign carried out in 2010, the Borexino detector is able to reconstruct the event position with an accuracy of $\sim$ 10 (at 1 MeV) and with energy resolution of about $\sigma(E)/E = 5\%/\sqrt{(E/[MeV])}$.

The Borexino data-set is traditionally divided in three Phases, determined by the hardware milestones: Phase-I, from mid-2007 to beginning of 2010, ended with the calibration campaign, in which the first measurement of the ^{7}Be solar neutrino interaction rate[8–10] was performed; Phase-II, from the-beginning of 2012 to mid-2016, started after an intense purification campaign, based on water extraction, with unprecedented suppression of the radioactive contaminants, in which the first

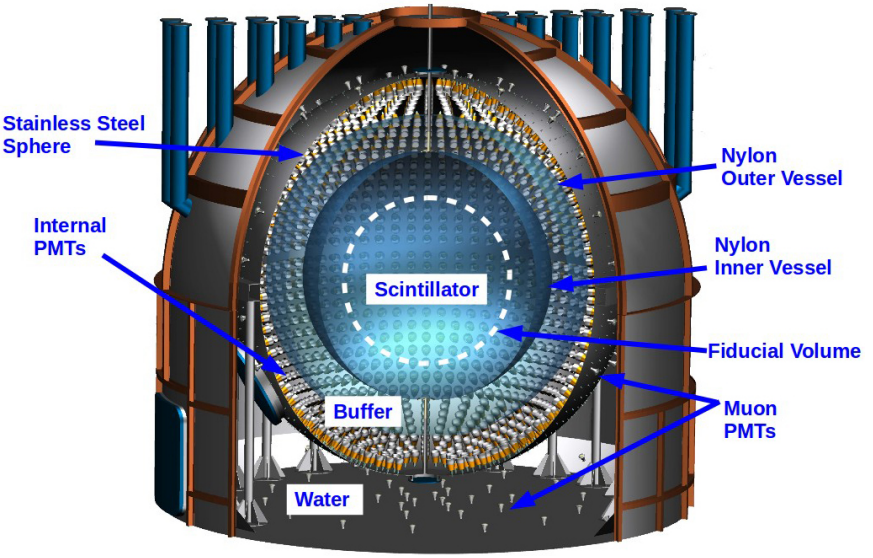

Fig. 1. Scheme of the Borexino detector.

evidence of the *pep* neutrinos[15] and a 10% measurement of the *pp* neutrinos[16] were published, later updated in the solar neutrino comprehensive analysis;[17–19] Phase-III, from mid-2016 to 2021 (still in progress), after the thermal insulation program, in which the first detection of the CNO neutrinos[11] discussed here was performed. Table 1 summarizes the most important results concerning solar neutrinos interaction rates measured by Borexino. Thanks to its unprecedented radio-purity, Borexino has also set a lot of limits on rare processes (see e.g.,[20–24] and performed other neutrino physics studies, as e.g. geo-neutrino detection (for review, see e.g.[25])

The CNO detection has required, as it is explained in Sec. 2, an independent constraint of the ^{210}Bi contaminant from the ^{210}Po through the secular equilibrium starting from the out-of-equilibrium parent ^{210}Pb, present in the liquid scintillator

after the purification carried out at the end of Phase-I. That constraint required the contaminants, and then the whole scintillator, to be stable against the the convective motions activated by the seasonal variation of the temperature in the experimental hall hosting the detector. In mid-2014 Borexino was equipped with a detailed temperature mapping. In mid-2015 the detector was covered with a thermal insulation and, from the beginning of 2016, a series of active temperature control system were installed around the water tank and at the end on the experimental hall. See for details Ref.[26].

The thermal insulation program was aimed at the realization of a vertical temperature gradient from the cold floor, made of constant temperature rock with a huge thermal capacitance, and the detector top, warmed up by the air flushed into the underground laboratory coming from the external environment out of the Gran Sasso mountain. This challenging enterprise was successful and the strongest convective motions, mixing the liquid scintillator and then the contaminants from the outermost regions into the center, were actually stopped and the conditions for the ^{210}Bi-^{210}Po link, described in Sec. 3 were finally met. Figure 2 shows the ^{210}Po contaminant evolution during the thermal insulation program in 59 small cubes enumerated from the bottom to the top inside a radius of 3 m from the center of the Inner Vessel. The red superimposed curve represents the average temperature in the same region. The dashed vertical lines show the most important milestones of the temperature stabilisation program: 1. Beginning of insulation; 2. Turning off of the water recirculation system in the Water Tank; 3. First operation of the active temperature control system; 4. Change of the active control set point; 5. Installation and commissioning of the Hall C temperature control system. The white vertical bands represent different technical DAQ breaks. The ^{210}Po shown in the figure is a

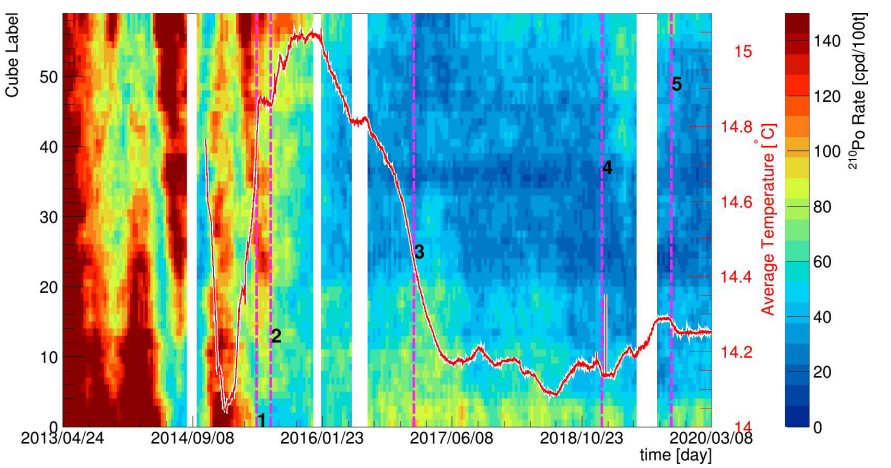

Fig. 2. Evolution of the ^{210}Po contamination during the thermal insulation program.

tracker of the convective motions, that are drastically damped as a consequence of the insulation program.

2. CNO detection strategy

Neutrinos emitted in the CNO cycle, see Fig. 3, have a continuous spectrum with a maximum energy of 1.74 MeV (see Fig. 4, left). In the Sun, the flux of CNO neutrinos is two orders of magnitude smaller than the one due to proton-proton neutrinos: this makes the expected rate in Borexino very low, of the order of few counts per day. Besides the low rate, the main difficulty in detecting CNO neutrinos with Borexino is the presence of two radioactive backgrounds which produce signal in approximately the same energy region: ^{11}C and ^{210}Bi. Furthermore, also solar neutrinos from the *pep* reaction are a significant background for the CNO analysis.

Fig. 4 (right) shows a MonteCarlo simulation of the energy spectrum of electrons scattered by neutrinos from the CNO cycle (red line) in comparison with the signal induced by the radioactive decay of ^{11}C (purple line) and ^{210}Bi (green line). The blue line is the *pep* signal. The relative proportion of the four contributions is approximately the one expected in reality. From this plot the difficulty of extracting the CNO signal from the background becomes evident: it is like looking for a needle in a haystack!

The cosmogenic ^{11}C is an isotope produced by residual muons crossing the scintillator which decays emitting a positron with a lifetime of approximately 30 minutes. It can be very effectively tagged by the Three Fold Coincidence (TFC) method described in,[27] which looks for the triple coincidence of the parent muon, the cosmogenic neutron produced together with ^{11}C and the positron emitted in the ^{11}C decay. This tagging method allows us to divide the data-set in two complementary parts, one rich and the other depleted in ^{11}C which are then simultaneously fitted in the multivariate analysis described in Section 4. This is a powerful tool to help the fit isolate the ^{11}C signal contribution, breaking the correlation with the CNO neutrino signal.

Separating the CNO signal from the ^{210}Bi and *pep* one is more tricky since their spectral shapes are quite similar and the multivariate fit has trouble in distinguishing between them, if no additional external contraints are imposed.

For what concerns *pep* neutrinos, we exploited the external and independent information coming from the available solar neutrino data, solar luminosity and the most recent oscillation parameters to put a constraint to their rate in the fit with a 1.4% uncertainty.

The remaining obstacle to the CNO neutrino detection is the contamination from ^{210}Bi. This isotope belongs to the ^{210}Pb chain, which in turn is the last segment of the ^{238}U chain. In Borexino, we found the ^{210}Pb chain to be out of equilibrium with respect to the ^{238}U chain and with a significantly higher activity, of the order of tens of counts per day per 100 tons of scintillator.

The ^{210}Pb chain is composed of three isotopes: the long lived ^{210}Pb father of the chain ($\tau \sim 32\,\mathrm{y}$), ^{210}Bi which has a relatively short lifetime ($\tau \sim 7.23\,\mathrm{d}$) and ^{210}Po which decays into ^{206}Pb (stable) emitting an alpha particle ($\tau \sim 199.1\,\mathrm{d}$). If secular equilibrium holds, the activities of ^{210}Bi and ^{210}Po are the same (apart for negligible corrections due to the finite ^{210}Pb lifetime). Measuring the ^{210}Po rate is in principle straightforward since an alpha peak is clearly separable from the continuous beta-like background underneath. Furthermore, alpha/beta discrimination techniques provide a powerful additional tool to isolate the ^{210}Po events.

Based on these premises, our strategy for the CNO detection relies on the ^{210}Bi-^{210}Po link to determine independently the ^{210}Bi content from ^{210}Po and constrain it in the multivariate fit. The next Section will describe in details the difficulties we encountered to apply this technique and how we were able of overcoming them.

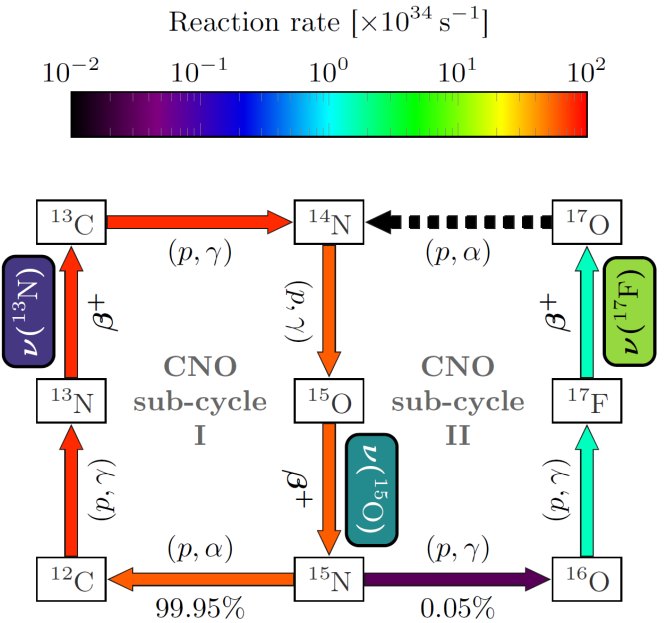

Fig. 3. Neutrinos in CNO cycle.

3. The ^{210}Bi–^{210}Po link

In order to exploit the ^{210}Bi–^{210}Po link to obtain an external constraint on the ^{210}Bi rate, we carefully studied the evolution in time and the spatial distribution

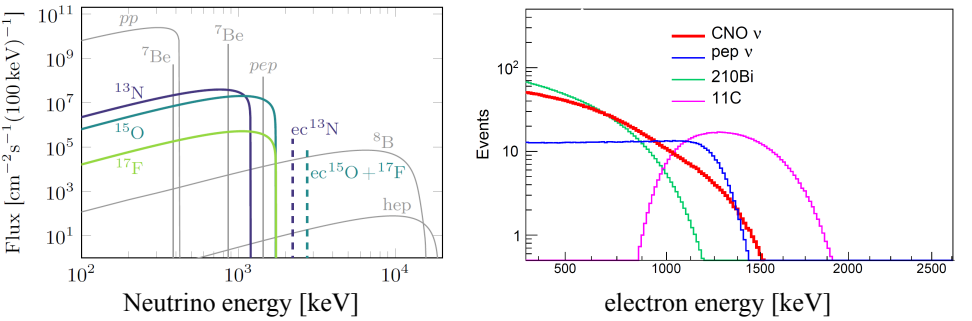

Fig. 4. (Left): Energy spectrum of neutrinos emitted in the CNO cycle (colored lines); (right): energy spectrum in Borexino for events of CNO (red), *pep* (blue), $^{@10}$Bi (geen) and ^{11}C (purple) obtained from MonteCarlo simulations.

of the polonium contamination in the detector during the Borexino data-taking. We soon realized that the ^{210}Po present in the fiducial region used in the analysis (an innermost subset of the scintillator volume) is actually the sum of two contributions: ^{210}Po from the intrinsic ^{210}Pb scintillator contamination (in equilibrium with ^{210}Bi); ^{210}Po from the nylon vessel containing the scintillator. This last contribution was found to be changing in time and highly correlated with variations of the temperature gradient in the detector, which induce convective motions strong enough to bring ^{210}Po from the vessel surface into the fiducial region. In order to reduce these convective motions, we thermally insulated the detector, as discussed in Section 1.

After the completion of the thermal insulation (2016), the temperature of the detector has become very stable and the convective currents inside the scintillator have significantly reduced. This has favoured the formation of an innermost region of the detector, called Low Polonium Field (LPoF), where the contribution to the ^{210}Po rate coming from the vessel is very small. A pictorial view of this region is shown in Fig. 5. This region exhibits an effective migration profile with a minimum in the ^{210}Po rate above the detector equator (dark blue region). The qualitative shape and approximate position of the LPoF is reproduced by fluid dynamical numerical simulations reported in .[28]

Assuming azimuthal symmetry around the detector z-axis (which was confirmed by a 3D analysis), the ^{210}Po minimum activity is determined by fitting LPoF with a 2D paraboloidal function:

$$\frac{d^2R(^{210}\mathrm{Po})}{d(\rho^2)dz} = \left[R(^{210}\mathrm{Po}_{\mathrm{min}})\epsilon_{\mathrm{E}}\epsilon_{\mathrm{MLP}} + R_\beta\right] \times \\ \times \left(1 + \frac{\rho^2}{a^2} + \frac{(z-z_0)^2}{b^2}\right), \tag{1}$$

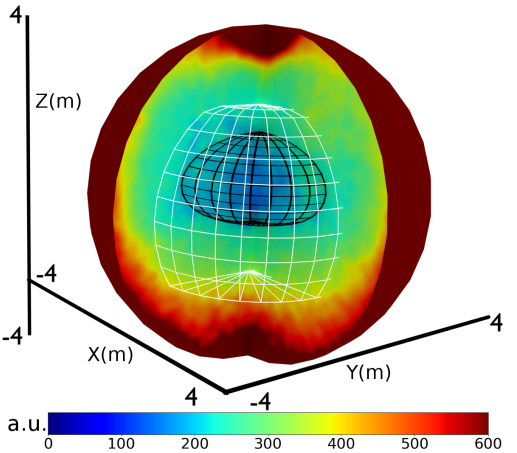

Fig. 5. Pictorial view of the ^{210}Po activity in the Borexino scintillator. The color scale goes from red (highest activity) to blue (lowest activity). The LPoF is the innermost blue region where the contribution of ^{210}Po from the vessel is the smallest (black grid). The white grid indicates the software defined fiducial volume used for the analysis to extract the CNO neutrinos.

Here, $\rho^2 = x^2 + y^2$, a and b are the paraboloid axes, z_0 is the position of the minimum along the z axis, ϵ_{E} and ϵ_{MLP} are the efficiencies of the cuts used to select ^{210}Po events, and R_β is the residual rate of β events after the selection. First, we performed the fit integrating data from 2 months (compatible results are obtained also changing the time bins) and we found that the minimum position slowly moves along the z direction by less than 20 cm per month. In order to perform a better estimation of the ^{210}Po minimum, we finally sum up all the time bins after aligning the 3D distributions with respect to z_0.

From this fit we extract the ^{210}Po minimum. This value might still have a small contribution from the vessel component, therefore this method provides only an upper limit for the ^{210}Bi rate. In order to cross-check the results, we performed the fit in different ways: adopting a standard likelihood fit with ROOT or a Bayesian tool called MultiNest. In addition to the 2D paraboloidal fit, we also performed the fit with a 3D ellipsoidal function or alternatively with a cubic spline. The differences in the results were included in the systematic error associated to the upper limit on ^{210}Bi. In the analysis to extract the CNO neutrino rate which will be described in Section 4, we would like to costraint the value of the ^{210}Bi to the upper limit found in the low polonium field region, extrapolating the results to the whole fiducial volume. In order to do so, we need to verify that ^{210}Bi is uniform in this volume during the time period over which the estimation is performed. For this reason, we studied the spatial distribution of β-like events in an energy window where the bismuth contribution is maximized. This distribution was found to be uniform within errors: we include in the systematic error budget a contribution of 0.78 cpd/100t accounting for residual non uniformity.

The final upper limit on ^{210}Bi including statistical and systematical errors added in quadrature is:

$$\text{Rate}(^{210}\text{Bi}) \leq (11.5 \pm 1.3)\,\text{cpd/100t}$$

4. Spectral analysis

We performed a multivariate analysis, simultaneously fitting the energy spectra in the window between 320 keV and 2640 keV and the radial distribution of the selected events, using the data collected from June 2016 to February 2020 (Borexino Phase-III). The fiducial volume (FV) is defined as r<2.8 m and z in the interval (-1.8 m, 2.2 m) (r and z being the reconstructed radial and vertical position, respectively). The total exposure corresponds to 1072 days · 71.3 tonnes. Free parameters in the fit procedure are: the interaction rate of CNO neutrinos, ^{85}Kr, ^{11}C, internal and external ^{40}K, external ^{208}Tl and ^{214}Bi, and ^{7}Be neutrinos. The pep neutrino rate is constrained to to 2.74 ± 0.04 cpd per 100 t by multiplying the standard likelihood with a symmetric Gaussian term. The upper limit to the ^{210}Bi rate is the one reported in previous section. It is enforced asymmetrically by multiplying the likelihood with a half-Gaussian term, i.e., leaving the ^{214}Bi rate unconstrained between 0 and 11.5 cpd per 100 t .

The reference spectral and radial distributions of each signal and background species are obtained with a complete GEANT4-based Monte Carlo simulation which models all physics processes occurring in the scintillator, including energy deposition, photon emission, propagation, and detection, generation and processing of the electronic signal. The simulation takes into account the evolution in time of the detector response and produces data that are reconstructed and selected following the same pipeline of real data. The results of the simultaneous multivariate fit of the energy spectra are given in Fig. 6, showing the TFC subtracted and TFC-tagged data. The fit is performed in the energy estimator N_{hits} (defined as the sum of all photons triggering a PMT, normalized to 2000 active PMTs) and the results are reported also in keV. The p-value of the fit is 0.3, demonstrating fair agreement between data and the underlying fit model. The fit clearly prefers a non-zero CNO neutrino rate as also shown in a detailed study of log-likelihood profile.

The best fit value of the CNO neutrinos interaction rate is 7.2 cpd per 100 t with an asymmetric confidence interval of -1.7 cpd per 100 t and +2.9 cpd per 100 t (68% C.L.), considering the statistical error only. The many details of the analysis, including the list and evaluation of the systematic effects are reported in.[26] Folding the systematic uncertainty over the log-likelihood profile we determine the final CNO interaction rate to be $7.2^{+3}_{-1.7}$ cpd per 100 t. The rate can be converted to of CNO neutrinos on Earth of $7.2^{+3.0}_{-2.0} \cdot 10^8$ cm^{-2} s^{-1} assuming MSW conversion in matter and a density of electrons in the scintillator of $(3.307 \pm 0.015) \cdot 10^{31}$ e$^-$per 100 t.

In order to evaluate the significance of our result in rejecting the no-CNO hypothesis, we performed a frequentist hypothesis test using the profile likelihood.

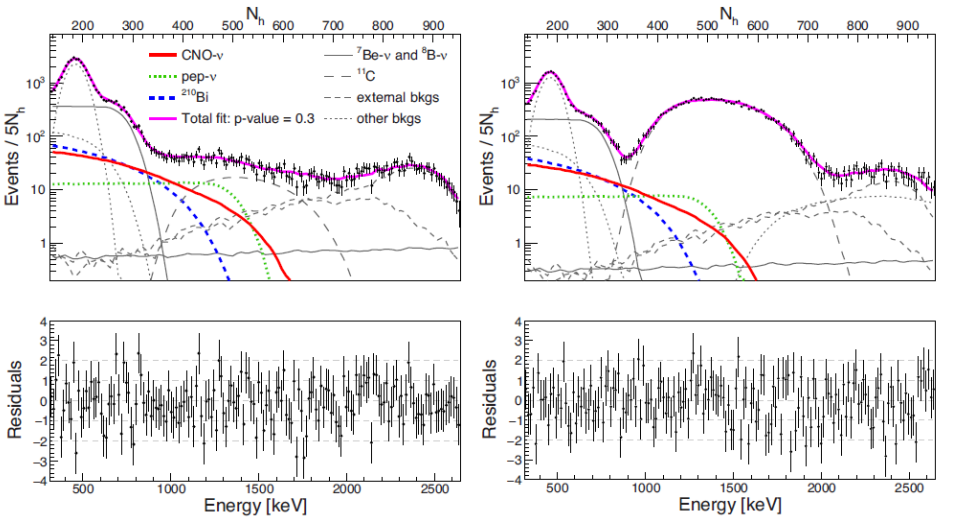

Fig. 6. Energy distributions from a multivariate fit of the Borexino data. Full multivariate fit results for the TFC-subtracted (left) and the TFC-tagged (right) energy spectra with corresponding residuals. In both graphs the magenta lines represent the resulting fit function, the red line is the CNO neutrino electron recoil spectrum, the green dotted line is the pep neutrino electron recoil spectrum, the dashed blue line is the ^{210} β spectrum, and in grey we report the remaining background (bkgs) contributions.

We defined a test statistics q, as the ratio between the maximum likelihood obtained by keeping the CNO rate fixed to zero or free. Figure 7 shows the q distribution obtained from 13.8 millions of pseudo-data sets simulated with deformed PDFs to include systematics effects, and no-CNO injected (q_0, grey curve). In the same plot, the theoretical q_0 distribution in case of no PDF deformation is shown (blue curve). The result on data obtained from the fit is the black line ($q_{data} = 30.05$). The results reported in Figure 7 allow us to reject the CNO = 0 hypothesis with a significance better than 5.0σ at 99.0% C.L. In the figure we also provide as reference the q distribution (red) obtained with one million pseudo-data sets including systematic deformations and injected CNO rate equal to 7.2 cpd per 100 t, i.e., our best fit value.

The results of the analysis based on the fit are also confirmed by that obtained with a nearly independent method (counting analysis), in which we simply count events in an optimized energy window (region of interest, ROI) and subtract the contributions due to known backgrounds. This method reveals a non zero CNO signal and its consistency with the multivariate analysis is remarkable. This method is simpler, albeit less powerful, with respect to the multivariate fit and is less prone to possible correlations between different species. However, while the multivariate analysis implicitly checks the validity of the background model by the goodness of the fit, the counting analysis relies completely on the assumption that there are no unknown backgrounds contributing to the ROI.

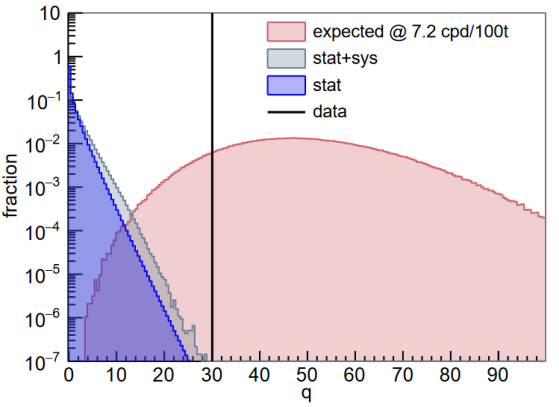

Fig. 7. Distribution of the test statistic q, as discussed in the text.

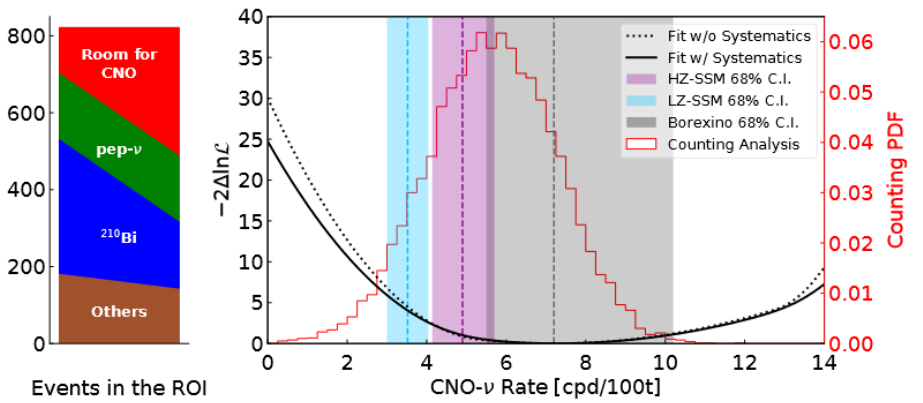

Fig. 8. Results of the CNO counting and spectral analyses. Left. Counting analysis bar chart. The height represents the number of events allowed by the data for CNO neutrinos and backgrounds in the ROI; on the left, the CNO signal is minimum and backgrounds are maximum, while on the right, CNO is maximum and backgrounds are minimum. It is clear from this figure that CNO cannot be zero. Right. CNO neutrinos rate negative log-likelihood profile directly from the multivariate fit (dashed black line) and after folding in the systematic uncertainties (black solid line). Histogram in red: CNO neutrino rate obtained from the counting analysis. Finally, the blue, violet, and grey vertical bands show 68% confidence intervals (C.I.) for the SSM-LZ (3.52±0.52 cpd per 100 t) and SSM-HZ (4.92±0.78 cpd per 100 t) predictions and the Borexino result (corresponding to black solid-line log-likelihood pro- file), respectively.

Conclusions

We have reported the results about the first direct detection of neutrinos from the CNO cycle in the Sun. This result proves the occurrence of the primary mechanism

for the stellar conversion of hydrogen into helium in the Universe. The observation of CNO neutrinos experimentally confirms the overall solar picture and shows that a direct measurement of the metallicity of the Sun's core is within reach of an improved, future measurement.

Borexino, a large volume detector for low energy neutrino spectroscopy, is currently taking data underground since 2007 at the Laboratori Nazionali del Gran Sasso, Italy. The main goal of the experiment is the real-time measurement of solar neutrinos, especially the low energy part of the spectrum. Neutrinos are detected via neutrino-electron scattering in an ultra-pure organic liquid scintillator. The light generated by the interaction is detected by 2212 phototubes. During many years of data taking the experiment provided several remarkable results as the first evidence of pep neutrinos, the real-time detection of the pp neutrinos, the evidence of CNO neutrinos, and the detection of antineutrinos from the Earth. All these results are based on an accurate modelling of the detector's response and performances. The contribution shows the design, the modelling of the detector's response, and the performances. Moreover it will be discussed how the performances and the response were studied by means of extensive calibration campaigns.

Keywords: Borexino; Neutrino; Solar neutrinos; calibrations

1. The Borexino detector

Borexino is a liquid-scintillator experiment at the hall C of the Laboratori Nazionali del Gran Sasso in Italy. Borexino looks for solar neutrinos scattering off electrons in its active volume. Given the tiny cross-section of neutrino interactions with electrons ($\sigma \sim 10^{-44}\, cm^2$ to $10^{-45}\, cm^2$ for the solar-neutrino energy range), the rates expected in Borexino are small, ranging from less than one to a few tens of counts per day per 100 tons for different solar-neutrino components. To cope with such a low event rate, Borexino has a large target mass (about 300 t) and it is housed deep underground, under 3,800 m water equivalent of dolomitic rock that suppresses the flux of cosmic radiation by a factor of approximately one million. The active core of the detector consists of about 300 t of pseudocumene (1,2,4-trimethylbenzene)

doped with 1.5 g per litre of PPO (2,5-diphenyloxazole) and contained in a spherical nylon inner vessel (radius R = 4.25 m). The scintillator is surrounded by a non-scintillating pseudocumene-based buffer liquid which serves as a passive shield against external radioactivity (see Figure 1). The scintillator fluorescence light is collected by 2,212 photomultiplier tubes mounted on the Stainless Steel Sphere (radius R = 6.9 m). The entire detector is enclosed in a domed, cylindrical tank filled with high-purity water, equipped with 208 photomultiplier tubes, which provides extra shielding against external radioactivity (photons and neutrons), and also serves as an active water Cherenkov veto against residual cosmic muons.[1] Together with the lack of directionality information from the scintillation light, the low rate demands a high detector radiopurity, a deep understanding of the backgrounds, and an accurate modeling of the detector response.

To achieve the extreme sensitivity required by the experiment, very stringent procedures of material selection and cleaning were adopted to limit radioactive background in the experiment. Since usual materials are contaminated at the order of Bq/kg, material selection played a key role in the success of the experiment. One example is the choice of oil coming from deep wells to produce pseudocumene. In this way a low content of ^{14}C is achieved in the detector. Several cycles of scintillation purification were performed during the years achieving the unprecedented contamination of $^{238}U < 9.4 \cdot 10^{-20}$ g/g (95% C.L.) and $^{232}Th < 5.7 \cdot 10^{-19}$ g/g (95% C.L.). Further details on the purification strategy can be found here.[2]

The position and pulse-shape of each event are reconstructed by exploiting the number of detected photons and their detection times. The information about the event energy is carried by the number of detected photoelectrons or just the number of hit PMTs, as in our energy range the PMTs mainly work in a single photoelectron regime. Moreover, from the time distribution of the emitted light it is possible to statistically discriminate between α and β^- events[3] and between β^+ and β^- events.[4]

Due to a small leak in the nylon vessel, the vessel shape changes with time. At analysis stage it is updated every three weeks looking at radioactive decays happening on in (mostly due to ^{210}Bi, ^{40}K, ^{208}Tl) as shown by Figure 2. This method enables to reconstruct the vessel shape with a ± 5 cm uncertainty.

2. The Borexino calibration campaign

Calibrations in Borexino are performed inserting radioactive sources inside the liquid scintillator (internal calibrations) and placing a ^{232}Th source close to the stainless steel sphere (external calibrations). The former is used to map the detector's response while the latter is used to better understand and modeling the backgrounds that are coming from the construction materials. To insert sources inside the detector, a complex system of rods and cameras is exploited. This ensures knowing the position of the source at $\sim$cm level.[6] Table 1 shows the used sources and their purpose.

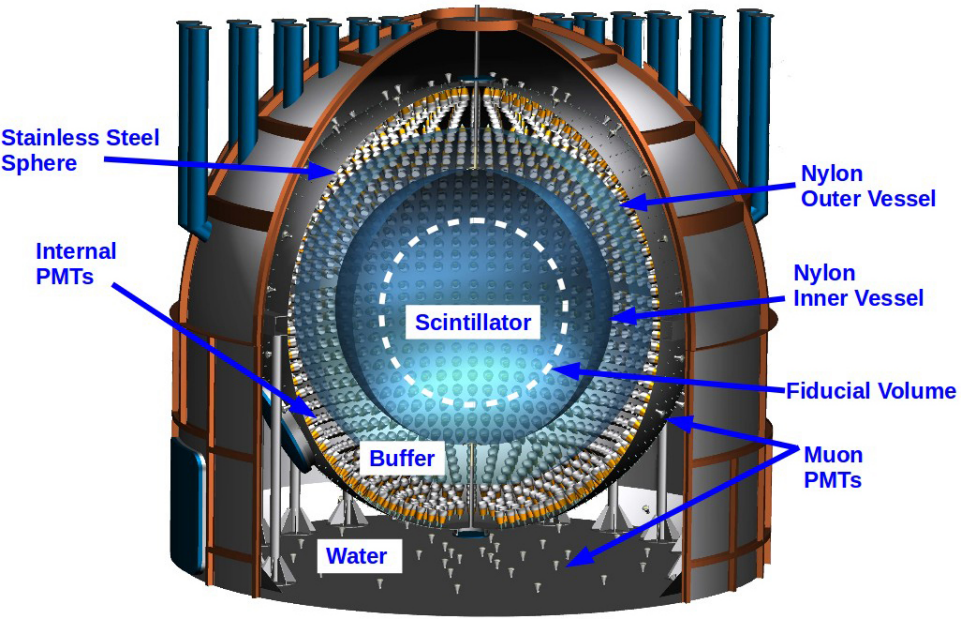

Fig. 1. The Borexino detector: Schematic view of the structure of the Borexino apparatus. From inside to outside: the liquid scintillator, the buffer liquid, the stainless steel sphere with the photomultipliers, and the water tank.[5]

Table 1. Used sources and placement during the internal calibration campaign.[6]

Source	Type	E [MeV]	Position	Motivations
^{57}Co	γ	0.122	in IV volume	Energy scale
^{139}Ce	γ	0.165	in IV volume	Energy scale
^{203}Hg	γ	0.279	in IV volume	Energy scale
^{85}Sr	γ	0.514	z-axis + sphere R=3 m	Energy scale + FV
^{54}Mn	γ	0.834	along z-axis	Energy scale
^{65}Zn	γ	1.115	along z-axis	Energy scale
^{60}Co	γ	1.173, 1.332	along z-axis	Energy scale
^{40}K	γ	1.460	along z-axis	Energy scale
^{222}Rn+^{14}C	β,γ	0-3.20	in IV volume	FV+uniformity
	α	5.5, 6.0, 7.4	in IV volume	FV+uniformity
^{241}Am^{9}Be	n	0-9	sphere R=4 m	Energy scale + FV
394 nm laser	light	-	center	PMT equalization

The position of an event is calculated by the time of arrival of the first photon on photomultipliers corrected by the hit multiplicity and minimizing a proper likelihood function. Figure 3 shows the resolution as function of the energy of the event. The reconstruction of calibration events and their comparison with the know source position shows a bias of maximum 4 cm in the vertical direction for events in the

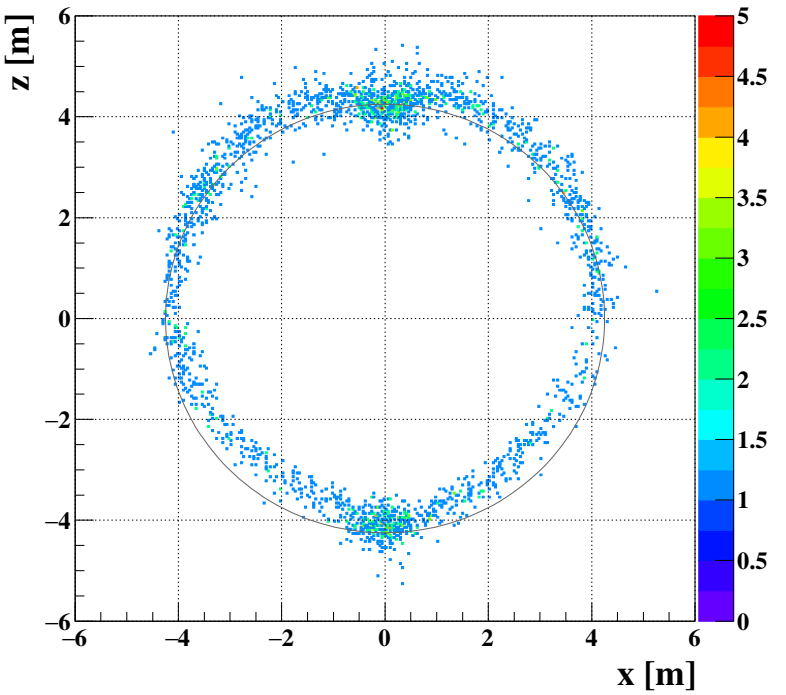

Fig. 2. A cross section (z-x plane, $|y| < 0.5$ m) view of the distribution of 2478 events, acquired during a 3 week period, and selected for the IV shape reconstruction. The color axis represents the number of events per cubic pixel of 0.04 m of size. This distribution reveals the IV shift and deformation with respect to its nominal spherical position shown in solid black line.[3]

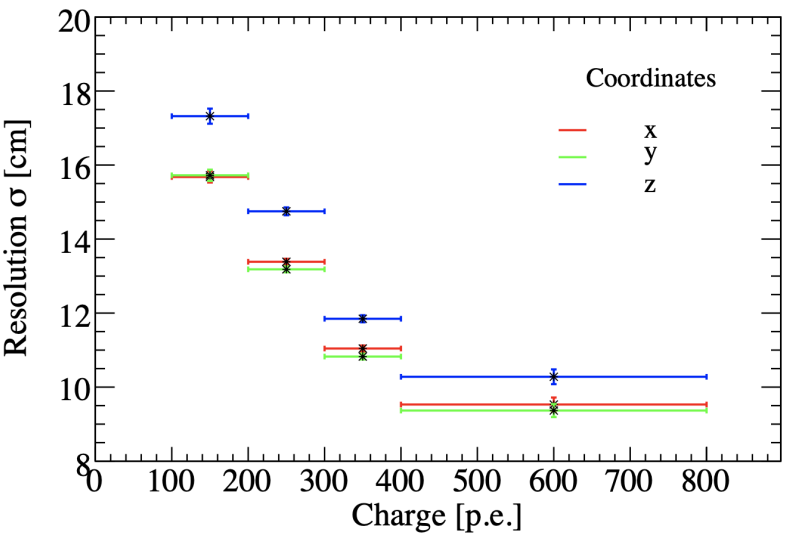

Fig. 3. Position resolution in Borexino as function of event energy.[6]

center. This bias has a small (less than 0.2%) impact on the fiducial volume determination. Since Borexino is a self triggering experiment, calibrations with laser and radioactive sources were performed to test the triggering efficiency, which is 100% at the energies of interest for solar neutrino detection.[7]

3. Modeling the detector response

The collaboration developed two independent approaches for modeling the detector's response. One is based on a particle physics simulation,[8] the other on an analytical model.[4]

The MC code developed for Borexino is a customized Geant4-based simulation package, which can simulate all processes following the interaction of a particle in the detector (energy loss including ionization quenching in the scintillator; scintillation and Cherenkov light production; optical photon propagation and interaction in the scintillator modelling absorption and re-emission, Rayleigh scattering, interaction of the optical photons with the surface of the materials; photon detection on the PMTs, and response of the electronics chain) including all known characteristics of the apparatus (geometry, properties of the materials, variable number of the working channels over the duration of the experiment as in the real data) and their evolution in time. The code thus produces a fully simulated detector response function because it provides a simulated version of all the measured physical variables. All the MC input parameters have been chosen or optimized using samples of data independent from the specific analysis (laboratory measurements and Borexino calibrations with radioactive sources.

In the analytical approach, a PDF for the energy estimator under consideration and analytical expressions for its mean value and variance are introduced. This PDF describes the detector's energy response function to monoenergetic events and, in brief, it is mainly influenced by the number of scintillation and Cherenkov photons and effects due to the nonuniformity of the light collection. The energy spectra of each species are transformed into the corresponding distributions of the energy estimators. Effects like the ionization quenching in the scintillator, the contribution of the Cherenkov light, the spatial dependence of the reconstructed energy and its resolution are accounted for through some parameters, part of which are fixed, while others are free to vary during the fit on the dataset.

4. Conclusion

Borexino is a neutrino detector able to measure the flux of all the neutrinos emitted by the Sun and the existence of antineutrinos emitted by the Earth.[3–5,9] Thanks to a wide calibration campaign the performances of the detector were assessed: for a 1 MeV event the energy resolution is ~ 50 keV and the position resolution is ~ 10 cm. The triggering efficiency is 100% for energies typical of solar neutrinos events. Moreover the Monte Carlo and analytical models were tested on calibration data with agreement better than 1%.

The largest amount of antineutrinos detected about the Earth is emitted by the natural radioactive decays of ^{232}Th and ^{238}U chains isotopes and of ^{40}K. Other flux components are yielded by cosmic rays interactions in the atmosphere or by possible extra-terrestrial sources such as supernovae explosions, gamma ray bursts, GW events and solar flares. This contribution is aimed to summarise the results obtained by the Borexino experiment about antineutrinos from the Earth and from extraterrestrial sources.

Keywords: Antineutrinos; Geonetrinos; solar flares; diffuse supernovae background.

1. Introduction

Large underground ultrapure liquid scintillators are very suitable to antineutrinos studies. Low energy neutrinos such as solar neutrinos are in general detected through the elastic scattering process on electrons but for electron antineutrinos a specific interaction channel can be exploited, the Inverse Beta-Decay (IBD) mechanism on the free proton:

$$\bar{\nu}_e + p \rightarrow n + e^+ \tag{1}$$

The emitted positron deposits its kinetic energy and annihilates almost immediately, inducing a prompt signal whose visible energy E_{prompt} is directly correlated with the incident antineutrino energy $E_{\bar{\nu}_e}$:

$$E_{prompt} = E_{\bar{\nu}_e} - 0.784\,\mathrm{MeV}. \tag{2}$$

The neutron thermalizes and is captured by a proton with the mean capture time: $\sim \tau = 254.5 \pm 1.8 \mu$s.[1] The IBD cross section is on average a factor ~ 100 higher than elastic scattering at few MeV. Moreover the fast time coincidence between the positron annihilation and the neutron capture provides an almost background free signature, that allows to investigate also tiny flux components. By exploiting this detection mechanism, Borexino[2] has robustly detected the geo-neutrino signal and begun to place constraints on the amount of radiogenic heating in the Earth's interior: the null-hypothesis of observing a geoneutrino signal from the mantle has been excluded at a 99.0% C.L. and the overall production of radiogenic heat constrained to $38.2\ ^{+13.6}_{-12.7}$ TW.[3] The extreme radiopurity of the Borexino detector has also allowed to set new limits on diffuse supernova antineutrino background for in the previously unexplored energy region below 8 MeV,[4] and to obtain the best upper limits on all flavor antineutrino fluences in the few MeV energy range from solar flares,[4] gamma-ray bursts[5] and from gravitational wave events.[6] In the following sections we detail the analysis procedures and the results obtained by Borexino about geoneutrinos, diffuse supernovae background and possible time correlated signals with solar flares.

2. Geo-neutrinos

Geoneutrinos are electron antineutrinos ($\bar{\nu}_e$) emitted in the β decays of long-lived isotopes, which are present in the Earth, such as ^{40}K and the ^{238}U and ^{232}Th chain unstable isotopes.[11] The decay schemes and the released heat are summarised in the following equations:

$$^{238}\mathrm{U} \rightarrow ^{206}\mathrm{Pb} + 8\alpha + 8e^- + 6\bar{\nu}_e + 51.7 \quad \mathrm{MeV} \tag{3}$$

$$^{235}\mathrm{U} \rightarrow ^{207}\mathrm{Pb} + 7\alpha + 4e^- + 4\bar{\nu}_e + 46.4\ \mathrm{MeV} \tag{4}$$

$$^{232}\mathrm{Th} \rightarrow ^{208}\mathrm{Pb} + 6\alpha + 4e^- + 4\bar{\nu}_e + 42.7\ \mathrm{MeV} \tag{5}$$

$$^{40}\mathrm{K} \rightarrow ^{40}\mathrm{Ca} + e^- + \bar{\nu}_e + 1.31\ \mathrm{MeV}\ (89.3\%) \tag{6}$$

$$^{40}\mathrm{K} + \mathrm{e} \rightarrow ^{40}\mathrm{Ar} + \nu_e + 1.505\ \mathrm{MeV} \quad (10.7\%) \tag{7}$$

Since the present-day isotopic abundance of ^{235}U is small (0.7%), the overall contribution of ^{238}U, ^{232}Th, and ^{40}K is largely predominant. Information about the deep Earth's composition is mainly based on indirect probes: seismologic data constrains the density profile, while geochemistry provides predictions based on chemical compositions of upper Earth's rocks, chondritic meteorites, and the Sun photosphere. The surface of the Earth is emitting an heat flow at an estimated rate of 47 ± 2 TW.[12] This result is based on $\sim$ 40,000 observations of heat conduction in surface rocks and corrected for hydrothermal circulation and volcanism. Measurements of Th, U and K in the continental crust rocks prove that at least $\sim$8 TW of this heat

is from radiogenic decays but is not at all known what proportion of the overall surface heat flow comes from radioactive decays and how much is from primordial sources such as the gravitational energy released after core formation or the kinetic energy of accretion bombardment.

Geo-neutrinos give us a way of measuring the amount of this radiogenic heat directly: the heat released is in a well fixed ratio with the total mass of Heat Producing Elements (HPE's) inside the Earth. Thus, it is possible to extract from the measured geo-neutrino fluxes several geological information unreachable by other means. The idea of studying geo-neutrinos dates back to the sixties[7,8] but only in 1998 it was proposed the idea of using solar neutrino and reactor neutrino detectors[9,10]: presently, two large-volume, liquid-scintillator neutrino experiments, KamLAND in Japan[13–15] and Borexino in Italy,[3,16–18] have been able to measure the geo-neutrino signal. The typical fluxes are of the order of 10^6 cm^{-2}s^{-1} and with cross section values of 10^{-43} cm^{-2} only a hand-full number of interactions, few tens per year are expected with the current-size detectors. This means, underground laboratories are crucial to shield the detector from cosmic radiation and make possible their measurement. Since the inverse beta decay (IBD) on protons has a threshold of 1.8 MeV (Eq. 1) and both the ^{40}K and ^{235}U geo-neutrinos spectra are below (Fig. 1), they cannot be detected by this process. However, the elemental abundances ratios are much better known than the absolute abundances. Therefore, by measuring the absolute content of ^{238}U and ^{232}Th, also the overall amount of ^{40}K and ^{235}U can be inferred with an improved precision.

Geo-neutrino spectrum extends up to 3.26 MeV and the ^{238}U and ^{232}Th contributions can be distinguished according to their different end-points (Fig. 1).

The most recent Borexino analysis is based on 3263 days of data taking in the period December 2007 - April 2019.

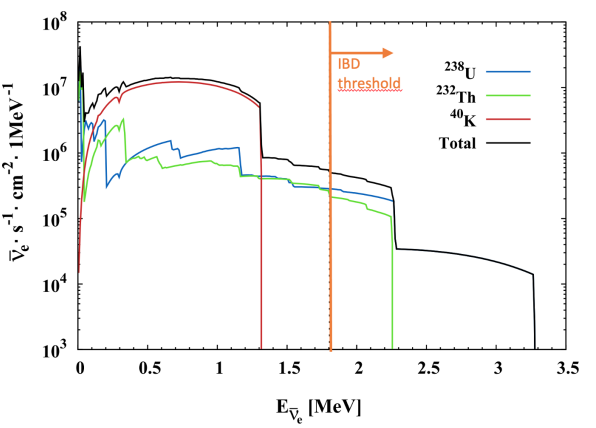

Fig. 1. Geoneutrino fluxes[3] from different isotopes and the overall signal at LNGS calculated with geophysical and geochemical inputs from[24] for the far-field lithosphere and from[23] for the local crust.

To select the $\bar{\nu}_e$ candidates we apply the following criteria: we discard events occurring within 2 ms of every muon crossing the outer detector to reject cosmogenic neutrons. In case of muons crossing the inner detector long-lived cosmogenic nuclides such a ^{9}Li may be produced: to reduce this possible background a different veto ranging from 0.2 to 2 s is applied after the muon depending on the deposited energy, the track reconstruction quality and the eventually associated neutrons. Independently from a detected muon, we ask that selected events are neither preceded or followed by neutron-like events within a 2 ms window. The coincidences are searched for at a distance between the reconstructed positions Δr < 1.3 m, that accounts for the uncertainty of the spatial reconstruction algorithm and the free path of the 2.2 MeV γ's and with Δt in the range 20–1280 μs ($\sim$5 neutron capture time) for single events, and 2.5–12.5 μs for double cluster events. We remind that if a decay triggering the Borexino DAQ is followed within 16.5 μs by other decays, it is classified as a unique event with multiple clusters. To reduce the external γ background from radioactive decays in the detector materials, we accept only candidates having the prompt event position reconstructed inside the inner detector at distance larger than 10 cm with respect to the the time-varying IV surface: $D_{IV,prompt} > 10\,cm$. The energy of the prompt event is required to be above the value corresponding to the IBD threshold, considering the energy resolution ($N_{p.e.,prompt} > 408$ p.e.), while for the delayed event, the energy cut was tuned to cover the gamma peak from neutron capture on proton and on carbon ($700 < N_{p.e.,delayed} < 3000$ p.e.). The lower limit is justified because photons at the edge of the scintillator can escape, depositing only a fraction of their total energy. This limit was increased to 860 p.e. during the detector purifications in 2010-2011 to remove the time-correlated $\beta + (\alpha + \gamma)$ decays of ^{214}Bi-^{214}Po, having a time constant close to the neutron capture time. Such background was relevant only during the purifications as a consequence of the increased radon contamination. Finally a pulse shape $\alpha - \beta$ discrimination is applied based on a trained MultiLayerPerceptron binary classifier [3] : $\mathrm{MLP}_D > 0.8$ for delayed signals.

The combined efficiency of the cuts is determined by Monte Carlo to be (85$\pm$1.0)%. The total efficiency-corrected exposure for the data set is (1.29 $\pm$ 0.05) $\times$ 10^{32} protons $\times$ year with an increase by a factor of two over the previous Borexino analysis reported in 2015. We have identified 154 candidates passing all the selection cuts. The estimated background, that mimics $\bar{\nu}_e$ candidates, amounts to 8.28 $\pm$ 1.01 events, mainly due to random coincidences, residual ^{9}Li decays and ^{13}C(α,n)^{16}O reactions in the scintillator.

Antineutrinos from nuclear reactor power plants are the main background to the geo-neutrino measurements. The $\bar{\nu}_e$ flux comes primarily from the beta decays of neutron-rich fragments produced in the fission of four isotopes: ^{235}U, ^{238}U, ^{239}Pu, and ^{241}Pu. The expected fluxes can be estimated from the knowledge of the monthly energy production at each reactor site, including the neutrino propagation effects. At present, there are about 440 nuclear power reactors in the world, providing,

nominally, a total amount of about 1200 Thermal GW, corresponding to about 400 Electrical GW. Since there are no nuclear power plants close by, the Gran Sasso laboratory is well suited for geo-neutrino studies. According to a detailed computation[22] based on the information retrieved by the International Atomic Energy Agency database[19] we expect 91-98 events in our sample whereas the main source of uncertainty in the prediction comes from the knowledge of the energy spectrum for each fuel component at the source. The lowest value (91.9 ± 1.6) is obtained when the spectra are normalised to the measurements of reactor neutrino experiments[20,21] and they include also the so called "5 MeV excess".

A smaller background can also be induced by atmospheric neutrinos. Because of the uncertainty of the relevant fluxes and cross sections, this contribution is poorly constrained: we have estimated 9.2 ± 4.6 event in our sample.

Both reactor and atmospheric $\bar{\nu}_e$ are more energetic respect to the geo-neutrino; therefore they can be experimentally disentangled thanks to a fit of prompt event energies. An unbinned likelihood fit of the energy spectrum of selected prompt events has been performed.

In Fig. 2 the selected candidates and the fit results are shown. Using the value ratio for the masses of Th and U, m(Th)/m(U)=3.9, suggested by the chondritic metheorithes, our best fit yield $N_{geo} = 52.6^{+9.4}_{-8.6}(stat)^{+2.7}_{-2.1}(sys)$ events, with 18% precision. A compatible result was found when contributions from ^{238}U and ^{232}Th were both fit as free parameters. Antineutrino background from reactors is fit unconstrained and found compatible with the expectations. The measured geo-neutrino signal corresponds to fluxes at the detector from decays in the U and Th chains of $\Phi_U = 2.8^{+0.6}_{-0.4} \cdot 10^6$ cm^{-2}s^{-1} and $\Phi_{Th} = 2.6^{+0.6}_{-0.4} \cdot 10^6$ cm^{-2}s^{-1} respectively.

To connect the number of geo-neutrinos detected by an experiment with the overall radioactivity in the crust and in the mantle, we have to rely on our knowledge

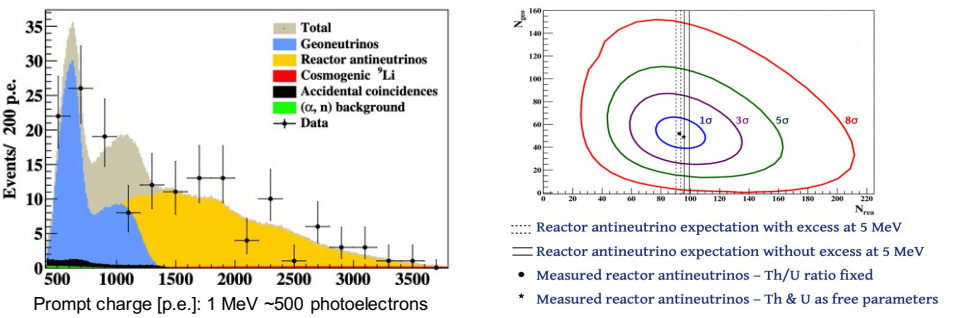

Fig. 2. **(Left)** Spectral fit of the data (black points assuming the chondritic Th/U ratio. Geoneutrinos (blue) and reactor antineutrinos (yellow) were kept as free fit parameters. Other non antineutrino backgrounds were constrained in the fit. **(Right)** The best fit point (black dot) and the 2D coverage contours for N_{geo} vs N_{rea}.

of the local geological conditions. Geoscientist developed models of the crust close to the Borexino site, based on geological surveys and on 3D models of all the layers up to the mantle boundary.[23,24] Both U and Th are lithophile i.e. "rock-loving" elements so they are believed to be concentrated in the crust and mantle and absent in the iron-made core. According to these studies 28.8 ± 5.6 events should have been induced by the crust radioactivity among the 154 candidates: we have therefore repeated the fit with separate contribution of mantle and crust geoneutrinos, the latter being constrained to the expectations within the error. A small difference in the relative amount of U and Th fraction in the two signals has been introduced according to geological predictions. The fit returns $N_{geo} = 23.7^{+10.7}_{-10.0}(stat)^{+1.2}_{-1.0}(sys)$ events: with a sensitivity study the null-hypothesis of observing geoneutrino signal from the mantle is excluded at a 99.0% C.L..

It is possible to extract from the measured geo-neutrino signal, the Earth's radiogenic heat power that is a fundamental question for understanding the plate tectonics and mantle convection. The uncertain distribution of HPE's in the deep Earth has to be included: two rather extreme cases are represented by the homogeneous mantle or by the assumption that all the U and Th are placed at the mantle core boundary. By following this conservative approach one can demonstrate that our measured mantle signal corresponds to the production of a radiogenic heat of 24.6 ± 11.1 TW (68% interval) from ^{238}U and ^{232}Th in the mantle. Assuming 18% contribution of ^{40}K in the mantle and 8.1 ± 1.9 TW of total radiogenic heat of the lithosphere, the Borexino estimate of the total radiogenic heat of the Earth is 38.2 ± 13.6 TW, which corresponds to ∼81% of the overall Earth's heat flux (47 TW). These values are compatible with different geological predictions, in the particular with the geodynamical BSE models,[25] however there is a $\sim 2.4\sigma$ tension with those Earth models which predict the lowest concentration of heat-producing elements in the mantle, such as cosmochemical ones.[25] In addition, by constraining the number of expected reactor antineutrino events, the existence of a hypothetical georeactor at the center of the Earth having power greater than 2.4 TW is excluded at 95% C.L..[26,27] In conclusion, Borexino confirms the feasibility of geoneutrino measurements as well as the validity of different geological models predicting the U and Th abundances in the Earth. This is an enormous success of both neutrino physics and geosciences. The next generation of large volume liquid scintillator detectors (such as JUNO and SNO+) has a strong potential to provide fundamental information about our planet and geoneutrinos may be the key tool to support the new discoveries about the deep Earth.

3. Diffuse supernovae neutrino background

The Diffuse Supernova Neutrino Background (DSNB) is formed by the stars that collapsed during the evolution of the Universe and it is made of neutrinos and antineutrinos of all flavours. The flux spectrum at the Earth can be parametrised

as[28]:

$$\frac{d\phi_\nu}{dE_\nu} = \frac{c}{H_0}\int_0^{z_{max}} \frac{dN_\nu(E'_\nu)}{dE'_\nu} \frac{R_{SN}(z)dz}{\sqrt{\Omega_m(1+z)^3+\Omega_\Lambda}}, \tag{8}$$

where c is the speed of light, z is the red shift, H_0 is Hubble constant, $R_{SN}(z)$ is the supernova rate at the distance z to the observer $\frac{dN_\nu(E'_\nu)}{dE'_\nu}$ is the neutrino emission spectrum for individual supernova, Ω_m and Ω_Λ are the relative densities of matter and dark energy in the Universe. The spectrum is sensitive to particular cosmological model through Ω_m and Ω_Λ and reflects the expansion of the Universe through the dependence on H_0.

The possible signal due to tiny, still undisclosed, extraterrestrial $\bar{\nu}_e$ fluxes, such as supernovae relic neutrinos, can be put in evidence as an excess of events with respect to the backgrounds and the known sources of $\bar{\nu}_e$. Borexino made a search for this possible signal, based on the data collected between December 2007–October 2017. The events selection is based on an approach similar to the one adopted in the geo-neutrino analysis, the only differences being more conservative muon and FV cuts. In detail we applied a veto of 2 s after each muon crossing the inner detector and we asked for a prompt event distance from the inner vessel larger than 25 cm: in the overall statistics we have selected 101 candidates.

As outlined in the previous sections, the most relevant sources of $\bar{\nu}_e$ events below 10 MeV are the Earth's radioactive isotopes and the nuclear reactors, while at higher energies the atmospheric neutrino background dominates the energy spectrum. Borexino made a comprehensive study of geo-neutrinos but the achieved precision, in particular on the mantle signal is still poor ($\sim$ 40%), With the aim to quote conservative limits, the minimal expected number of events for each background has been considered. For the geoneutrino signal we have therefore chosen the Minimal Radiogenic Earth model, which only includes the radioactivity from the crust and that, in our case, corresponds to 17.9 ± 2.1 events in our data sample.

The spectrum of reactor $\bar{\nu}_e$ is significant till $\sim$10 MeV. As discussed before, the flux calculation that includes the normalisation to reactor neutrino experiments data provides the lowest signal. We have taken this option being the most conservative: 61.1 ± 1.7 events among our candidates have been attributed to reactor $\bar{\nu}_e$. Finally the most serious background to the detection of DSNB fluxes at energies above 10 MeV is induced by the atmospheric neutrinos, i.e., the ν's and $\bar{\nu}$'s generated in the decay of secondary particles produced in the interactions of primary cosmic rays with Earth's atmosphere. After the simulation of detector response and by applying the same selection cuts as for real data, we have estimated 6.5 ± 3.2 IBD-like events in the present analysis statistics and in the equivalent $\bar{\nu}_e$ energy window 1.8–16.8 MeV. In the light of the large uncertainty on this background source, a conservative choice would be to not consider it at all in the upper limit calculations: this is the approach followed in Fig. 3. The model-independent limit for electron antineutrino

flux ($\Phi_{\bar{\nu}_e}$) in each energy bin (i) have been computed according to the equation:

$$\Phi_{\bar{\nu}_e,i} = \frac{N_{90,i}}{<\sigma> \cdot \varepsilon \cdot N_p \cdot T} \tag{9}$$

where N_{90} is the 90% C.L. upper limit for the number of antineutrino interactions obtained by following the Feldman-Cousins approach,[29] $<\sigma>$ is the mean cross-section of Inverse Beta Decay calculated according to[30] for each energy bin, ε=(0.850 $\pm$ 0.015) is the average detection efficiency, $N_p = (1.32 \pm 0.06) \times 10^{31}$ is the number of protons in the Borexino average fiducial volume mass and $T = 2485$ days is the total live-time. The other limits existing in literature are quoted on the same plot.

Borexino limits are the only existing below 8 MeV, thanks to the high energy resolution, the low intrinsic backgrounds, and the small reactor $\bar{\nu}_e$ flux at the Gran Sasso site.

4. Search for time correlated signals with solar flares

Solar flares are induced by the rearrangement of the solar magnetic field which also bring to the acceleration of charged particles. Pions, eventually produced in the flare's region by *pp*- and *pα*-collisions, could then decay by emitting neutrinos with a mean neutrino energy expected around $\sim 10\,\mathrm{MeV}$.[35]

In the eighties R. Davis[36,37] advanced for the first time the possibility of neutrino emissions correlated with solar flares as an explanation for the excess of events in several runs of the Homestake Cl-Ar experiment. In general the production of $\bar{\nu}_e$ is expected to be smaller respect to ν_e due to the higher threshold of π^- generation in *pp*-collisions: for this reason we have searched for ν_x and $\bar{\nu}_x$ ($x = e, \mu, \tau$)

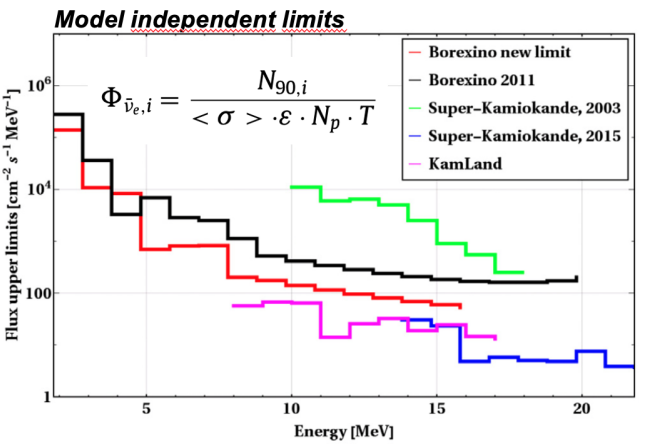

Fig. 3. Borexino model-independent limits on electron $\bar{\nu}_e$ fluxes from unknown sources compared with the results of other experiments (Super-Kamiokande,[31,32] KamLAND[33]) and older Borexino limits.[34]

signals correlated with solar flares by looking their elastic scattering on electrons in the Borexino scintillator. According to the assumption that the neutrino flux is proportional to the flare's intensity, we have only considered the most intense flares of M and X classes according to the GOES database.[38]

The analysis is based on the statistics collected between November 2009 and October 2017 : data acquired both by the primary and the FADC DAQ systems have been used in the energy interval of 1–15 MeV, while in the interval 0.25 – 1 MeV only the primary DAQ data have been considered. After removing muons and muon daughters, single events are selected without any fiducial volume cut in the interval of 1–15 MeV, while at lower energies a fiducial volume cut of 145 tons (75 cm from the IV) is applied to reduce the external radioactivity. In our study, an excess of single events above the measured background at the time of a flare is searched for. For the flare signal we choose a time window equal to the flare's duration according to the database, while the background is calculated in a time window of the same length but opened before the flare time. By requiring at least 95% of Borexino's up time for both windows we restrict our analysis to a 472 flares sample. No statistically significant excess of events is observed in correlation with the flares. The fluence limit for neutrinos of energy E_ν is calculated according to the equation:

$$\Phi_\nu(E_\nu) = \frac{N_{90}(E_\nu)}{N_e \sigma_{\text{eff}}(E_\nu)}, \tag{10}$$

where N_e is the number of electrons in the Borexino scintillator, that is, $N_e = 9.2 \cdot 10^{31}$ for the whole IV and $N_e = 4.8 \cdot 10^{31}$ for the 145 tons FV. The scattering of monoenergetic neutrinos with energy E_ν off electrons leads to recoil electrons with a Compton-like continuous energy spectrum with maximum energy $T_\nu^{max} = 2E_\nu^2/(m_e + 2E_\nu)$. For each neutrino energy bin, a corresponding recoiled electrons energy interval is computed by considering the cross section and the detector response function.

In order to set the fluence limits for flare-correlated neutrinos (antineutrinos) of electron and $(\mu + \tau)$ flavors individually, the corresponding cross section in Eq. 10 was set to σ_{ν_e} ($\sigma_{\bar{\nu}_e}$) and $\sigma_{\nu_{\mu,\tau}}$ ($\sigma_{\bar{\nu}_{\mu,\tau}}$), respectively. Figure 4 quotes Borexino limits obtained from the primary DAQ ($E_\nu < 3.5$ MeV) and the FADC DAQ ($E_\nu > 3.5$ MeV).

Limits for ν_e quoted by SNO[39] and an allowed band for the neutrino fluence that would have explained the Homestake run 117 excess of events are also shown for comparison.

As of today, Borexino sets the strongest limits on fluences of all neutrino flavors from the solar flares below 3–7 MeV. Under the hyphothesis that neutrino flux is proportional to the flare's intensity, Borexino's data excludes an intense solar flare occurred during run 117 of the Cl-Ar Homestake experiment as a possible source for the observed excess of events.

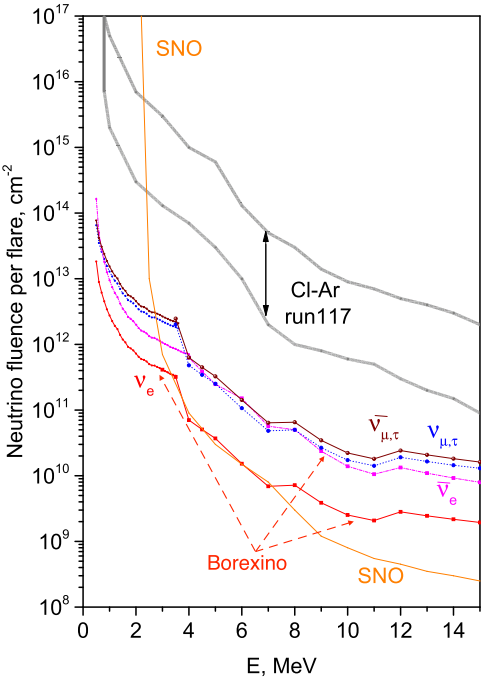

Fig. 4. Borexino 90% C.L. fluence upper limits obtained through elastic scattering for ν_e, $\bar{\nu}_e$, $\nu_{\mu,\tau}$, and $\bar{\nu}_{\mu,\tau}$. The limits by SNO[39] for ν_e are reported and the fluences that would have explained the Cl-Ar Homestake excess in run 117.

5. Conclusions

Large ultrapure liquid scintillators in underground laboratories have a strong potential for the comprehension of our planet energetics and in the various fields of experimental neutrino astronomy. Collecting more data in the incoming years with a network of detectors will be crucial to probe the very foundations of our understanding of the Universe and of our planet.

About 99% of solar energy is produced through sequences of nuclear processes that convert Hydrogen into Helium in the so-called *pp*-chain. The neutrinos emitted in five of these reactions represent a unique probe of the Sun's internal working and, at the same time, offer an intense natural neutrino beam for fundamental physics research.

The Borexino experiment consists of a large-volume liquid-scintillator detector designed and constructed for real-time detection of low energy solar neutrinos. It is installed at the underground INFN Laboratori Nazionali del Gran Sasso (L'Aquila, Italy) and started taking data in May 2007. Borexino has been the only experiment so far capable of performing a complete study of the *pp*-chain by directly measuring the neutrino-electron

[†] Current address: Dipartimento di Fisica "G. Occhialini", Università degli Studi and INFN Milano Bicocca, 20126 Milano, Italy.

elastic scattering rates for the neutrinos produced in four of its reactions: the initial proton–proton (*pp*) fusion, the electron capture of Beryllium-7, the proton–electron–proton (*pep*) fusion, and the Boron-8 β^+ decay. A limit on the neutrino flux produced in the helium-proton fusion (hep) was also set. This set of measurements further probes the solar fusion mechanism via the direct determination of the relative intensity of the two primary terminations of the *pp*-chain, and the computation of the solar neutrino luminosity. Moreover, the Beryllium-7 and Boron-8 fluxes are indicative of the Sun's core temperature, and their measurement shows a mild preference for the higher temperature expected from the high-metallicity Standard Solar Model scenario. Finally, the experimental survival probability of these solar electron neutrinos allows to simultaneously probe the MSW neutrino flavor conversion paradigm, both in vacuum and in matter-dominated regimes, at different energies.

The details of the strategy adopted by the Borexino collaboration for successfully isolating the spectral components of the *pp*-chain neutrinos signal from residual backgrounds in the total energy spectrum will be presented.

Keywords: Solar neutrinos, proton-proton chain, Borexino

1. Introduction

The study of neutrinos generated by nuclear processes in the Sun has been producing outstanding scientific results for more than 50 years in both the fields of astrophysics and particle physics. The measurements of solar neutrinos provided the first direct evidence of the nuclear origin of stars' luminosity, as well as the first indication of flavour transition in the neutrino sector. In the years, solar neutrino experiments have progressively improved their accuracy, bringing new insights on the functioning of the Sun and on the properties of neutrinos.

The Borexino experiment is a key player in this field, being the most sensitive detector so-far for low-energy solar neutrinos. One of the milestones of the Borexino physics program, which significantly exceeded the expected physics reach, is the (almost) complete investigation of neutrinos produced throughout the entire proton-proton fusion chain, the sequence of nuclear reactions responsible for $\approx 99\%$ of the Sun luminosity. This fundamental result, partially achieved already during the first phase of the experiment (2007-2010), has been further improved in the phase II (2011-2016) and made it possible to test our knowledge of the Sun and to constrain exotic properties of neutrinos.

We present in this contribution the latest results of Borexino regarding solar neutrinos emitted throughout the *pp*-chain and we discuss their implications for both neutrino and solar physics. Section 2 describes the proton-proton fusion chain and the neutrinos produced therein, while the Borexino detector is presented in Sec. 3. The spectrum of solar neutrinos spans across a wide energy range extended up to 19 MeV and their fluxes vary of several orders of magnitude, therefore we setup two separate analyses targeting the low- and high-energy region of the solar neutrino spectrum that are described in Secs. 4 and 5 respectively along with the main results of Borexino.

2. Solar neutrinos from the *pp*-chain

The Sun, as most of other stars, produces energy by fusing four protons into a helium nucleus. This idea, originally hypothesized by Perrin and Eddington,[1,2] was later formalized by Bethe and Critchfield and independently by Weizsäcker who proposed two mechanisms for the hydrogen burning, known as the proton-proton chain[3] (*pp*-chain) and the Carbon-Nitrogen-Oxygen (CNO) cycle.[4–6] The relative efficiency of these two processes depends heavily on the features of the star under consideration, specifically on its core temperature and on its chemical composition. While the CNO-cycle was initially believed to be the dominant energy-production mechanism in the Sun, in light of a more accurate estimate of the Sun core temperature it became clear that the *pp*-chain drives the energy production in the Sun. The relative weight of the two mechanisms is estimated by a detailed model of the Sun, also known as Standard Solar Model (SSM), which -provided an accurate description of all the physical processes driving the evolution of a star- is able to produce a comprehensive snapshop of the Sun by forcing the modelled star to match the current solar mass, radius, luminosity and surface composition. The most recent update of the SSM[7] indicates that only $\approx 1\%$ of the Sun energy is produced through the CNO-cycle, while the real "engine" of the Sun is the *pp*-chain, accounting for $\approx 99\%$ of the Sun luminosity.

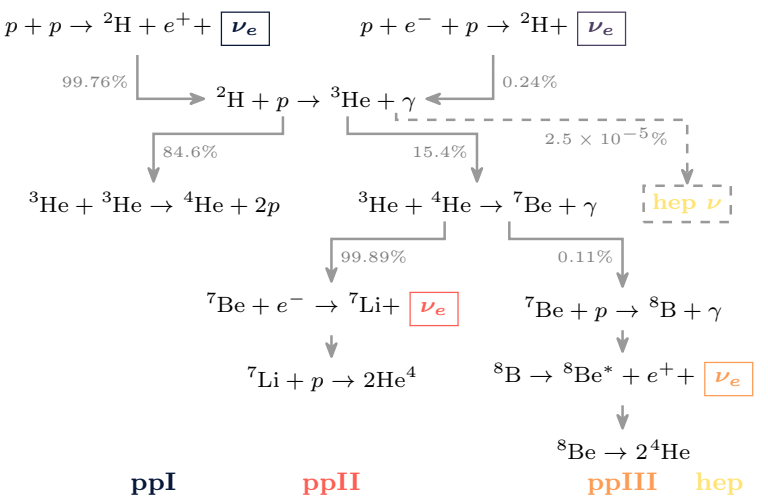

Fig. 1. The sequence of reactions composing the proton-proton fusion chain.

The sequence of reactions composing the *pp*-chain is shown in Fig. 1. Neutrinos are emitted in five of such processes, starting with the fusion of two protons into a deuteron which begins the chain (*pp* neutrinos). An alternative way of producing a deuteron, although $\approx$ 400 times less likely than the proton-proton fusion,

consists in the reaction between two protons and an electron, which releases a 1.44 MeV monoenergetic neutrino (*pep* neutrino). The *pp*-chain can progress into different branches, namely ppI, ppII, ppIII and hep. Depending on the evolution of the chain, different neutrinos can be emitted: while the most prominent branch (ppI) terminates the chain without releasing any additional neutrino, the ppII branch is characterized by monoenergetic neutrinos produced by electron-capture onto ^{7}Be, with energy of 0.86 MeV (branching ratio 89.5%) or 0.38 MeV (B.R. 10.5%) depending if the ^{7}Li nucleus in the final state is produced at its ground state or on the first excited state. The high-energy neutrinos emitted in the decay of ^{8}B (Q-value 15.5 MeV) tag the ppIII branch, and the faintest branch of all, the helium-proton fusion (hep) branch, produces neutrinos up to an energy of 19.8 MeV. The expected solar neutrino spectrum is shown in Fig. 2.

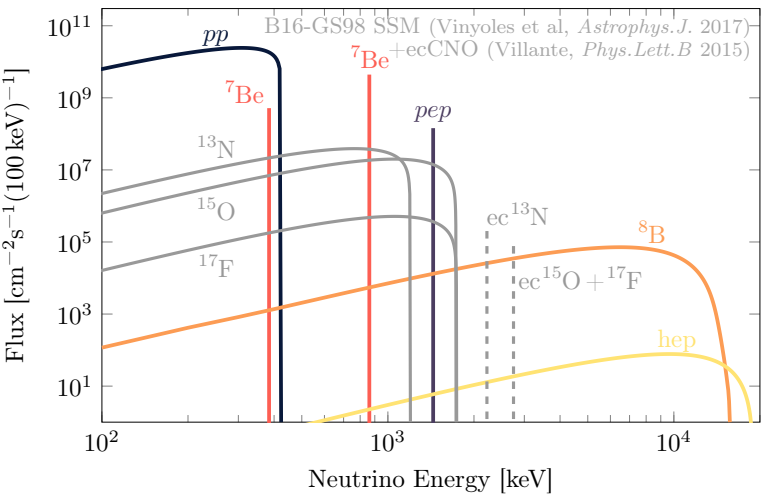

Fig. 2. Expected solar neutrino spectrum, with the neutrinos originating from the *pp*-chain shown with coloured lines and those produced in the CNO-cycle in grey. The fluxes are taken from[7,8] (note that the flux of monoenergetic neutrinos is reported in $\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$).

The fluxes of *pp*-chain solar neutrinos depends on the abundance of heavy elements in the Sun, which is currently not fully understood and affects the temperature profile thus impacting on the *pp*-chain nuclear reactions rate. Recent estimates of the photosphere composition[9] (AGSS09met) show a consistent reduction of the metallicity respect to previous studies[10] (GS98), but this new "low-metallicity" (LZ) SSM shows a worst agreement with observation of the sound speed profile as inferred by helioseismology measurements respect to the old "high-metallicity" (HZ) predictions.[7] The precision measurement of solar neutrino fluxes from the *pp*-chain and the CNO-cycle is a promising way to solve the controversy about solar metallicity and the impact of Borexino results in this connection is discussed in Sec. 6.

3. The Borexino experiment

The Borexino experiment can detect solar neutrinos which interact via elastic scattering with the electrons of a liquid scintillator (LS). This detection technique, which provides a low-energy threshold and a good energy resolution, makes it possible to separate the different components of the solar neutrino flux exploiting their specific signature in the energy spectrum, but requires an extremely careful strategy to reduce the indistinguishable radioactive background since the expected interaction rate is ≈ 9 orders of magnitude smaller than the average activity of ordinary water.

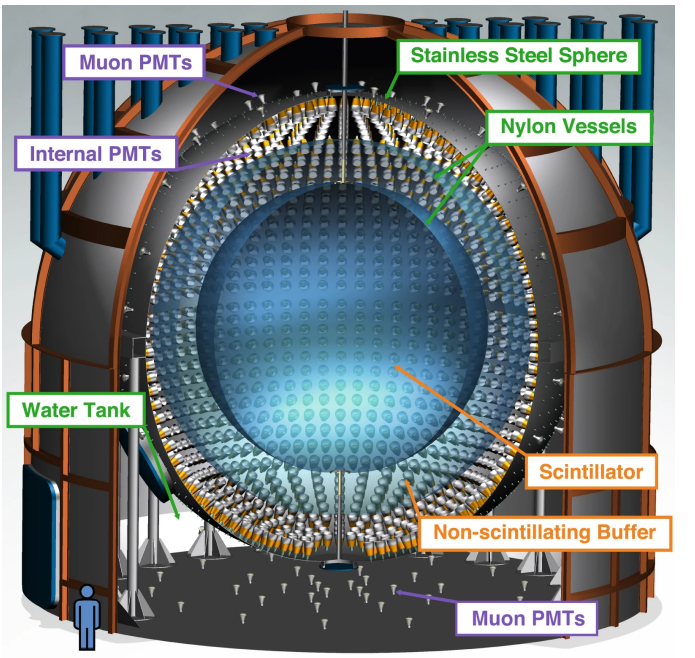

Fig. 3. Schematic view of the Borexino detector. Figure from.[11]

A cutaway of the detector is shown in Fig. 3. The experiment[12] is located in the INFN Gran Sasso National Laboratories, under the Gran Sasso massif in L'Aquila (Italy). The underground laboratories are shielded from cosmic radiation by 1400 m or rock (3800 m.w.e.), which attenuates the cosmic-ray flux by 6 orders of magnitude. Residual muons still reaching the experimental hall[13] ($3.432 \pm 0.003\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$) are tagged using a water Cherenkov detector equipped with 208 PMTs which surrounds the entire inner detector also providing an effective shielding against environmental neutrons and γ-rays. The detector active volume consists of ≈ 300 ton of pseudocumene mixed with 1.5 g/l of (PPO) as a wavelength shifter and is contained into a 125 µm-thick, 4.25 m radius spherical nylon vessel (Inner Vessel, IV). The light

produced by the energy deposition of charged particles is detected by 2212 8 in PMTs (1800 of which are equipped with a light collector cone) mounted onto a 6.85 m radius Stainless Steel Sphere. The space between the IV and the PMTs is filled with quenched LS in order to shield the active volume from the radiation coming from radioactive contamination in the PMTs' glass and in the steel of the support structure.

With the underground location and shielding strategies fighting the external background, the key of Borexino results has been the successful suppression of internal background, *i.e.* those radioactive contamination of the detector itself. This has been achieved thanks to a careful selection of materials and to the implementation of effective purification methods for the LS (primarily distillation and water extraction) which reduced the contamination of ^{238}U and ^{232}Th down to $< 9.5 \times 10^{-20}$ g/g and $< 7.2 \times 10^{-19}$ g/g respectively in the Phase II of the experiment.[14]

The reconstruction of the solar neutrino interaction rate and its separation from the residual background is based primarily (although not exclusively) on the signatures in the visible energy spectrum reconstructed from the scintillation light, therefore the understanding of the detector energy response is fundamental. The energy released in the detector is reconstructed by measuring the isotropic scintillation light produced by recoiling electrons in the LS; the information about the detected light is expressed using three different energy observable that are used in the analysis: the number of hit PMTs in a 230(400) time window ($N_p^{dt_{1(2)}}$), the number of reconstructed hits (N_h) and the total charge measured at the PMTs anode, *i.e.* the number of detected photoelectrons (N_{pe}).

Borexino can rely on two different methods to model the detector response function: the first is based on a full Monte Carlo (MC) simulation of the entire experimental apparatus,[15] which reproduces all the physical processes following the interaction of a particle in the detector (including the electronic chain response) and keeps track of evolution of the detector properties in time, such as the number of operating channels. The simulation has been tuned using both lab measurements and data collected in an extensive calibration campaign,[16] resulting in a sub-percent accuracy for the variables of interest for solar neutrino analysis.[15] An alternative method for modelling the detector energy response consists in an analytical model encapsulating the effect of ionization quenching, the contribution of Cherenkov light as well as the spatial dependence of the reconstructed energy and of the energy resolution.[14] With such model it is possible to reproduce the observed energy spectrum of a given signal by computing the convolution of the visible energy spectrum with the detector response function. More details about this procedure can be found in.[14]

The performance of the detector and the reliability of the response models have been carefully studied during the calibration campaign[16] and are constantly monitored using some known background (such as the ^{14}C, cosmogenic ^{11}C or the characteristic peak of ^{210}Po, see Sec. 4). During the Phase II of Borexino data taking, the energy resolution for 1 MeV deposited energy was close to 50 keV, while the

position of the event –reconstructed via a time-of-flight method– had an accuracy of $\approx 10\,\mathrm{cm}$

4. Low-Energy solar neutrino spectroscopy

The observation of low-energy solar neutrinos has been one of the main goal of the experiment, given their fundamental importance for both neutrino- and solar physics. Differently from the previous generation of low-energy solar neutrino experiments, which were able to measure the integrated neutrino flux over a given energy threshold, the key advantage of Borexino is the possibility to separate the individual contribution of neutrinos produced in different reactions thanks to their specific signature in the visible energy spectrum.

Already during the first phase[17] of the experiment Borexino was able to measure the interaction rate of ^{7}Be, ^{8}B and *pep* neutrinos,[18–20] while imposing an upper limit to the rate of CNO neutrinos.[20] We present in this section the result obtained from the analysis of low-energy neutrinos obtained in the second phase of the Borexino data taking, started in 2011 following a very successful purification campaign which further reduced the already low contamination level in the liquid scintillator. In Sec. 4.1 we discuss the measurement of *pp*-chain low-energy neutrinos reported in,[11,14] while in 4.2 we show the evidence of the time modulation of solar neutrinos interaction rate expected from the Earth's orbit eccentricity. In the second part of this section we report the search of exotic properties of neutrinos performed using low-energy solar neutrinos: in particular Sec. 4.3 presents a limit on the neutrino magnetic moment, while we discuss in Sec. 4.4 the search for neutrino non-standard interactions.

Given their low-flux and different energy scale, neutrinos from the ^{8}B decay require a separate analysis, which is presented in Sec. 5.

4.1. *Simultaneous measurement of low-energy solar neutrino fluxes*

The latest measurements of low-energy solar neutrinos produced by the *pp*-chain performed by Borexino is based on a dataset collected between December 14^{th}, 2011 and May 21^{st}, 2016 (1291.51 days). The increased exposure ($\approx$ 1.6 times larger than Phase I), combined with the lower contamination background and the improved understanding of the detector made it possible to simultaneously extract all the interaction rates of the low-energy components of the *pp*-chain in a single fit over a large portion of the energy spectrum (0.19–2.93 MeV), differently from previous Borexino results where the different solar neutrino species were studied separately optimising the choice of the energy window.

Data recorded by the detector are filtered to remove residual cosmic muons and short-living cosmogenic isotopes by applying a 300 ms veto.[14] In order to remove "external" γ-ray background generated in the material surrounding the liquid

scintillator (especially in the PMTs and in the nylon of the inner vessel) we select only those events reconstructed in a 71.3 tonnes fiducial volume defined in the innermost part of the detector.[14]

The reconstruction of solar neutrinos interaction rates from the energy spectrum is made more challenging by the presence of multiple backgrounds that still contaminates the dataset even after the successful purification of the scintillator and the data selection outlined above: in particular, the sensitivity of Borexino in the low-energy part of the spectrum is limited by the presence of ^{14}C in the LS molecules (β^-, $Q = 0.16\,\mathrm{MeV}$), which decay in the detector at an much higher rate than solar neutrino interactions. Other contamination affecting the energy window are ^{85}Kr (β^-, $Q = 0.69\,\mathrm{MeV}$), ^{210}Po (α, $E_\alpha = 5.3\,\mathrm{MeV}$, light quenched by a factor ≈ 10 in LS) and ^{210}Bi (β^-, $Q = 1.16\,\mathrm{MeV}$). At higher energies, the relevant background is mostly due to residual "external" γ-rays and to cosmogenic ^{11}C (β^+, $Q = 0.96\,\mathrm{MeV}$). The latter can be efficiently tagged by exploiting the fact that it is often produced together with one or more neutrons following muon spallation onto ^{12}C, therefore one can evaluate the likelihood for an event to be a ^{11}C decay on the basis of a set of observables such as the distance and time interval from a crossing muon, the distance of a detected neutron capture and the muon energy deposition profile.[21] Using this selection it has been possible to tag $(92 \pm 4)\,\%$ of ^{11}C events retaining $(64.28 \pm 0.01)\,\%$ of the total exposure, and those events classified as likely to be ^{11}C decays are used to build a separate, ^{11}C-tagged dataset that is analysed jointly with ^{11}C suppressed one.

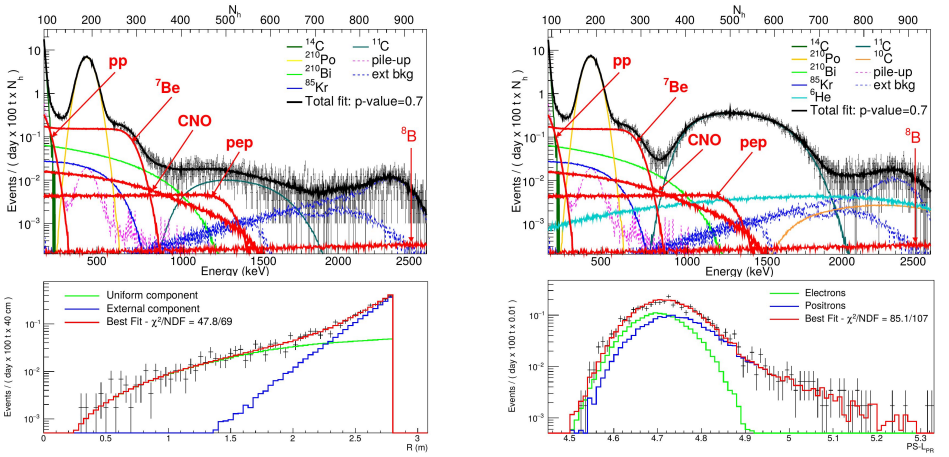

Fig. 4. Result of the simultaneous measurement of low-energy *pp*-chain solar neutrinos. *Top panel*: visible energy spectra in the ^{11}C-subtracted (left) and -tagged datasets. *Bottom left*: Distribution of the events distance from the detector centre. *Bottom right*: Distribution of the pulse shape parameter. All figures from.[14]

To help constraining some of these backgrounds, in some specific cases it is possible to rely on some distinctive features of the signal or on some independent measurements: this is the case of the rate of ^{14}C, which has been measured using a separate dataset to be 40 ± 1 Bq/100 t and that was constrained in the analysis together with the rate of random coincidences of ^{14}C decays. Differently, the signal from external γ-rays shows a clear exponential decrease towards the detector centre due to the shielding effect of LS, while energy release of positrons emitted in the β^+ decay of ^{11}C and its subsequent annihilation results in a slightly different time profile, that we used to define a Pulse Shape (PS) parameter[14] that improves the separation between β^+ and β^-events. In order to take into account these features, we implemented a multivariate analysis which include the events' distance from the detector centre and pulse shape parameter in addition to the energy observables in the region where they can help the analysis.

The analysis procedure has been tested running a detailed sensitivity study[14] based on simulated experiments. This study showed a significant correlation between the reconstructed rates of *pep*, CNO end ^{210}Bi events, which led to a reduced sensitivity for such parameters. For this reason, we decided to constrain in the analysis the rate of CNO neutrinos to the value expected from the prediction of the SSM (both HZ and LZ). The results of the fit[11,14] are reported in Tab. 1 next to the expectations from the SSM,[7] assuming the MSW-LMA oscillation parameters.[22] Similarly, the lower part of Tab. 1 reports the fluxes of solar netrinos inferred from Borexino measurements assuming the MSW-LMA solution. Figure 4 shows the different contributions of solar neutrinos and backgrounds to the energy spectrum as well as to the radial distance and pulse shape distributions.

Systematic uncertainties in the measurement account for possible deviations of the computed exposure, uncertainties in the detector response model as well as specific effects of the analysis methods.[11,14]

The results in Tab. 1 represents the most accurate experimental measurements of low-energy solar neutrinos from the *pp*-chain, improving Borexino previous findings: in particular, the interaction rate of ^{7}Be neutrinos is constrained at the 3 % level, twice as accurate as the expectation of the SSM, while the absence of *pep* neutrinos is disfavoured with a 5σ significance.

4.2. *Time modulations of neutrino signal*

The solar neutrino signal should follow the annual variations of the Sun-to-Earth distance, the effect appears as a 6.7% peak-to-peak seasonal amplitude modulation, with a maximum at the perihelion. The observation of seasonal variation would confirm the solar origin of the signal. Another possible modulation could be induced due to the Earth matter: neutrino are passing through the dense matter in the night and this could cause flavour regeneration with probability dependent on

Table 1. Results of Borexino-Phase II on the *pp*, ^{7}Be and *pep* solar neutrinos interaction rate. The first term of the associated uncertainty represents the statistical error obtained with a likelihood profile under the Wilk's approximation, while the second indicates the systematic uncertainty. The *pep* neutrino rate depends on the different SSM used to constrain the CNO neutrino flux, and therefore two results are quoted. The fluxes reported in the lower part of the table are computed assuming the MSW-LMA oscillation parameters[22]

Solar ν	**Borexino results** Rate (cpd/100 t)	**HZ SSM** Rate (cpd/100 t)	**LZ SSM** Rate (cpd/100 t)
pp	$134 \pm 10^{+6}_{-10}$	131.0 ± 2.4	132.1 ± 2.3
^{7}Be	$48.3 \pm 1.1^{+0.4}_{-0.7}$	47.8 ± 2.9	43.7 ± 2.6
pep (HZ)	$2.43 \pm 0.36^{+0.15}_{-0.22}$	2.74 ± 0.05	2.78 ± 0.05
pep (LZ)	$2.65 \pm 0.36^{+0.15}_{-0.24}$		
	Flux cm^{-2}s^{-1}	Flux cm^{-2}s^{-1}	Flux cm^{-2}s^{-1}
pp	$(6.1 \pm 0.5^{+0.3}_{-0.5}) \times 10^{10}$	$5.98(1 \pm 0.006) \times 10^{10}$	$6.03(1 \pm 0.005) \times 10^{10}$
^{7}Be	$(4.99 \pm 0.13^{+0.07}_{-0.10}) \times 10^9$	$4.93(1 \pm 0.06) \times 10^9$	$4.50(1 \pm 0.06) \times 10^9$
pep (HZ)	$(1.27 \pm 0.19^{+0.08}_{-0.12}) \times 10^8$	$1.44(1 \pm 0.009) \times 10^8$	$1.46(1 \pm 0.009) \times 10^8$
pep (LZ)	$(1.39 \pm 0.19^{+0.08}_{-0.13}) \times 10^8$		

the oscillation parameters. The fact of observation or non-observation of diurnal modulation can be used to restrict the neutrino oscillation parameters.

The seasonal modulation of the ^{7}Be neutrino signal was studied by Borexino collaboration in,[17,23] The earlier work was performed with Borexino Phase-I data acquired from May 2007 to May 2010; the period and phase were found to be consistent with a solar origin of the signal. More advanced analysis of 1456 astronomical days of Phase-II data can be found in more recent paper.[23] The analysis of neutrino signal variations on the many years time-scale is complicated by the presence of time-dependent background components. Three methods have been used to extract the time modulations: the analytical fit to event rate, and two more elaborated techniques: Lomb-Scargle and the Empirical Mode Decomposition. The results obtained with these methods are in excellent agreement. The duration of astronomical year measured with neutrino by using fit to the event rate is 367 ± 10 days with phase shift of $T_0 = 14 \pm 22$ days, i.e. in good agreement with the expected values. Also, the observe eccentricity $\epsilon = 0.0174 \pm 0.0045$ corresponds to the modulation amplitude of $(7.1 \pm 1.9)\%$.

In contrast to the annual signal modulation, no variation of day/night solar neutrino signal at the level of 1% is observed in Borexino data.[24] The measured asymmetry $A_{dn} = 0.001 \pm 0.012(stat) \pm 0.007(syst)$ agrees with the prediction of LMA solution for MSW mechanism. Moreover, this result disfavours MSW oscillations with mixing parameters in the LOW region at more than 8.5σ. The LOW

solution was previously excluded by using the reactor antineutrino data, which involves the assumption of CPT symmetry.

4.3. *Neutrino magnetic moment*

One of the explanation of recent puzzling result of the XENON1T collaboration at few keV electronic recoils could be due to the scattering of solar neutrinos with large Majorana transition magnetic moments[25] (MM). The required transition MM strengths lie within the range that can be probed by current or near future experiments.

Borexino is spectroscopic detector with a relatively good energy resolution at low energies of about 5% at 1 MeV. The spectroscopic feature provides a good possibility to search for the deviations from the standard shape of recoils electrons scattered off monoenergetic ^{7}Be neutrinos. The manifestation of the large neutrino magnetic moment in the electron recoils spectrum would be an additional term in the cross section with a characteristic $1/\mathrm{T}_e$ (T is electron recoil kinetic energy) signature. A sensitive search for the deviations of the electron recoil spectra from the predicted by the Standard Model was performed using Borexino Phase-II data in.[26] A model-independent limit on the effective moment of the solar neutrino of $\mu_{\text{eff}} < 2.810^{-11}\,\mu_B$ at 90% C.L. was obtained. This could be compared to the best direct limit on the magnetic moment of electron antineutrino $\mu_{\text{eff}} < 2.910^{-11}\,\mu_B$ at 90% C.L. obtained using Ge detectors in the most sensitive reactor experiment GEMMA.[27] The Borexino limit is free from uncertainties associated with predictions of the SSM neutrino flux and with the detector's fiducial volume, and is obtained by constraining the sum of the solar neutrino fluxes using the results from radiochemical (gallium) experiments.

Since neutrinos are a mixture of mass eigenstates the effective magnetic moment for neutrino-electron scattering is:

$$\mu^2_{\text{eff}} = \sum_j |\sum_k \mu_{kj} A_k(E_\nu, L)|^2, \tag{1}$$

where μ_{jk} is an element of the neutrino electromagnetic moments matrix and $A_k(E_\nu, L)$ is the amplitude of the k-mass state at the point of scattering. For the Majorana neutrino, only the transition moments are nonzero, while the diagonal elements of the matrix are equal to zero due to CPT-conservation. For the Dirac neutrino, all matrix elements may have nonzero values. The effective magnetic moment can be expanded both in terms of the mass eigenstates or the flavor eigenstates.

In the general case the expression for the effective magnetic moment in the mass eigenstate basis will have a complex form consisting of interference terms $\propto \mu_{jk}\mu_{ik}$. Without significant omissions the solar neutrinos arriving at the Earth can be considered as an incoherent mixture of mass eigenstates. In the case of Dirac

neutrinos assuming that only diagonal magnetic moments μ_{ii} are nonvanishing:

$$\mu^2_{\rm eff} = P^{3\nu}_{e1}\mu^2_{11} + P^{3\nu}_{e2}\mu^2_{22} + P^{3\nu}_{e3}\mu^2_{33} \tag{2}$$

where $P^{3\nu}_{ei} = |A_i(E,L)|^2$ is the probability of observing the i-mass state at the scattering point for an initial electron flavor.

In the case of Majorana transition magnetic moments the effective moment is:

$$\mu^2_{\rm eff} = P^{3\nu}_{e1}(\mu^2_{12} + \mu^2_{13}) + P^{3\nu}_{e2}(\mu^2_{21} + \mu^2_{23}) + P^{3\nu}_{e3}(\mu^2_{31} + \mu^2_{32}) \tag{3}$$

For the well-known approximation of three- to two- neutrino oscillation probabilities for solar neutrinos: $P^{3\nu}_{e1} = \cos^2\theta_{13}P^{2\nu}_{e1}$, $P^{3\nu}_{e2} = \cos^2\theta_{13}P^{2\nu}_{e2}$ and $P^{3\nu}_{e3} = \sin^2\theta_{13}$ – one can get the effective magnetic moment expressed in well-established oscillation parameters in the mass eigenstate basis. Equation (2) can be rewritten as:

$$\mu^2_{\rm eff} = C^2_{13}P^{2\nu}_{e1}\mu^2_{11} + C^2_{13}P^{2\nu}_{e2}\mu^2_{22} + S^2_{13}\mu^2_{33} \tag{4}$$

where $C^2_{13} \equiv \cos^2\theta_{13}$ and $S^2_{13} \equiv \sin^2\theta_{13}$, and $P^{2\nu}_{e1} + P^{2\nu}_{e2} = 1$. Similarly, assuming CPT-conservation ($\mu_{jk} = \mu_{kj}$) relation (3) for the transition moments can be rewritten as:

$$\mu^2_{\rm eff} = C^2_{13}P^{2\nu}_{e1}\mu^2_{12} + (1 - C^2_{13}P^{2\nu}_{e2})\mu^2_{13} + (1 - C^2_{13}P^{2\nu}_{e1})\mu^2_{23} \tag{5}$$

In general, $P^{2\nu}_{e1}$ and $P^{2\nu}_{e2}$ (and $P^{2\nu}_{ee}$) depend on the neutrino energy, but in the energy region below 1 MeV the probabilities can be assumed constant.

Since $\mu^2_{\rm eff}$ is the sum of positively defined quantities, one can constrain any term in (4) and (5). By using the most probable values of $P^{2\nu}_{ee}$, θ_{12} and θ_{13} one can obtain the following limits from the relation $\mu_{\rm eff} \leq 2.8 \times 10^{-11}\mu_B$:

$$|\mu_{11}| \leq 3.4; \quad |\mu_{22}| \leq 5.1; \quad |\mu_{33}| \leq 18.7; \tag{6}$$

$$|\mu_{12}| \leq 2.8; \quad |\mu_{13}| \leq 3.4; \quad |\mu_{23}| \leq 5.0; \tag{7}$$

all measured in units of $10^{-11}\mu_B$ and for 90% C.L.

The effective magnetic moment for the LMA-MSW solution in flavour basis assuming the survival probability of *pp* and ^{7}Be solar neutrinos is the same:

$$\mu^2_{\rm eff} = P^{3\nu}\mu^2_e + (1 - P^{3\nu})(\cos^2\theta_{23}\cdot\mu^2_\mu + \sin^2\theta_{23}\cdot\mu^2_\tau), \tag{8}$$

where $P^{3\nu} = \sin^4\theta_{13} + \cos^4\theta_{13}P^{2\nu}$ is the probability that ν_e is detected in its original flavor (survival probability), with $P^{2\nu}$ calculated in the "standard" 2-neutrino scheme, θ_{13} and θ_{23} are the corresponding mixing angles. Though $P^{2\nu}$ depends on E_ν, the difference between $P^{2\nu}(400) = 0.57$ for a neutrino energy close to the *pp*-neutrino spectrum end point of 420 keV (only a small fraction of the total *pp*-neutrino spectrum close to the end point contributes to the sensitive region in analysis) and $P^{2\nu}(862) = 0.55$ for ^{7}Be-neutrinos (higher energy line) is negligible. An estimate of $P^{2\nu} = 0.55$ was used in calculations.

The limits on the flavor magnetic moment can be obtained from (8) because individual contributions are positive. With $\mu_{\rm eff} < 2.8 \cdot 10^{-11}\mu_B$ and for $\sin^2\theta_{13} = 0.0210 \pm 0.0011$ and $\sin^2\theta_{23} = 0.51 \pm 0.04$ for normal hierarchy (or $\sin^2\theta_{23} = 0.50 \pm 0.04$ for inverted hierarchy) the following limits were obtained: $\mu_e < 3.9 \cdot 10^{-11}\mu_B$, $\mu_\mu < 5.8 \cdot 10^{-11}\mu_B$ and $\mu_\tau < 5.8 \cdot 10^{-11}\mu_B$, all at 90% C.L.

The values above were calculated for the choice of hierarchy providing a more conservative limit.

In another paper[28] the Borexino collaboration performed a search for the hidden antineutrino sources in the data. The presence of antineutrinos in original neutrino fluxes can be a consequence of neutrino electromagnetic interactions induced by the non-zero neutrino magnetic moment. The limit derived for solar antineutrino flux is 384 cm^{-2} s^{-1} (90% C.L.), assuming an undistorted solar ^{8}B neutrinos energy spectrum, corresponding to a neutrino-antineutrino transition probability $P_{\nu\to\overline{\nu}} < 7.2 \times 10^{-5}$ (90% C.L.) for E_ν above inverse beta-decay threshold of 1.8 MeV. Based on the upper limit of the antineutrino admixure in the Solar neutrino flux the following limit on the magnetic moment was obtained:

$$\mu_\nu < 6.0 \cdot 10^{-9} B_\perp[\text{kG}] \cdot \mu_B \ (90\%\ \text{CL}) \tag{9}$$

where $B_\perp$ is transverse component of the strength of the solar magnetic field. The estimates of B in the solar core varies by some orders of magnitude ranging from $B < 600$ G to $B < 7$ MG. These estimations correspond to upper limits of the neutrino magnetic moment between $1.0 \cdot 10^{-8}\mu_B$ and $8.5 \cdot 10^{-13}\mu_B$ (90% C.L.). The latter value is stronger than the current limit from astrophysical observations while the former limit is overlaid by other measurements.

4.4. *Neutrino non-standard interactions*

The observed neutrino contribution in Borexino spectra are determined by the fraction of the electron neutrino in the total neutrino flux at the surface of the Earth (or electron neutrino survival probability P_{ee}(E)), and the neutrino-electron scattering cross section defined by the chiral couplings of the neutrino and electron. Some theories beyond the Standard Model postulate the existence of Non-Standard Interactions (NSI's) which can modify the chiral couplings and P_{ee}. Phenomenologically, NSI's of the neutral current (NC) type are described by the Lagrangian density

$$\mathcal{L}_{\rm NSI} = -2\sqrt{2}G_F\varepsilon_{\alpha\beta}^{ff'C}(\bar{\nu}_\alpha\gamma^\mu\nu_\beta)(\bar{f}\gamma_\mu C f')$$

where $\alpha, \beta = e, \mu, \tau$ label the neutrino flavor, f and f' are leptons or quarks of the same charge but not necessarily the same flavor, C is the chirality of the ff' current (L or R), and $\varepsilon_{\alpha\beta}^{ff'C}$ is a dimensionless coupling constant parametrizing the strength of the NSI interaction normalized to G_F. In the Borexino data analysis

the attention was paid to the flavor-diagonal case $f = f' = e$ and $\alpha = \beta$, so it is convenient to denote $\varepsilon^{fC}_{\alpha\beta}$ as ε^{C}_{α}. Borexino, relying on neutrino-electron elastic scattering, is particularly sensitive to this type.

At detection, ε_α shifts the coupling constants that appear in the expression for the differential cross section for the weak interactions

$$g^C_\alpha \to \tilde{g}^C_\alpha = g^C_\alpha + \varepsilon^C_{\alpha\beta}$$

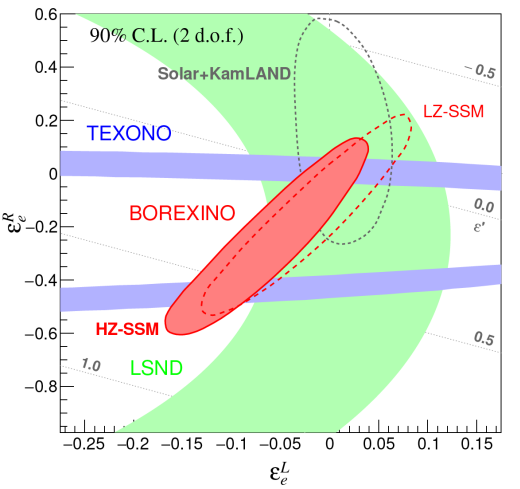

Fig. 5. Allowed region for NSI parameters in $\varepsilon^{L/R}_e$ plane obtained in.[29] The parameters $\varepsilon^{L/R}_\tau$ are fixed at zero. Both HZ- (filled red) and LZ- (dashed red) SSM's were considered. The bounds from the LSND and TEXONO experiments are provided for comparison. Besides, the contour obtained from the global analysis of solar neutrino experiments is presented by dashed black line,[30] NSI's are included in detection and propagation. All contours correspond to 90% C.L. (2 d.o.f.). The dotted gray lines represent the corresponding range of ε' parameter, relevant for NSI's at propagation.

The Borexino Phase II data data were used for the search of the flavor-diagonal neutral current interactions responsible for the ν_{ee} and and $\nu_{\tau e}$ couplings not excluded by other experiments. The solar luminosity constraints were implied to improve the sensitivity to the effects under study, both high- and low-metallicity (HZ and LZ) Standard Solar Model (SSM) predictions of the solar neutrino fluxes were considered. No indications of new physics were found at the level of sensitivity of the detector. The constraints on the parameters of the NSI's were obtained[29] compatible with or better than the existing ones. The results for $\varepsilon^{L/R}_e$ and $\varepsilon^{L/R}_\tau$ parameters are shown in Fig. 5 and Fig. 6 correspondingly.

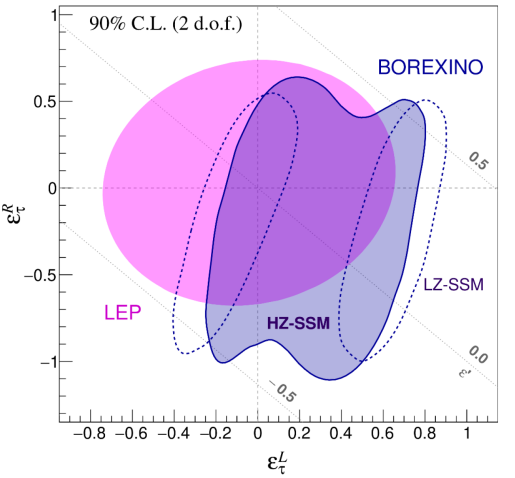

Fig. 6. Allowed region for NSI parameters in $\varepsilon_\tau^{L/R}$ plane obtained in.[29] The $\varepsilon_e^{L/R}$ are fixed at zero. Both HZ- (filled dark blue) and LZ- (dashed dark blue) SSM'sare considered. The contour from LEP experiment is provided for comparison. Both contours correspond to 90% C.L. (2 d.o.f.). The dotted gray lines represent the corresponding range of ε' parameter, relevant for NSI's at propagation.

5. High-energy solar neutrinos in Borexino

As already discussed, Borexino's original goal was the measurement of low energy solar neutrinos and this objective was fully centered. However, through the years, Borexino turned out to be a quite versatile experiment and the collaboration succeeded in measuring also neutrinos belonging to the above-MeV part of the solar neutrino spectrum. In particular, in 2020, Borexino presented a refinement of the measurement of the ^{8}B solar neutrino interaction rate,[31] also setting a new limit on the interaction rate of solar *hep* neutrinos.

The High-Energy Region (HER) work is based on 2062.4 live days of data, collected between January 2008 and December 2016 (detector's purifications and calibrations period excluded). In order to better handling the backgrounds, the analysis is performed with MonteCarlo radial fits, independently performed on two energy subranges: the HER-I (1650, 2950 p.e., roughly 3.2-5 MeV) and the HER-II (2950, 8500 p.e., roughly 5-16 MeV). The HER-I sector includes events originated from natural radioactivity while the HER-II sector is characterized by intense external γ rays following the neutron capture processes that happens on the Stainless Steel Sphere. In Borexino, the energy depositions of natural radioactivity never exceeds 5 MeV (Q-value of the ^{208}Tl β decay) since the α scintillation signals are strongly quenched and end below this analysis threshold. As of 2020, the ^{8}B neutrinos are detected via their elastic scattering off electrons on a fiducial mass of 300 t of liquid scintillator (the entire Borexino active mass) resulting in a total exposure of

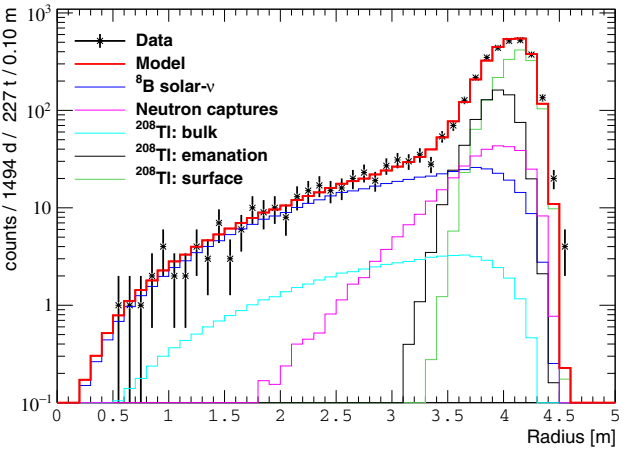

Fig. 7. Fit of the event radial distribution in the HER-I range[31] [1650,2950]p.e.

1.5 ktonne x year: an impressive 11.5-fold increase with respect to the previous Borexino ^{8}B measurement.[19]

In the HER analysis, the selection of data is performed via software cuts that tag/remove the primary/secondary backgrounds associated with the interaction of cosmic muons in the detector. The identification of the ^{8}B neutrino signal is then based on its different radial distribution with respect to that of background: neutrino events are expected to be uniformly distributed in the active volume while the remaining background event distribution is strongly radial dependent (Fig. 7).

The radial fit estimator is a binned likelihood and the χ^2/dof of the radial fits are 31.3/36 (HER-I), and 30.4/35 (HER-II) excluding empty bins.
The best-fit rates for the ^{8}B solar neutrinos are found to be:

$$R_{\mathrm{HER-I}} = 0.136\,^{+0.013}_{-0.013}\,(\mathrm{stat})\,^{+0.003}_{-0.003}\,(\mathrm{syst})\ \ \mathrm{cpd}/\,100\ \mathrm{t}$$
$$R_{\mathrm{HER-II}} = 0.087\,^{+0.080}_{-0.010}\,(\mathrm{stat})\,^{+0.005}_{-0.005}\,(\mathrm{syst})\ \ \mathrm{cpd}/\,100\ \mathrm{t}$$
$$R_{\mathrm{HER}} = 0.223\,^{+0.015}_{-0.016}\,(\mathrm{stat})\,^{+0.006}_{-0.006}\,(\mathrm{syst})\ \ \mathrm{cpd}/\,100\ \mathrm{t}$$

The precision of the HER ^{8}B rate analysis is then about 8% and it improves more than a factor 2 our previous result.[19] The equivalent ^{8}B neutrino flux inferred from the HER analysis[31] is $\Phi(^{8}\mathrm{B}) = 2.57\,^{+0.17}_{-0.18}\,(\mathrm{stat})\,^{+0.07}_{-0.07}\,(\mathrm{syst}) \times 10^{6}\ \mathrm{cm}^{-2}\,\mathrm{s}^{-1}$ well in agreement with the previous Borexino result[19] and with the high-precision measurement performed by Super Kamiokande.[32] The B16 HZ-SSM[7] expected ^{8}B neutrino flux is $5.46 \pm 0.66 \times 10^{6}\ \mathrm{cm}^{-2}\,\mathrm{s}^{-1}$ but the apparently missing flux is fully compatible the MSW-LMA neutrino oscillation scenario.

The Borexino experiment is not optimized for a clear detection of neutrino fluxes as low as those predicted by the SSM for the *hep* neutrinos ($\sim 10^{3}\ \mathrm{cm}^{-2}\,\mathrm{s}^{-1}$). Nevertheless, this elusive type of neutrinos is searched via their elastic scattering

on electrons as well as via their neutral current-mediated inelastic scattering on Carbon nuclei. The Borexino collaboration was able to set a limit on the number of expected *hep* events of 4.37 (90% C.L.), corresponding to a limit on the flux of $< 1.8 \times 10^5$ cm^{-2} s^{-1} which is about 1.2 times stronger than the one we previously reported in 2018.[11]

6. Conclusion and discussion

Solar neutrinos are an essential tool to understand stellar physics, being able at the same time to reveal some of their fundamental properties. The Borexino experiment, with its 14-years-long data taking, has been one of the key players in the investigation of these particles. Thanks to its outstanding radiopurity and to the deep understanding of the detector behaviour, Borexino has been able to overcome the intrinsic limitations of the previous generations of radiochemical experiments and to provide a precision measurement of all the components of the solar neutrino spectrum with the only exception of the very low flux of neutrinos from the Helium-proton fusion for which an upper limit has been set. In particular, in this contribution we report the Borexino results on neutrinos produced in the proton-proton fusion chain, which is by far the main energy production mechanism in our star. With a separate analysis of the low- and high-energy region of the energy spectrum, the individual fluxes of *pp*, *pep*, ^{7}Be and ^{8}B neutrinos were directly measured for the first time by a single experiment.

This result has significant implications for solar and particle physics: by measuring the flux of *pp* neutrinos with a 11% accuracy and the ^{7}Be flux with an unprecedented 3% precision, we could compute the luminosity of the Sun using neutrinos,[11] finding an excellent agreement with the photon-inferred result ($L_\odot^{\rm ph} = (3.846 \pm 0.015) \times 10^{33}\,{\rm erg\,s^{-1}}$ vs $L_\odot^{\nu} = (3.89^{+0.35}_{-0.42}) \times 10^{33}\,{\rm erg\,s^{-1}}$), thus confirming the nuclear origin of the solar power and the thermodynamical equilibrium of the Sun over the timescale required for radiation to flow from the core to the surface of the Sun, which is in the order of 10^5 years. Using the measurements of *pp* and ^{7}Be neutrino fluxes we could also study the relative weight of the two main terminations of the *pp*-chain (ppI and ppII in Fig. 1), which is the ratio $R_{\rm I/II}$ between the ^{3}He$-^4$He and ^{3}He$-^3$He fusion rates. Neglecting the small contribution of the ppIII branch and assuming the local kinetic equilibrium of ^{2}H and ^{3}He, we find $R_{\rm I/II} = 0.178^{+0.027}_{-0.023}$, in good agreement with the predictions of both the HZ and LZ SSM[11] ($R^{\rm HZ}_{\rm I/II} = 0.180 \pm 0.011$, $R^{\rm LZ}_{\rm I/II} = 0.161 \pm 0.010$). Furthermore, we could exploit the strong dependence of ^{7}Be and ^{8}B fluxes upon the Sun core temperature to test the predictions of the SSM implementing a different chemical composition. Changes in the Sun metallicity will indeed lead to different expectations of the temperature profile, affecting the expected neutrino fluxes. Borexino *pp*-chain results are compatible with the predictions of both HZ and LZ SSM,[11] but an hypothesis test show a mild preference for the higher core temperature expected from the HZ SSM.[11]

In its long scientific life, Borexino exceeded the expectations of its physics reach and is now among the leading solar neutrino experiments. This extraordinary journey recently culminated with the first observation of solar neutrinos from the CNO-cycle,[33] adding a new fundamental piece to our understanding of the Sun and of all stars.

The Borexino experiment, located at the Laboratori Nazionali del Gran Sasso in Italy, has been the first and so far unique experiment capable to measure the interaction rate of all solar neutrino components produced by the Sun through the so called *pp*-chain and CNO-cycle fusion mechanisms. Particularly, Borexino has measured the rate of *pp*, ^{7}Be, *pep* and ^{8}B neutrinos, which span a wide energy range from a few hundreds keV up to almost 15 MeV. This capability offered Borexino the unique opportunity to experimentally test the expected electron neutrino survival probability predicted by the theory. The paper briefly summarises this important achievement and discusses possible future developments.

Keywords: Solar neutrinos; electron neutrino survival probability; neutrino oscillations; LMA-MSW effect

1. Introduction

The Sun is a powerful source of low energy neutrinos that are a unique tool to test the solar theory and to probe neutrino physics. A remarkable set of discoveries have been made by means of solar neutrinos, among which the most important is the discovery electron neutrino oscillations into muon and tau neutrinos made by the SNO[1,2] experiment, which led to the Nobel prize of Art McDonald in 2015.[3]

It is quite well known that the stellar theory has long predicted two mechanisms for hydrogen fusion into helium in the Sun, known as the *pp*-chain and the

CNO cycle.[4] Both mechanism are based on a sequence of nuclear reactions, some of which produce electron neutrinos. The *pp*-chain is initiated by the fusion of two protons and produce neutrinos through four detectable mechanisms[a]. The CNO cycle bears this name because carbon, nitrogen and oxygen act as catalysers and produce neutrinos as well.[4] Fig. 1 shows the electron neutrino spectrum predicted by[4] without any neutrino oscillation effect.

The two fusion reactions occur in the Sun's core, and because of the relatively low solar temperature, they contribute very unequally to energy production: about 99% of the solar luminosity is due to the *pp*-chain, while the rest is due to the CNO cycle. The CNO cycle is dominant for more massive stars.

Borexino is the first experiment that was able to measure directly all individual solar neutrino components emitted by the *pp*-chain reactions[5] and by the CNO cycle in the Sun.[6] This fact is by itself a remarkable experimental achievement, which was obtained thanks to almost 30 years of activity.[7] It has also the consequence that the

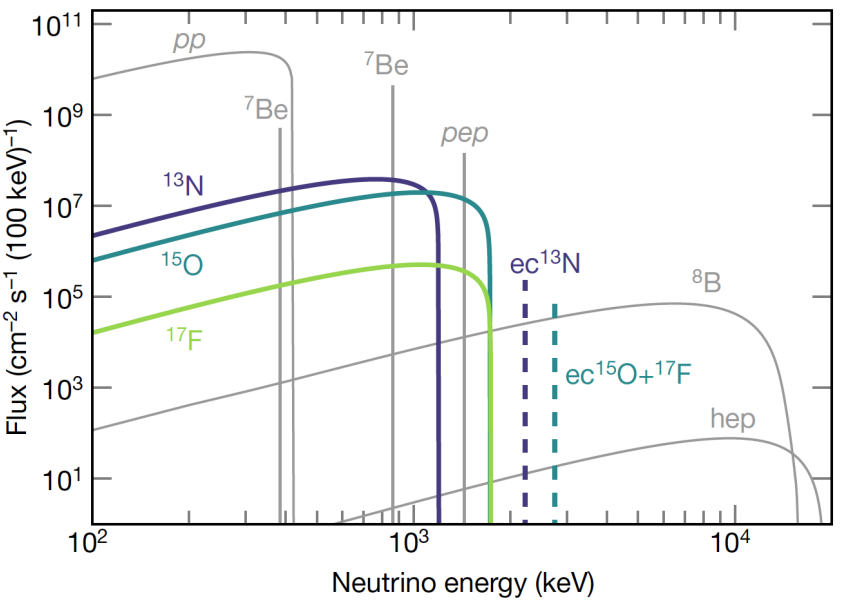

Fig. 1. The spectrum of solar neutrinos as predicted by Vinyoles et al. Hep neutrinos, while at high energy, have a flux that is too low to be detected by current generation experiments. All other components have been measured directly by Borexino through spectral analysis, exploiting the very low radioactive background, the low energy threshold and the good energy resolution of the liquid scintillator detector. Borexino has been so far the only experiment being able to perform such a comprehensive spectral measurement.

[a] A fifth mechanism due to the fusion of ^{3}He with a proton (hep neutrinos) is too small to be detected.

experiment was able to measure the survival probability of neutrinos as a function of the energy and to test directly the LMA-MSW[8] theory of neutrino oscillations. LMA refers to Large Mixing Angle solution, while MSW to the Mikheyev-Smirnov-Wolfenstein mechanism.[9–11]

According to MSW theory, at energy above a few MeV the different refractive index affecting the propagation of electron neutrinos with respect to that affecting the muon and tau neutrinos propagation introduce an additional phase shift that can change the survival probability of electron neutrinos from the central core to the Earth. At some energies the effect can be very large because of a resonance.[10,11] As a consequence, the LMA-MSW theory predicts that solar neutrino oscillations are strongly energy dependent and particularly are dominated by the matter effects above above a few MeV. Vacuum oscillations are dominant at lower energies.

When the LMA-MSW theory is taken into account, the neutrino fluxes predicted by the Standard Solar Model[4] are translated into a well defined prediction of the neutrino interaction rate in Borexino, which depends both on the total electron neutrino flux and on the fraction of electron neutrinos and other neutrino types reaching the Earth.

In this paper we show how the precision measurement pp, ^{7}Be, pep and ^{8}B neutrino rate made by Borexino translates into the first direct measurement of the electron neutrino survival probability as a function of the neutrino energy.

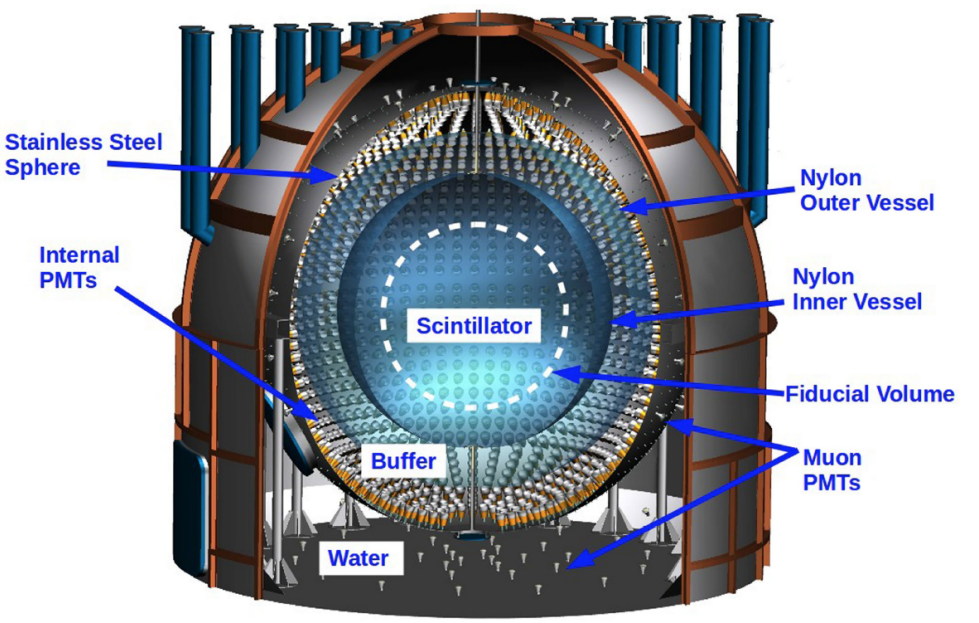

Fig. 2. Drawing of the Borexino detector. The various components are labelled in the picture. To give a feeling of the size, we quote the diameter of the Stainless Steel Sphere, which is 13.7 m.

2. The Borexino experimental setup

Borexino is a very pure liquid scintillator detector[12–15] designed for the real–time observation of low energy solar neutrinos. It is located in Italy deep underground ($\simeq$3800 meters of water equivalent, m w.e.) in the Hall C of the Laboratori Nazionali del Gran Sasso, where the muon flux is suppressed by a factor of $\approx 10^6$ with respect to sea level.

The detector is schematically depicted in Fig. 2. The inner part is an unsegmented stainless steel sphere (SSS) that is both the container of the scintillator and the mechanical support of the photomultipliers. Within this sphere, two nylon vessels separate the scintillator volume in three shells of radii 4.25 m, 5.50 m and 6.85 m, the latter being the radius of the SSS itself. The inner nylon vessel (IV) contains the liquid scintillator solution, namely PC (pseudocumene, 1,2,4-trimethylbenzene $C_6H_3(CH_3)_3$) as a solvent and the fluor PPO (2,5-diphenyloxazole, $C_{15}H_{11}NO$) as a solute at a concentration of approximately 1.5 g/l (0.17 % by weight). The second and the third shell contain PC with a small amount (few g/l) of DMP (dimethylphthalate, $C_6H_4(COOCH_3)_2$) that is added as a light quencher in order to further reduce the scintillation yield of pure PC.[12]

The Inner Vessel is made of 125 μm thick Nylon-6 carefully selected and handled in order to achieve maximum radio–purity. Since the PC/PPO solution is slightly lighter (about 0.4 %) than the PC/DMP solution, the Inner Vessel is anchored to the bottom (south pole of the SSS) with a set of nylon strings. The outer nylon vessel (OV) has a diameter of 11 m and is built with the same material as the inner one. The OV is a barrier that prevents ^{222}Rn emanated from the external materials (steel, glass, photomultiplier materials) to di?use into the fiducial volume.

The buffer fluid between the Inner Nylon Vessel and the SSS (PC/DMP solution) is the last shielding against external backgrounds. The use of PC as a buffer is convenient because it matches both the density and the refractive index of the scintillator, thus reducing the buoyancy force for the nylon vessel and avoiding optics aberrations that would spoil the spatial resolution.

The addition of the DMP quenches the scintillation yield of the buffer fluid by a factor of 20. This is important in order to avoid the unacceptable trigger rate due to the radioactivity of the photomultipliers.

The scintillation light is collected by nominally 2212 photomutipliers (PMTs) that are uniformly attached to the inner surface of the SSS. All but 384 photomultipliers are equipped with light concentrators that are designed to reject photons not coming from the active scintillator volume, thus reducing the background due to radioactive decays originating in the buffer liquid or γ's from the PMTs. The PMTs without concentrators are used to measure this background, and to help identify muons that cross the buffer, but not the Inner Vessel.

The number of active PMTs has changed over time during the almost 15 years of data taking, so that collection efficiency is a function of time and run–dependent.

The SSS is supported by 20 steel legs and enclosed within a large tank that is filled with ultra-pure water. The tank has a cylindrical base with a diameter of 18 m and a hemispherical top with a maximum height of 16.9 m. The Water Tank (WT) is a powerful shielding against external background (γ rays and neutrons from the rock) and is also used as a Cherenkov muon counter and muon tracker. The muon flux, although reduced by a factor of 10^6 by the 3800 m w.e. depth of the Gran Sasso Laboratory, is of the order of 1 m^{-2} h^{-1}, corresponding to about 4000 muons per day crossing the detector. This flux is well above Borexino requirements and a strong additional reduction factor (about 10^4) is necessary and was indeed achieved[13] by the combined use of WT signal and inner detector signal. More details on the detector can be found in.[12,13]

3. Neutrino detection

Low energy neutrinos of all flavours are detected by means of their elas- tic scattering off electrons or, in the case of electron anti–neutrinos, by means of their inverse beta decay on protons or carbon nuclei. The electron (positron) recoil energy is converted into scintillation light, which is then collected by a set of pho- tomultipliers. Neutron detection is often possible as well, through its capture on proton and emission of energetic gamma. A tiny amount of Cherenkov light is also produced, though it is mostly absorbed and re–emitted.

Scintillation light offers several advantages with respect to both the water Cherenkov detectors and the older radiochemical detectors used before Borexino in solar neutrino experiments. Water Cherenkov detectors, in fact, can not effectively detect solar neutrinos whose energy is below approximately 3.5 MeV, both because the Cherenkov light yield is low and because the intrinsic radioactive background cannot be pushed down to suffciently low levels. On the other hand, radiochemical experiments cannot intrinsically perform spectral measurements and do not detect events in real time. Cherenkov detector, however, can effciently detect the direction of the scattered electron and therefore of the incoming neutrino, which is not possible yet in liquid scintillators.

A liquid scintillator, on the other hand, solves these problems: the detection of low energy neutrino becomes possible possible because the light yield is high, offering an energy threshold as low as a few tens ofkeV[b]; the organic nature of the scintillator, and its liquid form at ambient temperature, provide very low solubility of ions and metal impurities, and yield the technical possibility to purify the material as required. However, no measurement of the direction of the incoming neutrino is possible[c] and, even more importantly, the neutrino induced events are intrinsically

[b]However, the unavoidable contamination of ^{14}C that is present in any organic liquid practically limits the "neutrino window" above ?200 keV

[c]Very recently Borexino has shown that some of this prompt Cherenkov light can be detected and identified. Future detector might be able to make useful use of this additional information.

indistinguishable from β and γ radioactivity, posing formidable requirements in terms of radio–purity of the scintillator and of the detector materials.

The total number of detected photons and their arrival times are used to reconstruct the electron recoil energy and the interaction point in the detector, respectively. The energy and spatial resolution of Borexino is not constant because it has slowly deteriorated over time owing to the steady loss of photomultiplier tubes (on average 1238 channels were active during the recent CNO analysis, with larger numbers available at the time of *pp*-chain analysis), with current values of $\sigma_E/E \approx 6\%$ and $\sigma_{x;y;z} \approx 11$ cm for 1 MeV events at the centre of the detector. The time profile of the scintillation light provides also a powerful way to distinguish between different particle types α, β and β^+ via pulse-shape discrimination methods.[16,17]

The final radio–purity levels achieved by Borexino on ^{238}U and ^{232}Th chains, and on several other radioactive contaminants, are many orders of magnitude lower than those either set as design goals or achieved by any other low–background experiment. In this short paper it is simply not possible to give an account of the amount of work done, nor a detailed description of the final numbers obtained. We invite the interested reader to look at the bibliography and particularly to[16,17] and references therein.

The total cross section of electron neutrinos on electrons depends on both charged and neutral currents weak interactions, while that of muon and tau neutrinos is induced by neutral currents only. The interaction rate depends therefore on the neutrino type at the target, a fact that makes the experiment sensitive to neutrino oscillations occurring along the path from the production site in the Sun's up to the detector. This is the key element that allows the direct measurement of the energy dependence of the flavour conversion probability through the Sun induced by the LMA-MSW effect.

The extraction of the survival probability can be obtained from the measured rate using the total fluxes predicted by the Standard Solar Model through the formula:

$$R_x(E) = \Phi_x \left[P_{ee}(E)\sigma_e + (1 - P_{ee}(E))\,\sigma_\mu\right] \tag{1}$$

where R_x is the measured rate of the x neutrino component with average energy E (x can be *pp*, ^{7}Be, *pep*, ^{8}B), Φ_x is the predicted electron neutrino flux of the x component at the Sun's core, P_{ee} is the electron neutrino survival probability, and σ_e and σ_μ are the neutrino-electron total cross sections for electron and muon neutrinos respectively. It is clear from the equation above that for any given measured rate the corresponding value of P_{ee} can be directly measured using as inputs the very well known standard model cross sections (which introduce a negligible uncertainty) and the solar model predictions, which drive most of the uncertainty beside experimental errors.

At the time of the proposal, the main goal of Borexino was the precise measurement of the rate induced by the monochromatic electron neutrinos (0.862 keV)

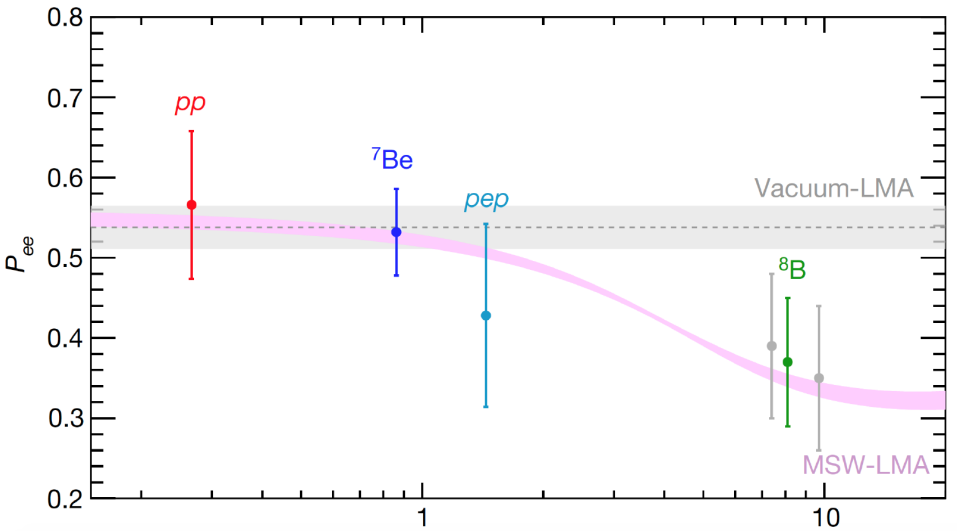

Fig. 3. The measured survival probability for the four neutrino components of the *pp*-chain. The pink band is the theoretical prediction of the P_{ee} with its uncertainty. The error on each value of P_{ee} depends on both theoretical errors and experimental error. See text for more details.

produced by the electron capture decay of ^{7}Be in the Sun. However, the very high radio purity of the scintillator offered new unexpected results, such as a clear evidence of the *pep* solar neutrinos,[18] a low energy threshold (3 MeV) detection of ^{8}B neutrinos,[19] the first direct measurement of *pp* neutrinos,[20] an unambiguous detection of geo-neutrinos,[21–23] and, last but definitely not least, the first prove of the existence of the CNO cycle in the Sun.[6]

After a careful detector calibration with internal sources[15] and an extensive purification campaign performed in 2010-2011, the complete *pp*-chain has been studied. This chain includes four reactions that emit four electron neutrino components of quite different energies: the *pp* neutrinos, whose average energy is around 200 keV, the ^{7}Be neutrinos, which offer a monochromatic line at 0.862 keV, the *pep* neutrinos, which offer another monochromatic line at 1.44 MeV, and ^{8}B neutrinos, which have a broad β^+ energy spectrum reaching about 15 MeV. These four neutrino components have very different survival probabilities in the Sun matter because of MSW effect, as we will see in the next section.

Although not relevant for LMA-MSW measurement, it is worth recalling that Borexino, after a substantial effort devoted to the thermal stabilisation of the detector developed in 2016-2018, has been able to measure the small and diffcult CNO neutrino signal.

In next section we focus on the complete measurement of the *pp*-chain neutrinos and on the consequence of these measurements to the knowledge of LMA-MSW effect in the Sun.

4. Electron neutrino survival probability measurement

The neutrinos produced in the *pp*-chain fusion reactions are all electron neutrinos because they originate from reactions with either an electron in the initial state (^{7}Be and *pep*) or with a positron in the final state (^{8}B and *pp*). However, neutrinos may undergo flavour transitions through the propagation inside solar matter, in the vacuum between the Sun and the Earth and, in the case of ^{8}B neutrinos, also while propagating at night through the Earth itself.

Without matter effects the conversion probability would be just a constant that depends on the vacuum mixing angle θ_{12}, with very little dependence on the other mixing angles and no dependence at all on mass splittings, because for solar neutrinos quantum coherence is completely lost. Indeed, coherence is washed out by the fact that the core of the Sun (diameter approximately 200.000 km) is comparable to the wavelength induced by mass-splitting at solar energies $(2\pi\ E/(1.27 \cdot \delta m^2_{12}) \simeq (2\pi\ 1\ MeV)/(1.27 \cdot 7.\ 10^{-5}\ eV^2) \simeq 70.000$ km) and also because the relative high temperature inside the Sun induce full decoherence of the neutrino beam ($k_B T \gg \delta m_{12}$).

However, since the late '80s and early '90s it was noticed that neutrino flavour oscillations may explain the solar neutrino problem only by assuming that the survival probability is energy dependent, chiefly because the neutrino deficit observed by Gallex[24] and SAGE[25] was different from that observed by Homestake[26] and also from that observed by the SuperKamiokande experiment.[27] The LMA-MSW effect provides an elegant mechanism to recover the energy dependence of the survival probability and Borexino is the first experiment which has been able to test it directly by measuring the survival probability of several neutrino components of various energies.

The LMA-MSW theory predicts a very well defined value of P_{ee} which is shown in Fig. 3 as a pink band whose thickness corresponds to the theoretical error. The same figure also shows the result of the P_{ee} computed using Borexino data using the measurements of *pp*, ^{7}Be, *pep* and ^{8}B neutrinos by means of formula (2). Neutrinos from *pp* initial fusion into deuteron are very low energy and their flavour conversion is dominated by vacuum oscillations. The grey band labelled as Vacuum-LMA corresponds to:

$$P_{ee}^{vac} = 1 - \frac{1}{2}\sin^2 2\theta_{12}\,, \tag{2}$$

which is the expected value for vacuum oscillations in case of completely incoherent propagation.

The neutrinos produced by ^{7}Be electron capture and *pep* three body fusion are mono–chromatic, so they bear no uncertainty in horizontal axis. *pep* is well within the transition region and shows a hint of that, with a large statistical uncertainty. ^{7}Be energy is still in the vacuum regime region and its corresponding P_{ee} is well consistent with that. Finally, ^{8}B neutrinos, on the other side, are well within the matter dominated LMA-MSW regime. Being a broad β^+ spectrum it is possible

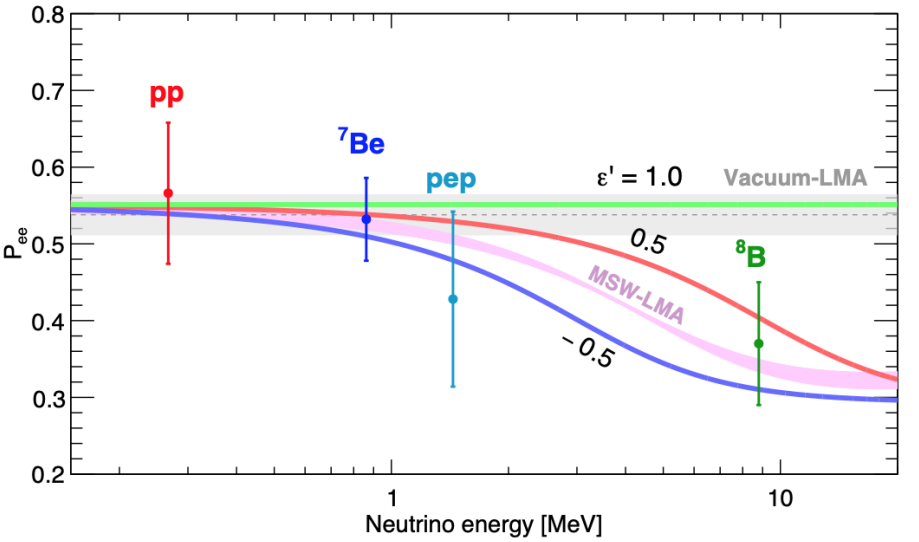

Fig. 4. Electron neutrino survival probability P_{ee} as a function of neutrino energy in LMA-MSW solution with uncertainties of oscillation parameters taken into account (pink band), and LMA-MSW + NSI solutions for ϵ'= -0.5, 0.5, 1.0 and average values of oscillation parameters. Vacuum oscillations scenario with LMA-MSW parameters is also shown (grey band). The definition of the non–standard interaction parameter is that of reference.[28]

to bin in energy, offering the data points shown in grey, while the green one is the average value. The error are too large, however, to show any hint of the expected rise of P_{ee} at lower energies (the slight uprise of the points has no real statistical significance, though consistent).

Globally, Borexino data clearly are well consistent with the theoretical expectation, confirming LMA-MSW effect, though the error are still large. Unfortunately, there is no room for Borexino to improve further.

In order to improve the result significantly two elements are important, depending on the energy. The ^{7}Be point has an error dominated by the theoretical uncertainty on the expected flux, while other points have also a relevant error coming from the rate measurement. Therefore, a better test of LMA-MSW theory requires an improvement in the Standard Solar Model predictions. For a discussion of the main sources of uncertainties see.[5]

The result obtained on the P_{ee} can be used to test the existence of low energy non–standard neutrino interactions beyond those predicted by the Standard Model. We have carefully studied this opportunity, parametrising the effect of non–standard interactions in terms of a single parameter ϵ'.[28] Fig. 4 shows that with the current theoretical and experimental uncertainties there is still quite a lot of room for new physics and that the future better measurement of this curve might be worth pursuing.

5. Conclusions

Borexino is the first and sole experiment able to measure all neutrino components from *pp*-chain reactions in the Sun and probe the electron neutrino survival probability as a function of energy.

The results confirm the LMA-MSW scenario with nice agreement with Standard Model physics. The precision is still low and room for new physics exists.

Borexino has opened the era of precise solar neutrino spectroscopy, but even better experiments are desirable to complete the job.

Acknowledgements

I thank the organisers of the Sixteenth Marcel Grossman meeting for the beautiful conference and for offering me the opportunity to give this talk. I am also grateful to the whole Borexino Collaboration for the long and beautiful journey we made all together. Finally, I warmly thank the Laboratori Nazionali del Gran Sasso for the continual support given to Borexino over a period of more than thirty years.

We discuss the present status of Standard Solar Models in order to provide the scientific framework to fully understand the relevance of the latest solar neutrino flux measurements performed by Borexino. After reviewing recent Standard Solar Model calculations, we discuss the solar abundance problem and the composition-opacity degeneracy. We then focus on hydrogen burning and neutrino production in Sun, discussing an analytical model that helps understanding the dependence of neutrino fluxes on solar core temperature and composition and the possibility they offer for determining physical characteristics of the solar interior.

Keywords: Solar neutrino fluxes, solar physics, solar models

1. Introduction

Being the closest star to us, the Sun can be investigated by a variety of different approaches/messengers. We can e.g. study the electromagnetic radiation that is emitted from its photosphere, determining its luminosity $L_\odot$, surface temperature $T_{\rm eff}$ and radius $R_\odot$. By looking at the absorption lines that are formed in the solar atmosphere, we are also able to infer the surface composition through spectroscopic techniques, more precisely the present-day abundance of chemical elements relative to hydrogen, usually summarized in the metal-to-hydrogen ratio $(Z/X)_\odot$. At the same time, the properties of the solar core, in particular its temperature and composition, can be probed by measuring the fluxes of neutrinos produced by nuclear reactions responsible for hydrogen burning. Finally, the properties of the solar interior, namely the sound speed stratification and the depth and helium abundance of

the external convective envelope, can be inferred with high accuracy by helioseismology, i.e. by looking at non-radial oscillations of the solar surface. As a result of these observations, we have a redundancy of experimental information that make the Sun an over-constrained system. This allows us to use the Sun as a laboratory for fundamental physics and a benchmark for stellar astrophysics.

As a remarkable example, the development of increasingly more precise Standard Solar Models[1,2] (SSMs), i.e. self calibrated theoretical models of the solar interior that automatically implements the observational values of $L_\odot$, $R_\odot$ and $(Z/X)_\odot$ and have no free parameters, and the fact that they were able to successfully reproduce the tight constraints imposed by helioseismology,[3] suggested that solution of the solar neutrino problem had to be found outside the realm of astrophysics, as had originally been suggested a few years earlier.[4] Simultaneously, Super-Kamiokande[5,6] led to the precise measurement of ^{8}B neutrino flux which, in combination with the results of radiochemical experiments Homestake,[7] Gallex[8] and SAGE[9] strongly hinted at the existence of solar neutrino oscillations, result confirmed just a few years later by SNO results.[10,11]

The discovery of neutrino oscillations and the accurate and precise determination of neutrino fluxes from individual reactions changed the focus of interest of solar physics. Starting from 2007, Borexino has obtained an almost complete characterization of the spectrum of neutrinos from the pp-chain.[12,13] Together with the very precise measurement of the ^{8}B flux from SNO[14] and Super-Kamiokande,[15] we have come full circle and results from solar neutrino experiments can now be used to learn about the properties of the Sun. This is timely. There is a lingering dispute about which is the detailed chemical composition of the Sun, the solar abundance problem, that is intimately linked to the uncertainties in our knowledge of radiative opacities in the solar interior. Solar neutrino data can in principle be used to disentangle this problem,[16–18] in particular if the promising results by Borexino on solar CN neutrinos[19] can be further improved.

The goal of this work is to discuss the present status of SSMs and to provide the scientific framework to fully understand the relevance of the recent solar neutrino flux measurements performed by Borexino. After reviewing recent SSM calculations (Sect. 2), we discuss the solar abundance problem (Sect. 3) and the composition-opacity degeneracy (Sect. 4). We then focus on hydrogen burning (Sect. 5) and solar neutrino production (Sect. 6), discussing an analytical model (Sect. 7) that helps understanding the dependence of neutrino fluxes on solar core temperature, composition and nuclear cross sections, and the possibility they offer for determining physical characteristics of the solar interior (Sect. 8).

2. Standard solar models

SSMs are a snapshot in the evolution of a $1\,M_\odot$ star, calibrated to match present-day surface properties of the Sun. Two basic assumptions in SSM calculations are: 1) after the phase of star formation the Sun was chemically homogenized as a

result of the fully convective phase during its contraction along the Hayashi track and before nuclear reactions start altering its initial composition and, 2) at all moments during its evolution up to the present solar age $\tau_\odot = 4.57\,\mathrm{Gyr}$ mass loss is negligible. The calibration is done by adjusting the mixing length parameter (α_{MLT}) and the initial helium and metal mass fractions (Y_{ini} and Z_{ini} respectively) in order to satisfy the constraints imposed by the present-day solar luminosity $\mathrm{L}_\odot = 3.8418 \times 10^{33}\,\mathrm{erg\,s^{-1}}$, radius $\mathrm{R}_\odot = 6.9598 \times 10^{10}\mathrm{cm}$,[20] and surface metal to hydrogen abundance ratio $(\mathrm{Z/X})_\odot$, see sect.3. As a result of this procedure, SSM has no free parameters and completely determines the physical properties of the Sun. It can be then validated (or falsified) by other observational constraints, in particular by those provided by solar neutrino fluxes measurements and helioseismic frequencies determinations.

The physics input in the SSM is rather simple and it accounts for: convective and radiative transport of energy, chemical evolution driven by nuclear reactions, microscopic diffusion of elements which comprises different processes but among which gravitational settling dominates. For over more than 25 years, since the modern version of the SSM was established with the inclusion of microscopic diffusion,[21,22] the continuous improvement of the constitutive physics has brought about the changes and the evolution of SSMs. In particular, a lot of effort has gone into experimental and theoretical work on nuclear reaction rates. But changes in radiative opacities and the equation of state were also relevant. We take here as a reference the results of recent SSM calculations,[23] the so-called Barcelona 2016 (B16, for short) SSMs, which are based on the following state of the art ingredients. The equation of state is calculated consistently for each of the compositions used in the solar calibrations by using FreeEOS.[24] Atomic radiative opacities are from the Opacity Project (OP),[25] complemented at low temperatures with molecular opacities from Ref. 26. Nuclear reaction rates for the pp-chain and CNO-bicycle are from the Solar Fusion II compilation[27] with important updates for the rates of $\mathrm{p(p},e^+\nu_e)\mathrm{d}$, $^7\mathrm{Be(p},\gamma)^8\mathrm{B}$ and $^{14}\mathrm{N(p},\gamma)^{15}\mathrm{O}$ reactions, see Refs. 28–32. Microscopic diffusion coefficients are computed as described in Ref. 33. Convection is treated according to the mixing length theory.[34] The atmosphere is grey and modeled according to a Krishna-Swamy $T-\tau$ relationship.[35]

3. The solar composition problem

The solar surface composition, determined with spectroscopic techniques, is a fundamental input in the construction of SSMs. The development of three dimensional hydrodynamic models of the solar atmosphere, of techniques to study line formation under non-local thermodynamic conditions and the improvement in atomic properties (e.g. transition strengths) have led since 2001 to a complete revision of solar abundances. Table 1 lists the abundances determined by different authors for the most relevant metals in solar modeling: GN93,[36] GS98,[37] AGSS09,[38] C11,[39] AGSS15,[40–42] and AAG20.[43]

Table 1. Solar photospheric composition through time and authors for most relevant metals in solar modeling. Abundances are given in the standard astronomical scale $\epsilon_i = \log_{10}(n_i/n_{\rm H}) + 12$, where n_i is the number density of a given atomic species.

El.	GN93	GS98	AGSS09	C11	AGSS15	AAG20
C	8.55	8.52	8.43	8.50	—	8.46
N	7.97	7.92	7.83	7.86	—	7.83
O	8.87	8.83	8.69	8.76	—	8.69
Ne	8.08	8.08	7.93	8.05	7.93	8.06
Mg	7.58	7.58	7.60	7.54	7.59	7.55
Si	7.55	7.55	7.51	7.52	7.51	7.51
S	7.33	7.33	7.13	7.16	7.13	7.12
Fe	7.50	7.50	7.50	7.52	7.47	7.46
$(Z/X)_\odot$	0.0245	0.0230	0.0180	0.0209	—	0.0187

Note that only abundances relative to hydrogen can be obtained from spectroscopy because the intensity of spectroscopic lines is measured relative to a continuum that is determined by the hydrogen abundance in the solar atmosphere. The last row in the table gives the total photospheric present-day metal-to-hydrogen ratio $(Z/X)_\odot$ and it is the quantity used as observational constraint to construct a solar model. In fact, the solar composition set used in solar models determines not only $(Z/X)_\odot$ but also the relative abundances of metals in the models. In this sense, $Z_{\rm ini}$ acts as a normalization factor that, together with $Y_{\rm ini}$ and the relation $X_{\rm ini} + Y_{\rm ini} + Z_{\rm ini} = 1$, determines completely the initial composition of the model.

There is no complete agreement among authors, and some controversy still remains as to what the best values for the new spectroscopic abundances are. See in particular recent work on solar oxygen,[44] based on the same 3D atmosphere models as used by the Asplund group, but improved atomic data and methods, leads to $\epsilon_{\rm O} = 8.75 \pm 0.03$, i.e. very close to the C11 value. However, at the moment there seems to be consensus in that all determinations of the solar metallicity based on the new generation of spectroscopic studies yield a solar metallicity lower than older spectroscopic results,[36,37] in particular for the volatile and most abundant C, N, and O. For refractories elements, like Fe, Si, Mg and S that have important role in solar modeling being important contributors to the radiative opacity, meteorites offer a very valuable alternative method (see e.g. Ref. 45) and, in fact, elemental abundances determined from meteorites have been historically more robust than spectroscopic ones.

Considering that uncertainties of element abundances are difficult to quantify, it has become customary to consider two canonical sets of abundances to which we refer to as high metallicity (HZ) and low metallicity (LZ) solar admixtures as reference assumptions for SSM calculations. These are obtained by using the photospheric (volatiles) + meteoritic (refractories) abundances from GS98 and AGSS09 respectively, and are reported in Table 2. In the last column, we give the fractional differences $\delta z_i \equiv z_i^{\rm HZ}/z_i^{\rm LZ} - 1$ where $z_i \equiv Z_i/X$ is the ratio of the $i-$element

Table 2. The two canonical HZ and LZ solar mixtures given as $\epsilon_i = \log_{10}(n_i/n_{\rm H}) + 12$. The two compilations are obtained by using the photospheric (volatiles) + meteoritic (refractories) abundances from GS98 and AGSS09 respectively, and correpond to the admixture labelled as GS98 and AGSS09met in Ref. 23.

abundance with that of hydrogen, to facilitate comparison among the two admixtures. Even if GS98 abundances are presumably surpassed by the more recent determinations, they are still considered as a valid option to construct solar models because they lead to a temperature stratification that well reproduces the helioseismic constraints.

This can be better appreciated by considering Tab. 3 and Fig. 1 where we compare theoretical predictions of SSMs implementing HZ and LZ surface composition with helioseismic determinations of the surface helium abundance $Y_{\rm s}$, of the convective envelope depth $R_{\rm CZ}$ and the solar sound speed $c_\odot(r)$. We see that solar models implementing the LZ abundances fail to reproduce all helioseismic probes of solar properties. This disagreement constitutes the so-called *solar abundance problem*[46–48] that has defied a complete solution. All proposed modifications to physical processes in SSMs offer, at best, only partial improvements in some helioseismic probes (e.g.[49–53]). An alternative possibility is to consider modifications to the physical inputs of SSMs at the level of the constitutive physics, radiative opacities in particular (see next section).

4. The opacity-composition degeneracy

The interpretation of the solar abundance problem is complicated by the degeneracy between effects produced by a modification of the radiative opacity $\kappa(\rho, T, Y, Z_i)$ and effects induced by a change of the heavy element admixture $\{z_i\}$, expressed here in terms of the quantities $z_i \equiv Z_i/X$ where Z_i is the surface abundance of the i-element and X is that of hydrogen.

This degeneracy was discussed in quantitative terms in Ref. 55 by using the linear solar model (LSM) approach introduced in Ref. 56. By neglecting the role of

Table 3. Main characteristics of SSMs with different surface composition.[23] The observational values for Y_s and R_{CZ} are taken from Ref. 46 and 54, respectively. The quantity $\delta c/c = (c_\odot - c_{mod})/c_{mod}$ is the fractional difference between sound speed helioseismic determination and model prediction.

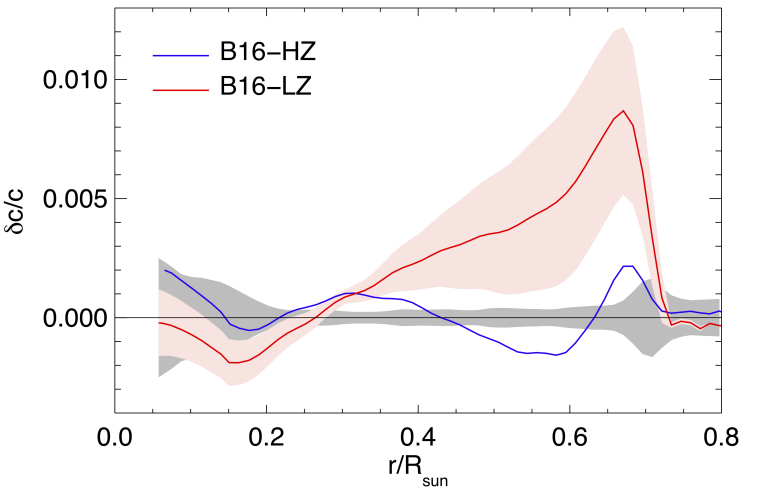

Fig. 1. Fractional sound speed difference in the sense $\delta c/c = (c_\odot - c_{mod})/c_{mod}$. Grey shaded regions corresponds to errors from helioseismic inversion procedure. Red shaded region corresponds to uncertainties in SSM predictions which we chose to plot around the B16-LZ central value (solid red line). An equivalent relative error band holds around the central value of the B16-HZ central value (solid blue line) which we do not plot for the sake of clarity.

metals in the equation of state and in the energy generation coefficient, it was shown that the source term $\delta\kappa(r)$ that drives the modification of the solar properties and that can be constrained by observational data can be written as the sum of two contributions:

$$\delta\kappa(r) = \delta\kappa_I(r) + \delta\kappa_Z(r) \quad (1)$$

The first term $\delta\kappa_{\rm I}(r)$, which we refer to as *intrinsic* opacity change, represents the fractional variation of the opacity along the solar profile and it is given by:

$$\delta\kappa_{\rm I}(r) = \frac{\kappa(\overline{\rho}(r), \overline{T}(r), \overline{Y}(r), \overline{Z}_i(r))}{\overline{\kappa}(\overline{\rho}(r), \overline{T}(r), \overline{Y}(r), \overline{Z}_i(r))} - 1 \tag{2}$$

where the notation $\overline{Q}$ indicates, here and in the following, the value for the generic quantity Q in reference SSM calculation. The second term $\delta\kappa_{\rm Z}(r)$, which we refer to as *composition* opacity change, describes the effects of a variation of $\{z_{\rm i}\}$. It takes into account that a modification of the photospheric admixture implies a different distribution of metals inside the Sun and, thus, a different opacity profile, even if the function $\kappa(\rho, T, Y, Z_i)$ is unchanged. The contribution $\delta\kappa_{\rm Z}(r)$ is given by:

$$\delta\kappa_{\rm Z}(r) = \frac{\overline{\kappa}(\overline{\rho}(r), \overline{T}(r), \overline{Y}(r), Z_i(r))}{\overline{\kappa}(\overline{\rho}(r), \overline{T}(r), \overline{Y}(r), \overline{Z}_i(r))} - 1 \tag{3}$$

where $Z_i(r) \simeq \overline{Z}_i(r)\,(z_i/\overline{z}_i)$ and can be calculated as:

$$\delta\kappa_{\rm Z}(r) \simeq \sum_i \left.\frac{\partial \ln \overline{\kappa}}{\partial \ln Z_i}\right|_{\rm SSM} \delta z_i \tag{4}$$

where δz_i represents the fractional variation of z_i and the symbol $|_{\rm SSM}$ indicates that we calculate the derivatives along the density, temperature and chemical composition profiles predicted by the reference SSM. Equation (1), although being approximate, is quite useful because it makes explicit the connection (and the degeneracy) between the effects produced by a modification of the radiative opacity and of those produced by a modification of the heavy element admixture.

Early works[57,58] suggested that a localized increase in opacities could solve or, at least, alleviate the disagreement of low-Z solar models with helioseismology. Refs. 59 and 55 have concluded that a tilted increase in radiative opacities, with a few percent increase in the solar core and a larger (15-20%) increase at the base of the convective envelope could lead to low-Z SSMs that would satisfy helioseismic probes equally as well as SSMs based on the older, higher, metallicities. Incidentally, the above conclusion is confirmed by the analysis presented in Ref. 18 where helioseismic and solar neutrino data are used to infer the optimal composition of the Sun (see their Fig. 10).

Recent years have seen a surge of activity in theoretical calculations of atomic radiative opacities. Updated calculations[25] by the Opacity Project have led the way, followed by OPAS,[60,61] STAR[62] and a new version of OPLIB, the opacities from Los Alamos.[63] For conditions in solar interiors, all theoretical opacities agree with each other within few %. Interestingly, Ref. 64 have presented the first ever measurement of opacity under conditions close to those present in the solar interior. Four measurements were carried out to measure the iron opacity, each at different temperature and electron densities. The most extreme conditions used in the experiment approach those at the base of the solar convective envelope. While the experiment has been carried out only for iron, their conclusion is that all theoretical

calculations predict a too low Rosseland mean opacity, at a level of $7 \pm 4\%$, for the temperature and density combinations realized in the experiment. Further experimental work on chromium and nickel opacities[65] helps to evaluate discrepancies between experimental and theoretical results on iron opacity. Results point towards shortcomings that affect models, particularly in the case of open electronic L-shell configurations such as is present in iron at the base of the convective envelope. Also, the disagreement between theoretical and measured line shapes for the three elements indicates shortcomings in the theoretical understanding of atomic interaction with the plasma. On the other hand, the results also indicate that the quasicontinuum opacity determined experimentally agrees well with the chromium and nickel experiments, contrary to results from the iron experiment. However, the chromium and nickel experiments were carried out at lower temperatures than those used in the extreme conditions of the original iron experiment, which suggests that the problem of missing quasicontinuum opacity might have an unknown temperature dependence, or that a systematic error affected the high temperature iron measurements. Moreover,[66] in a recent theoretical analysis of line broadening modeling in opacity calculations, have found that uncertainties linked to this are larger at the base of the convective envelope than in the core. These arguments suggest that opacity calculations are more accurate in the solar core than in the region around the base of the convective envelope.

5. Hydrogen burning in the Sun

The Sun is powered by nuclear reactions that transform hydrogen into helium-4. The overall effect of these reactions is the conversion:

$$4\,\mathrm{p} + 2\,e^- \rightarrow {}^4\mathrm{He} + 2\,\nu_\mathrm{e} \tag{5}$$

with the production of a fixed amount of energy $Q = 4\,m_\mathrm{p} + 2m_\mathrm{e} - m_{^4\mathrm{He}} = 26.7\,\mathrm{MeV}$ per synthesized ^{4}He nucleus. Most of this energy is released in the solar plasma and slowly diffuses toward the solar surface supporting the radiative luminosity of the Sun. A small fraction of it, that depends on the specific channel by which hydrogen burning proceeds, is emitted in neutrinos. According to SSM calculations, the two neutrinos carry away about 0.6 MeV on the average.

The SSM predicts that most of the solar energy ($> 99\%$) is produced by the pp-chain, i.e. the hydrogen fusion reaction chain displayed in the left panel of Fig. 2. The pp-chain is is mostly initiated by $\mathrm{p}(\mathrm{p}, e^+\nu_e)\mathrm{d}$ reaction and, to a minor extent, by electron capture reaction $\mathrm{p}(\mathrm{p}e^-, \nu_e)\mathrm{d}$ and has several possible terminations that depend on the specific mechanism by which helium-3 nuclei, which are produced by $\mathrm{d}(\mathrm{p}, \gamma)^3\mathrm{He}$ reaction, are converted to heavier elements. In the Sun, the dominant mechanism is $^3\mathrm{He}(^3\mathrm{He}, 2p)^4\mathrm{He}$ that corresponds to the so-called pp-I termination of the pp-chain. Alternatively, helium-3 can lead to production of ^{7}Be through the reaction $^3\mathrm{He}(^4\mathrm{He}, \gamma)^7\mathrm{Be}$. Depending on the destiny of ^{7}Be, that can be processed either by the electron capture $^7\mathrm{Be}(e^-, \nu_e)^7\mathrm{Li}$ or by the (largely sub-dominant)

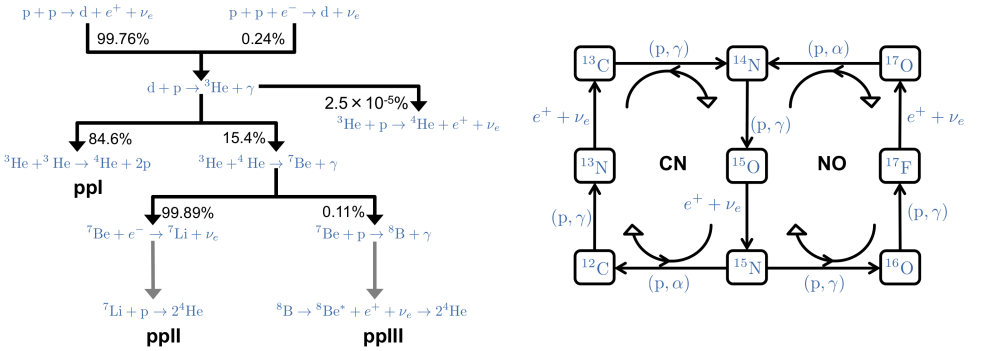

Fig. 2. Left Panel: The pp-chain; Right Panel: The CNO-bicycle.

proton capture reaction $^7\mathrm{Be}(\mathrm{p},\gamma)^8\mathrm{B}$, one obtains the pp-II or the pp-III terminations of the chain. Finally, a very small amount of helium-4 nuclei is produced by $^3\mathrm{He}(\mathrm{p},e^+\nu_e)^4\mathrm{He}$ reaction. The relative importance of the different branches of the pp-chain depends primarily on the core temperature of the Sun and on the cross section of specific reactions, as will be discussed in next section. The numbers given in Fig. 2 show the branching ratios in the present Sun.

An alternative hydrogen burning mechanism is provided by the CNO-bicycle that is displayed in the right panel of Fig. 2. The CNO-bicycle uses carbon, nitrogen and oxygen nuclei that are present in the core of the Sun as catalysts for hydrogen fusion. It is composed by two different branches, i.e. the CN-cycle and the NO-cycle, whose relative importance depends on the outcome of proton capture reaction on $^{15}\mathrm{N}$. In the Sun, the $^{15}\mathrm{N}(\mathrm{p},\alpha)^{12}\mathrm{C}$ channel is largely dominant and so, in practice, the CNO-bicycle is reduced to the CN-cycle with a marginal contribution by the NO-cycle. Note that the CN-cycle conserves the total number of C and N nuclei in the core of the Sun, but alters their distribution as it burns into equilibrium, eventually achieving equilibrium abundances proportional to the inverse of the respective rates. The reactions controlling conversion of $^{12}\mathrm{C}$ and $^{14}\mathrm{N}$ in the solar core and the approach to equilibrium are $^{12}\mathrm{C}(\mathrm{p},\gamma)^{13}\mathrm{N}$ and $^{14}\mathrm{N}(\mathrm{p},\gamma)^{15}\mathrm{O}$: these are the next-to-slowest and slowest rates in the CN-cycle, respectively. The temperature above which the $^{12}\mathrm{C}$ burning time through $^{12}\mathrm{C}(\mathrm{p},\gamma)^{13}\mathrm{N}$ is smaller than the Sun's lifetime is $T \sim 10^7\,\mathrm{K}$. In the SSM, the entire energy-producing core, $r \lesssim 0.2R_\odot$ and $m \lesssim 0.3M_\odot$ is at temperature larger than this value, so that nearly all of the core's $^{12}\mathrm{C}$ is converted to $^{14}\mathrm{N}$. The slower $^{14}\mathrm{N}(\mathrm{p},\gamma)^{15}\mathrm{O}$ reaction determines whether equilibrium is achieved. The $^{14}\mathrm{N}$ burning time is shorter than the age of the Sun for $T \gtrsim 1.3 \times 10^7\,\mathrm{K}$. Therefore equilibrium for the CN cycle is reached only for $R \lesssim 0.1R_\odot$, corresponding to the central 7% of the Sun by mass. Consequently, over a significant portion of the outer core, $^{12}\mathrm{C}$ is converted to $^{14}\mathrm{N}$, but further reactions are inhibited by the $^{14}\mathrm{N}(\mathrm{p},\gamma)^{15}\mathrm{O}$ bottleneck.

Table 4. Solar neutrino fluxes predicted by SSMs with different surface composition.[23] Units are: 10^{10} (pp), 10^{9} (^{7}Be), 10^{8} (pep, ^{13}N, ^{15}O), 10^{6} (^{8}B,^{17} F), 10^{5} (eN, eO) and 10^{3} (hep, eF) cm^{-2}s^{-1}.

Flux	B16-HZ	B16-LZ

6. Solar neutrinos

A very effective tool to investigate the properties of the Sun is provided by neutrinos which are necessarily produced along with ^{4}He nuclei during hydrogen burning, in order to satisfy lepton number conservation. Neutrinos free stream in the solar plasma and reach the Earth in about 8 minutes where they can be detected by solar neutrino experiments. While the total amount of neutrinos produced in the Sun can be easily estimated from the solar luminosity constraint (see below), the evaluation of their spectrum requires the knowledge of the individual rates of neutrino producing reactions and thus the construction of a complete solar model. We report in Fig. 3 and Tab. 4, the SSM predictions for the different components of the solar neutrino flux, named according to the specific reaction by which they are produced.[23] We also include, for completeness, ecCNO neutrinos, i.e. neutrinos produced by electron capture reaction in the CNO-bicycle (in addition to the "standard" CNO neutrinos produced by β decays of ^{13}N, ^{15}O and ^{17}F) that were originally calculated in Refs. 67 and 68 and recently reevaluated in Ref. 69[a]. The two columns "B16-HZ" and "B16-LZ" reported in Tab. 4 are obtained by considering two different options for the solar surface composition, as it discussed in Sect. 3. During the last few decades, solar neutrino experiments have allowed us to determine with great accuracy most of the components of the solar flux. As an example, ^{7}Be and ^{8}B neutrino fluxes are measured with accuracy better than $\sim 3\%$ by Borexino,[13] Super-Kamiokande[15] and SNO.[14] The pp and pep-neutrino flux can be determined

[a]In order to take into account the new inputs in B16-SSM calculations, the ecCNO fluxes given in Tab. 4 have been scaled with respect to the values quoted in Ref. 69 proportionally to the corresponding β-decay fluxes. This follows from the assumption that the ratio of electron capture and beta decay processes in the Sun is equal to what evaluated in Ref. 69

with $\lesssim 1\%$ accuracy by assuming the solar luminosity constraint, see e.g. Ref. 70. These fluxes, however, have been also directly measured by Borexino[13,71,72] with $\sim 10\%$ and $\sim 17\%$ accuracy, respectively. Finally, Borexino has recently obtained the experimental identification of CNO neutrinos,[19] providing the first direct evidence that CNO-bicycle is active in the Sun.

The solar luminosity constraint

SSM calculations predict that the Sun is very close to thermal equilibrium and that evolutionary timescales are much longer than the heat diffusion time across the solar structure. In this case, the amount of energy which is produced (in unit time) by nuclear reactions in the solar core almost exactly counterbalance the luminosity radiated at the surface of the Sun, with the contribution of gravothermal energy to the solar luminosity being $< 0.1\%$. Since a fixed amount of energy Q and two electron neutrinos are produced for synthesized ^{4}He nucleus, and neglecting the small gravothermal contribution, this argument implies a relationship between the measured solar luminosity and the solar neutrino fluxes that can be expressed as

$$\frac{\mathrm{L}_\odot}{4\pi D^2} = \sum_i \left(\frac{Q}{2} - \langle E_\nu \rangle_i \right) \Phi(i) \tag{6}$$

where the index i indicates the different components of the neutrino flux and the quantity $\langle E_\nu \rangle_i$ is the average energy of neutrinos produced by a specific reaction. This argument was illustrated and discussed e.g. in Ref. 73,74 and has been recently reviewed in Refs. 75, 76.

It is clearly important to experimentally confirm the validity of the solar luminosity constraint because this represents a test of fundamental assumptions in the SSM paradigm, e.g. that the Sun is stable on timescales much longer than the heat diffusion time ($\sim 10^5$y), and that the are no additional energy losses or production mechanisms besides those normally included in solar model calculations. The recent Borexino direct identification of the pp-neutrino flux,[13] which provides the dominant term in the r.h.s of Eq. (6), has finally made this test possible, confirming the energy balance employed by SSMs at the $\sim 10\%$ level. Future more accurate measurements will be important to further constrain non standard scenarios.

7. The dependence of neutrino fluxes on the central temperature of the Sun

Even a small modification of the central temperature of the Sun reflects into large variations of solar neutrino fluxes. The dependence of solar neutrino fluxes on the core temperature of the Sun was recently re-analyzed in Ref. 77 (see also Refs. 78 and 74 for previous discussions on the subject) where an analytical model that helps understanding the possibility they offer for determining physical characteristics of the solar interior was also provided. We summarize the main results of Ref. 77.

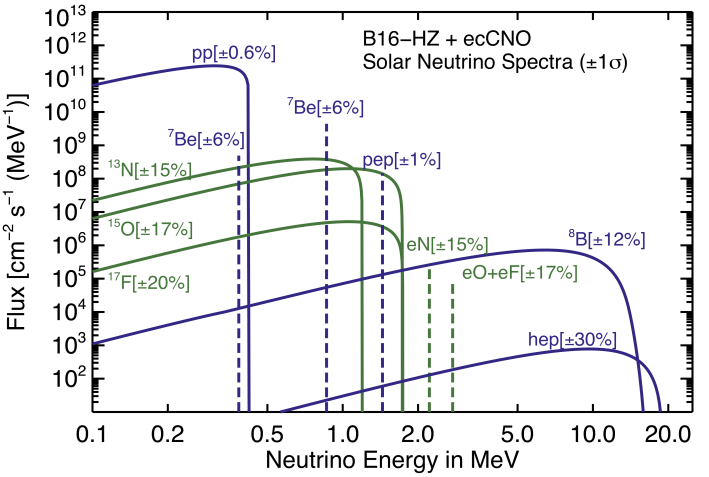

Fig. 3. The solar neutrino spectrum.

The pp-neutrino flux:
The flux $\Phi(\mathrm{pp})$ is basically fixed by the solar luminosity constraint and it is expected to be mildly dependent on the central temperature of the Sun and nuclear reaction cross sections. By taking into account that the two largest contributions to the r.h.s of Eq. 6 are provided by pp and ^{7}Be-neutrinos, one arrives at the conclusions that $\delta\Phi(\mathrm{pp}) \simeq -\eta\,\delta\Phi(^7\mathrm{Be})$, where $\delta\Phi(i)$ represent the fractional variation of the i-neutrino flux and $\eta \equiv \Phi(^7\mathrm{Be})/\Phi(\mathrm{pp}) \simeq 0.08$. By considering the dependence of $\Phi(^7\mathrm{Be})$ on solar central temperature and nuclear cross sections (discussed below), one obtains the following relationship

$$\delta\Phi(\mathrm{pp}) = -\eta\,\delta S_{34} - \frac{\eta}{2}\,(\delta S_{11} - \delta S_{33}) + \beta_{\mathrm{pp}}\,\delta T_{\mathrm{c}} \tag{7}$$

where $\beta_{\mathrm{pp}} = -\eta\beta_{\mathrm{Be}} \simeq -0.9$, δT_{c} is the fractional variation of the core temperature and δS_{ij} indicates the fractional variations of the astrophysical factor S_{ij}.

The pep-neutrino flux:
The pep-neutrinos are produced by electron capture reaction $\mathrm{p}(\mathrm{p}e^-,\nu_e)\mathrm{d}$ which is linked to the β-decay process $\mathrm{p}(\mathrm{p},e^+\nu_e)\mathrm{d}$ by well-known nuclear physics. The ratio between their rates is roughly proportional to $T_{\mathrm{c}}^{-1/2}\,n_e$ (see e.g. Ref. 27 for a review). We can thus assume $\Phi(\mathrm{pep}) \propto T_{\mathrm{c}}^{1/2}\,\Phi(\mathrm{pp})$, allowing us to conclude:

$$\delta\Phi(\mathrm{pep}) = -\eta\,\delta S_{34} - \frac{\eta}{2}\,(\delta S_{11} - \delta S_{33}) + \beta_{\mathrm{pep}}\,\delta T_{\mathrm{c}} \tag{8}$$

where $\beta_{\mathrm{pep}} = \beta_{\mathrm{pp}} - 1/2 \simeq -1.4$.

The ^{7}Be-neutrino flux:
The Be-neutrino flux is linked to the rate of the $^3\mathrm{He}(^4\mathrm{He},\gamma)^7\mathrm{Be}$ reaction, since the electron capture reaction $^7\mathrm{Be}(e^-,\nu_e)^7\mathrm{Li}$ largely dominates over the competing

proton-capture reaction. By considering that ^{3}He abundance in a large part of the solar core can be estimated by using the equilibrium condition $X_3 \simeq X_{3,\rm eq} \propto (\langle\sigma v\rangle_{11}/\langle\sigma v\rangle_{33})^{1/2}$, one obtains the expression:

$$\delta\Phi(^7\mathrm{Be}) = \delta S_{34} + \frac{1}{2}\,(\delta S_{11} - \delta S_{33}) + \beta_{\rm Be}\,\delta T_{\rm c} \tag{9}$$

where $\beta_{\rm Be} = \gamma_{34} + (\gamma_{11} - \gamma_{33})/2 \sim 11$ and we considered that $\langle\sigma v\rangle_{ij} \propto S_{ij}\, T_{\rm c}^{\gamma_{ij}}$.

The ^{8}B-neutrino flux:
The ^{8}B neutrinos constitute a largely subdominant component of the solar flux which is produced when ^{7}Be nuclei capture a proton (instead of an electron) producing ^{8}B (instead of ^{7}Li). The ^{8}B-neutrino flux is thus given by $\Phi(^8\mathrm{B}) = r\,\Phi(^7\mathrm{Be})$ where r is the ratio between proton and electron capture rates on ^{7}Be. The parameter r scales as $r \propto (S_{17}/S_{e7}) \cdot T_{\rm c}^{\alpha}$ where $\alpha = \gamma_{17} + (1/2)$ and we have considered that $\langle\sigma v\rangle_{e7} \propto S_{e7}\, T_{\rm c}^{-1/2}$ for electron capture reaction. Taking this into account, we obtain the following equation:

$$\delta\Phi(^8\mathrm{B}) = (\delta S_{17} - \delta S_{e7}) + \delta S_{34} + \frac{1}{2}\,(\delta S_{11} - \delta S_{33}) + \beta_{\rm B}\,\delta T_{\rm c} \tag{10}$$

with $\beta_{\rm B} = \beta_{\rm Be} + \gamma_{17} + 1/2 \simeq 24$. The large value of $\beta_{\rm B}$ indicates that ^{8}B neutrinos are a very sensitive probe of the core temperature of the Sun.

The CNO neutrino fluxes:
The neutrino fluxes produced in the CN-cycle by β-decay (and electron capture reactions) of ^{13}N and ^{15}O nuclei, besides depending on the solar central temperature, are approximately proportional to the stellar-core number abundance of CN elements. This dependence is extremely important because, as it is discussed in Refs. 16, 17, 79, it permits us to use CNO neutrinos, in combination with other neutrino fluxes, to directly probe the chemical composition of the Sun. By considering an analytical model to calculate the abundance of carbon and nitrogen in the core of the Sun, Ref. 77 obtained the following expressions;

$$\delta\Phi(^{15}\mathrm{O}) = \beta_{\rm O}\,\delta T_{\rm c} + (1-a)\,\delta X_{12,\,\rm s} + a\,\delta X_{14,\,\rm s} + b\,\left(\Delta^{(\rm cs)} - 0.16\right) + \delta S_{114} \tag{11}$$

$$\delta\Phi(^{13}\mathrm{N}) = \beta_{\rm N}\,\delta T_{\rm c} + (1-a')\,\delta X_{12,\,\rm s} + a'\,\delta X_{14,\,\rm s} + b\,\left(\Delta^{(\rm cs)} - 0.16\right) + f\,\delta S_{114}$$

with $\beta_{\rm O} = \gamma_{114} \simeq 20$, $f = \Phi(^{15}\mathrm{O})/\Phi(^{13}\mathrm{N}) = 0.74$, $a = 6\xi/(6\xi + 7) \simeq 0.20$ and $\xi = (X_{14,\,\rm s}/X_{12,\,\rm s}) \simeq 0.30$, $b = 0.86$, $\beta_{\rm N} \equiv f\,\beta_{\rm O} = 15$ and $a' \equiv f\,a = 0.15$. In the previous relations, $\delta X_{12,\,\rm s}$ and $\delta X_{14,\,\rm s}$ are the fractional variations of the carbon-12 and nitrogen-14 surface abundances. The quantity $\Delta^{(\rm cs)}$ takes into account the effects of elemental diffusion that enhances heavy element abundances in the solar core with respect to surface. It is defined by:

$$\mathcal{N}_{\rm c} = \mathcal{N}_{\rm s}\left[1 + \Delta^{(\rm cs)}\right] \tag{12}$$

where $\mathcal{N}_{\rm c}$ ($\mathcal{N}_{\rm s}$) is the central (surface) value of the total number abundance of CN nuclei defined as $\mathcal{N} \equiv X_{12}/12 + X_{13}/13 + X_{14}/14$. Reference SSM calculations[23] gives $\Delta^{(\rm cs)} = 0.16$ but this value can be different in non standard scenarios and/or if diffusion coefficients are modified.

8. Using CNO neutrinos to probe the solar core composition

In Refs. 16 and 17, it was suggested to combine the CN-neutrino fluxes with the boron neutrino flux that, due to the exquisite precision of current experimental results and the large temperature sensitivity can be efficiently used as solar thermometer. As can be understood by considering Eqs.(10) and (12), the following combinations can be formed:

$$\delta\Phi(^{15}\mathrm{O}) - x\,\delta\Phi(^{8}\mathrm{B}) = (1-a)\,\delta X_{12,\,\rm s} + a\,\delta X_{14,\,\rm s} + b\,\left(\Delta^{(\rm cs)} - 0.16\right) + \delta S_{114} - x\left(\frac{\delta S_{11}}{2} - \frac{\delta S_{33}}{2} + \delta S_{34} + \delta S_{17} - \delta S_{e7}\right) \quad (13)$$

$$\delta\Phi(^{13}\mathrm{N}) - x'\,\delta\Phi(^{8}\mathrm{B}) = (1-a')\,\delta X_{12,\,\rm s} + a'\,\delta X_{14,\,\rm s} + b\,\left(\Delta^{(\rm cs)} - 0.16\right) + \delta S_{114} - x'\left(\frac{\delta S_{11}}{2} - \frac{\delta S_{33}}{2} + \delta S_{34} + \delta S_{17} - \delta S_{e7}\right) \quad (14)$$

where $x = \beta_{\rm O}/\beta_{\rm B} \simeq 0.8$ and $x' = f\,x \simeq 0.6$, that are independent from $\delta T_{\rm c}$. This possibility is extremely important because it allows us to cancels out the dependence on the radiative opacity (implicit in $\delta T_{\rm c}$). The uncertainty of available opacity calculations is indeed not easily quantified and may be potentially underestimated. Moreover, it breaks the degeneracy between composition and opacity effects on solar observable properties. Indeed, the considered flux combinations only depend on the carbon and nitrogen abundance in the solar core allowing us to test the chemical composition and evolution of the Sun. The first two terms in the r.h.s. of Eqs. (13,14) quantify the effects of a variation of the surface C and N abundances. A change of the diffusion efficiency is instead described in terms of a variation of $\Delta^{(\rm cs)}$ from the SSM value, i.e. by assuming $\Delta^{(\rm cs)} - 0.016 \neq 0$. It should be remarked that the ability to probe solar composition by using this approach is only limited by experimental accuracy of flux determinations and by nuclear cross section uncertainties.

While the above relationships are based on the simplified arguments discussed in the previous section, the optimal combinations $\delta\Phi(\nu_1) - x_{12}\delta\Phi(\nu_2)$, or equivalently weighted ratios $\Phi(\nu_1)/\Phi(\nu_2)^{x_{12}}$, can be determined by using the power-law coefficients $\alpha(\nu, I)$ given in Ref. 23. The parameter x_{12} is obtained by minimizing the residual

$$\rho = \sum_{I=1}^{N} \left[\alpha(\nu_1, I) - x_{12}\,\alpha(\nu_1, I)\right]^2 \sigma_I^2 \quad (15)$$

where the sum extends to the N input parameters whose dependence we want to cancel out and σ_I are the corresponding uncertainties. The minimal value for ρ gives

the intrinsic error in the considered approach. This method, originally proposed by Refs. 16 and 17, has been recently adapted to Borexino in Ref. 80. By taking into account that the measured CNO neutrino signal in Borexino is basically probing $\delta\phi^{\rm BX}_{\rm CNO} \equiv \xi\,\delta\Phi(^{15}{\rm O}) + (1-\xi)\,\delta\Phi(^{13}{\rm N})$ with $\xi = 0.764$, it was concluded that the surface composition of the Sun can be probed by the combination:

$$\delta R^{\rm BX}_{\rm CNO} - 0.716\,\delta\Phi(^8{\rm B}) = 0.814\,\delta X_{12,\,\rm s} + 0.191\,\delta X_{14,\,\rm s} \pm 0.5\%\,({\rm env}) \pm 9.1\%\,({\rm nucl}) \pm 2.8\%\,({\rm diff}) \qquad (16)$$

where $\delta R^{\rm BX}_{\rm CNO}$ is the fractional difference of the observed CNO signal with respect to SSM expectations and the quoted uncertainties are obtained by propagating errors of SSM input parameters. The error budget is presently dominated by the uncertainty of the CNO signal Borexino measurement. However, a relevant error ($\sim 10\%$) is also provided by nuclear reactions, with the largest contributions coming from S_{114} (7.6%), S_{34} (3.4%), and S_{17} (3.5%). In the perspective of future improvements of the CNO signal determination, it is evidently important to have reliable and accurate determinations of these cross sections.

9. Final remarks

The standard solar model establishes a well-defined framework for studying solar interior physics. Despite all its success, still faces difficulties, mainly the solar abundance problem, as diagnosed by helioseismic constraints. The advancements in solar neutrino experiments, and in particular those by Borexino in the last 10 years, have added solar neutrinos as an independent probe of the solar interior properties, complementary to helioseismology. In addition to the now seemingly routine accurate measurement of the ^{7}Be flux, Borexino has opened up the possibilities of quantitative and model independent tests of the origin of solar luminosity and has detected solar CN-neutrinos for the first time (the first direct experimental evidence of the CN-cycle operating in stars). Future improvements in the CN flux measurement by Borexino might help in the quest for the solar abundances, a fundamental open problem in solar physics. This is a prerequisite for developing robust and physically sound solar models beyond the standard model paradigm. Non-standard solar physics requires unfortunately the introduction of free parameters (e.g. to treat non-standard mixing processes) that can be calibrated robustly only once the standard solar model is set on firmer grounds.

Finally, we would like to express that the value of Borexino for solar physics does not only lie in the direct results obtained by the experiment, but also in the development of experimental techniques, which represent a very valuable legacy for future neutrino experiments.

E-mail: aldo.ianni@lngs.infn.it

Borexino has recently observed CNO solar neutrinos. This measurement confirms an energy production mechanism in stars predicted about a century ago. The CNO cycle in the Sun is sub-dominant with respect to the pp-chain energy production. However, it is definitely important in more massive stars. We describe the main characteristics of the CNO cycle in the Sun and in massive stars.

Keywords: Solar neutrinos; CNO cycle; stars; energy production in stars.

1. Energy production in stars and the role of the CNO bi-cycle

The fundamental paradigm for energy production in the Sun and similar stars is the transformation of hydrogen into helium through the process: $4p \rightarrow^4 He + 2e^+ + 2\nu_e + 26.73\,\mathrm{MeV}$.[1] This mechanism makes electron neutrinos of mainly sub-MeV energy. Due to the fact that neutrinos can travel through matter affected only by weak interactions, the observation of solar neutrinos allows to probe the interior of the Sun. Therefore, the Sun becomes a laboratory to understand the physics in stars. Solar neutrino measurements have been carried out since 1968.[2]

The main source of energy in the Sun is the so-called pp-chain shown in Figure 1. The pp-chain has three terminations. Each termination produces 26.2 MeV effective thermal energy and it burns 3.7×10^{38} hydrogen/sec, which corresponds to 612 ton/sec. Therefore, assuming 10% of solar mass involved in energy production, the timescale of the pp-chain for the Sun is of the order of 10^{10} years. This mechanism is dominant in first generation stars. In second or third generation stars a different mechanism is also at work. This latter involves light elements, such as carbon and nitrogen, generated after the production of helium. The idea of a second energy production mechanism was independently introduced by von Weizsaker and Bethe between 1937[3] and 1939.[4] Second and third generation stars contain some "heavy" elements, such as nitrogen and carbon. These elements allow the transformation of hydrogen into helium. The process can start from the reaction $p + {}^{12}_{6}\mathrm{C} \rightarrow {}^{13}_{7}\mathrm{N} + \gamma$, which is followed by the beta decay of ${}^{13}_{7}\mathrm{N}$ to ${}^{13}_{6}\mathrm{C}$ accompanied with the emission of an electron neutrino of maximum energy equal to 1.2 MeV. Afterward ${}^{14}_{7}\mathrm{N}$ is formed by $p + {}^{13}_{6}\mathrm{C} \rightarrow {}^{14}_{7}\mathrm{N} + \gamma$. ${}^{14}_{7}\mathrm{N}$ allows the production of ${}^{15}_{8}\mathrm{O}$, which decays beta to ${}^{15}_{7}\mathrm{N}$ with the emission of another electron neutrino of maximum energy equal to 1.7 MeV. At this point ${}^{15}_{7}\mathrm{N}$ allows the production of ${}^{12}_{6}\mathrm{C}$ through the process

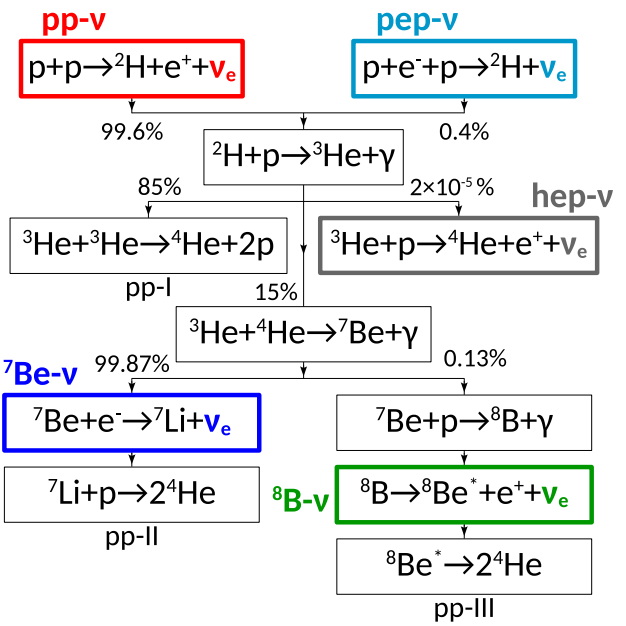

Fig. 1. Set of reactions in the pp-chain, which is the main source of energy in the Sun and in low mass H-burning stars with mass smaller than $1.3 M_{\odot}$.

$p + {}^{15}_{7}\mathrm{N} \rightarrow {}^{12}_{6}\mathrm{C} + \alpha$. With ${}^{12}_{6}\mathrm{C}$ the sequence of reactions can start over again. This so-called CN cycle is shown in Figure 2. ${}^{12}_{6}\mathrm{C}$ is used as a catalyst. This cycle produces two electron neutrinos, helium, and the same amount of energy produced by the pp-chain. The CN cycle till 1950 was considered the main source of energy in the Sun. The slowest reaction in the CN cycle is ${}^{14}_{7}\mathrm{N}(p,\gamma){}^{15}_{8}\mathrm{O}$, which has the highest Coulomb barrier.

The CN cycle might develop into a CNO bi-cycle as show in Figure 2. As a matter of fact, with a probability of order 10^{-3}, ${}^{16}_{8}\mathrm{O}$ can be produced by ${}^{15}_{7}\mathrm{N}(p,\gamma){}^{16}_{8}\mathrm{O}$. This second branch produces ${}^{17}_{9}\mathrm{F}$, which decays beta with the emission of an electron neutrino with maximum energy equal to 1.74 MeV. The CNO bi-cycle produces three electron neutrinos from beta decays of ${}^{13}\mathrm{N}$, ${}^{15}\mathrm{O}$ and ${}^{17}\mathrm{F}$. These are the so-called CNO solar neutrinos. The flux of these neutrinos is related to the abundance of these elements in the Sun's core. Therefore, a measurement of CNO solar neutrinos is a probe of the Sun's metallicity.

Measurements of stellar interaction rates have shown that the CN cycle is not dominant in the Sun. This information is used by the Solar Standard Model (SSM),[1] which is the theoretical framework to describe the evolution of the Sun. According to the SSM the CNO bi-cycle in the Sun is responsible for only 1% of the energy production. The CNO bi-cycle is important for the nucleosynthesis of ${}^{16}_{8}\mathrm{O}$, ${}^{17}_{8}\mathrm{O}$, and other light elements. The CNO bi-cycle is also referred to as the "cold" CNO cycle[5] with respect to the "hot" cycle which is discussed in the next Section.

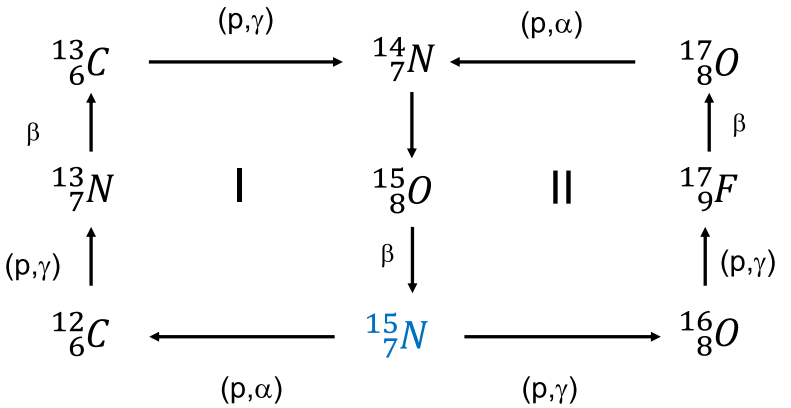

Fig. 2. The CNO bi-cycle divided in its two sub-cycles. The dominant one in the Sun is the CN cycle on the left side.

2. The CNO cycle in massive stars

The Sun's core temperature is 15×10^6 K, which we write as $15T_6$. As predicted by the SSM at this temperature the energy production for the pp-chain and the CNO bi-cycle scales as $\propto T^4$ and $\propto T^8$, respectively. For stellar masses smaller than $1.3M_\odot$, the pp-chain dominates the energy production. In more massive stars with a higher core temperature, the CNO cycle is by far the dominant source of energy. In this case one has to take into account two competing processes, namely $^{17}_{8}\mathrm{O}(p,\alpha)^{14}_{7}\mathrm{N}$ and $^{17}_{8}\mathrm{O}(p,\gamma)^{18}_{9}\mathrm{F}$. For some temperature ranges the reaction rates for these processes are comparable.[6] In this case the CNO cycle is tri-cycling as shown in Figure 3.[7] In addition, for temperature ranging up to 10^{10} K the interaction rate for $^{18}_{8}\mathrm{O}(p,\alpha)^{15}_{7}\mathrm{N}$ and $^{18}_{8}\mathrm{O}(p,\gamma)^{19}_{9}\mathrm{F}$ is of order 100 with a flat minimum between T_9 and $7T_9$.[5] Therefore, with a probability of order 1% a fourth CNO cycle can develop. This fourth cycle is also shown in Figure 3. The third and fourth CNO cycles are referred to as the "hot" CNO cycles. It turns out that when $^{19}_{9}\mathrm{F}(p,\gamma)^{20}_{10}\mathrm{Ne}$ is dominat the CNO catalytic cycling stops.

One fundamental empirical properties of stars is the relationship between their total mass and surface luminosity:[8] $L/L_\odot = (M/M_\odot)^\alpha$, with $3 \lesssim \alpha \lesssim 4$[9] and $L_\odot$ and $M_\odot$ the solar surface luminosity and mass, respectively. This property is confirmed by basic stellar theory. One can make some general arguments for the role of the CNO cycle in stars in the rage of masses $[1,10]M_\odot$. In this range it turns out that the luminosity scales as $\propto M^{\sim 4}$.[9] This implies that more massive stars have a smaller lifetime, for the lifetime scales as $\propto M^{-3}$. In addition, considering that the stars number density scales as $\propto M^{-2.5}$,[10] the energy production in a given bin of mass $[M_i, M_{i+1}]$ is written as:

$$\epsilon \propto \int_{M_i}^{M_{i+1}} M^{1.5} dM \tag{1}$$

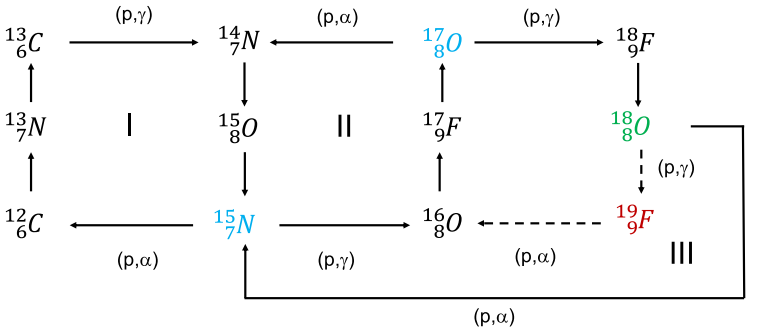

Fig. 3. The CNO tri-cycle in massive stars.

This implies that stars where the CNO energy production is dominant, namely $M > 1.3M_{\odot}$, are producing about 100 times more energy in a much shorter timescale.

3. The role of Borexino

In 2020 Borexino has reported the first ever observation of CNO neutrinos from the Sun.[11] The null hypothesis (no CNO neutrinos) has been rejected at 5σ level. Indeed, Borexino has shown that this energy production mechanism predicted about a century ago is at work in stars. Although the accuracy of the measurement at present is still large ($\sim 35\%$), this measurement allows to probe the SSM in terms of neutrino emission, metallicity, and energy production. The solar luminosity, $L_{\odot}$ can be related to the solar neutrino fluxes:[12,13]

$$\frac{L_{\odot}}{4\pi AU^2} = \sum_i \alpha_i \phi_i \tag{2}$$

where AU is one astronomical unit, ϕ_i are the neutrino fluxes, and α_i are coefficients related to the energy production in the reactions taking place in the pp-chain and CNO bi-cycle, respectively. The Borexino measurement implies that:

$$\frac{L_{CNO}}{L_{\odot}} = 1.0^{+0.4}_{-0.3}\% \tag{3}$$

This is an important confirmation of the SSM prediction. Previously Borexino had measured all the main neutrinos produced by the pp-chain,[14] proving that this mechanism is the main energy production in the Sun with an experimental accuracy of the order of 10%. Therefore, at present, solar neutrino observations have demonstrated that the pp-chain and the CNO bi-cycle are producing energy in stars as it was predicted about a century ago.

Tohoku University,
Sendai 980-8578, Japan
E-mail: mitsui@awa.tohoku.ac.jp

for the KamLAND Collaboration

Neutrinos from the Earth's interior "geoneutrinos" have been observed to reveal Earth's composition, heat budget, and the origin of the Earth. Observations by KamLAND and Borexino experiments for 15 years are reviewed.

Keywords: Neutrino; Geoneutrino

1. Geoneutrino

Recent progress on the research about "why and how the sun and the stars shine" is quite notable, which has been summarized in this parallel session. Here I would like to review neutrinos from another familiar celestial body, the Earth. Neutrinos from the Earth ("geoneutrinos") are low-energy electron antineutrinos ($\bar{\nu}_e$) emitted in the decay chains of uranium (U), thorium (Th), and potassium (K) in the Earth's interior. Geoneutrino is expected as a probe of Earth's chemical composition. Also the decay of those radioactive elements contributes to the Earth's heat production. Then geoneutrino is a tool to reveal the Earth's energy budget. Although the existence of geoneutrino is predicted more than 50 years ago[1–3] experimental research has been difficult. Since Borexino and KamLAND experiments were planned, they have been hoped as the first experimental research of geoneutrinos.

With those liquid scintillator detectors, geoneutrinos (geo-$\bar{\nu}_e$'s) are detected via "inverse β decay" mode: $\bar{\nu}_e + p \to e^+ + n$. Considering the difference of masses of neutron (m_n) and proton (m_p), $m_n - m_p = 1.3$ MeV, the mass of positron ($m_e = 0.5$ MeV), and neglecting the small neutron recoil, the threshold of this reaction is $E_{th} \simeq m_n - m_p + m_e = 1.8$ MeV, above which neutrino energy E_ν and positron energy E_{e^+} (the kinetic energy of the positron plus the electron-positron annihilation energy) are related as $E_\nu \simeq E_{e^+} + E_{th} - 2m_e = E_{e^+} + 0.8$ MeV. The potassium neutrino is below E_{th}, so liquid scintillator detectors observe only uranium and thorium neutrinos. With energy spectrum (E_{e^+} spectrum which reflects E_ν spectrum), uranium (U) and thorium (Th) neutrinos can be separately measured. To obtain total geoneutrino flux with less statistical uncertainty, the relative abundance of U and Th is sometimes assumed to be Th/U = 3.9, based on geological consideration.

As Borexino and KamLAND plans started, calculation of expected flux of geoneutrinos, and expected signals of these detectors have also been performed. One of the examples is Ref. 4, in which expected "peaks" of geoneutrinos around $E_{e+} \simeq 1$ to 3 MeV are shown. Also shown are the expected background spectra of nuclear reactor $\bar{\nu}_e$, showing that reactor $\bar{\nu}_e$ of Borexino is much less than that of KamLAND.

2. Experimental Research

In 2005, the first experimental research of geoneutrinos has been done,[5] in which KamLAND measured low-energy spectrum of $\bar{\nu}_e$ and fitted it to geoneutrino, reactor neutrino and other background spectra. As shown in Fig. 1, geoneutirno contribution is indicated although the statistical power is limited.

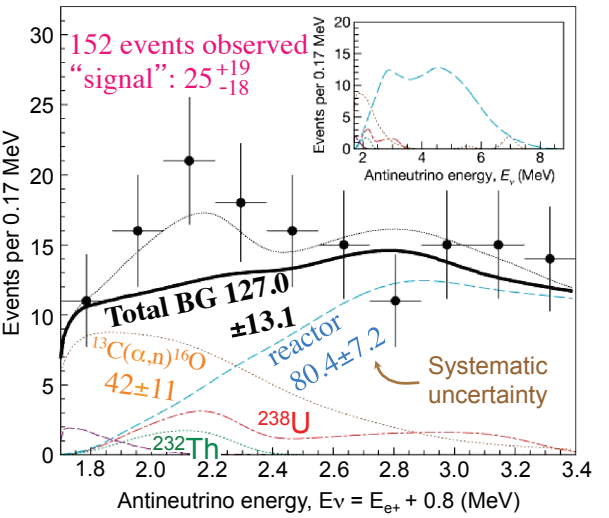

Fig. 1. First experimental research of geoneutrinos. Points are data, lines with labels and numbers are estimated background (thin line around 1.8 MeV is random coincidence). Lines labeled as ^{238}U and ^{232}Th are best-fit geoneutrino signals. Thick black line is the estimated total background, and thin black line is that with the best-fit signals added.

In 2010, Borexino collaboration reported their first result of geoneutrino observation,[6] with which the observation with two detectors on the Earth started. Borexino is an ultra pure detector and reactor neutrino flux is much less than KamLAND site. Thanks to those low background environment, the existence of geoneutrino was confirmed at 4.2 σ confidence level.

In an updated result of KamLAND,[7] it has been shown that the radiogenic heat source inferred from geoneutrino flux is significantly less than the total heat flow from the Earth's interior. With this result they concluded that there is contribution of secular cooling of the Earth to the total heat source of the Earth.

In the updated result of Borexino[8] released in 2013, the signal of geoneutrino became clearer and the probability for null geoneutrino measurement was shown to be 6×10^{-6}. The latest data of KamLAND was also shown[9] in 2013, which included the data of the period with most of Japanese nuclear reactors off. With these data, low background observation of geoneutrino was done also with KamLAND. The reactor $\bar{\nu}_e$ background was also unambiguously estimated using reactor on and off data. In those reports in 2013,[8,9] existence of mantle geoneutrino contribution was indicated by using both data in a cooperating way because crust contributions are different between KamLAND and Borexino sites.

In 2015, Borexino collaboration released new result[10] and reported that the probability for null geoneutrino measurement is 3.6×10^{-9} corresponding to 5.9 σ confidence level. This should be a conclusive result for geoneutrino existence. The latest result of Borexino was shonw in Ref. 11. This comprehensive report includes all the aspects of geoneutrino research, i.e., physics, geology, experiment, and data analysis of geoneutrino. All the researchers involved in geoneutrino study are recommended to read it carefully so that they are stimulated for new research. Also in this report, multiple Earth models are carefully tested with their latest data, including cosmochemical, geochemical, and geodynamical models.

3. Research in Geology and Theory

With those experimental data, research in geology and theory also became active. Combined analysis of KamLAND and Borexino data has been done by theorists. Ref. 12 is one of combined analysis, in which common and independent uncertainties of KamLAND and Borexino are treated properly and carefully with considering correlation.

New calculations of geoneutrino flux have also been done using up-to-date data and more precise and refined method of calculation. For example, such up-to-date "reference models" are reviewed in Refs. 11–13.

4. Future Experiments

Although the observation with two detectors has lasted for more than 10 years, new detectors will be ready and expected to start their observations. SNO+[14] is a large liquid scintillator detector in Canada to search for neutrinoless double beta decay. It can also observe geoneutrinos. Large flux of geoneutrino is expected from the continent crust. In April 2021, SNO+ completed liquid scintillator filling. We have to stay tuned.

JUNO[15] is a multipurpose neutrino detector planned to be constructed in China. Their main purpose is to measure reactor neutrino oscillation to further improve Daya Bay achievements. When completed it will be the largest liquid scintillator detector (20 kton) in the world. The construction already started.

Jinping Neutrino Experiment[16] is planned in China. When completed, it will be the deepest detector in the world, with 2400 m overburden of rocks. It aims at

observing large flux of geoneutrinos from Himalaya, which is a part of one of the largest continental crust of the present-day Earth.

For more research, especially for mantle geoneutrino detection, large liquid scintillator in the deep ocean[17] is one possibility. Directional measurement of electron antineutrinos is another future possibility in order to get more information about geoneutrino source distribution. Although the directional measurement was done by Chooz experiment,[18] application for large detector is not easy and under development. Considering the observation at a lot of points are essentially important, design of cheap detector[19] may be useful to construct as many detector as possible.

Acknowledgments

The author thanks organizers for their kind hospitality under the current unusual situation. The KamLAND experiment is supported by JSPS KAKENHI, the World Premier International Research Center Initiative (WPI Initiative), MEXT Japan, Netherlands Organization for Scientific Research (NWO), the U.S. Department of Energy (DOE), and the National Science Foundation (NSF). The Kamioka Mining and Smelting Company has provided service for activities in the mine. We acknowledge the support of NII for SINET4.

E-mail: gianpaolo.bellini@mi.infn.it

This article is the synthesis of the MG16 session "Why and how the Sun and the stars shine". A brief scientific history of the Borexino experiment and its discoveries are traced.

Keywords: Solar neutrinos, neutrinos physics, geo-neutrinos

In this session the technical and scientific results obtained with the Borexino experiment have been presented. In 1989 we began a feat that seemed absolutely impossible, that is to build a detector able to study, in real time, solar neutrinos from few tens of keV of energy by measuring separately the fluxes produced by the various nuclear fusion reactions that take place in the Sun. The difficulty was the natural radioactivity present in any material as well as the emissions from the rocks of the underground laboratory, the Gran Sasso lab., where it was decided to install the detector. Just owing to the natural radioactivity, the experiments before Borexino set a threshold between 4 and 5 MeV, then measuring only a tail towards the largest energies of the neutrino energy spectrum, corresponding to about 0.01% of the total flux.

The activity for Borexino started in 1990 and the first five years (1990-1995) were spent to develop innovative methods that would be able to break down the radioactivity of liquids up to ultra-traces. In order to measure the reached level of radio-purity and to understand if it was satisfying the very high level requested by the project, a special detector was needed; therefore a reduced and simplified version of Borexino has been constructed, the Counting Test Facility, which functioned as a bench mark. At 1995 this detector was able to demonstrate that our methods were able to reduce the radioactivity up to about 10^{-16} g of contaminants/g of pure material, as per project requests.

The construction, installation and tuning of the detector took a long time and only in 2007 we started the data taking; this time has been necessary because nothing is standard in Borexino: all the materials were carefully selected, all the parts of the detector and the components were developed on purpose also in collaboration with external companies, most of the activities were carried out in clean room, the detector itself has been equipped as a 10,000 level clean room. All these special cares were aimed to an exceptional suppression of the radioactive background.

Borexino is designed like an onion: the more internal a shell, the greater the radiopurity. At the center, a 125 micron-thick nylon vessel -IV, with a 4.5 m radius,

contains about 100 t of scintillator, with pseudocumene as solvent and PPO as solute. It is enclosed in a 6.75 m radius stainless steel sphere, SSS, which supports 2212 photomultipliers: the space between IV and SSS is filled with about 1000 t of pseudocumene added a quencher. A 5.50 m-radius nylon balloon functions as a barrier against to ^{222}Rn emitted by the SSS steel and the photomultipliers. All is inside a water tank (radius 9 m, height 16.9 m), which contains 2800 t of highly purified water and 208 PMTs, which, by means of the Cherenkov light, signal the muons crossing the detector. The water shields the IV from rocks and environment γs and ns.

The radio purification effort was very successful: for ^{238}U and ^{232}Th and their progeny the radiopurity reached some 10^{-20} and 10^{-19} g/g, respectively, and per the ubiquitous ^{222}Rn, < 1 count per day for 100 t of scintillator. Borexino is the unique detector which until now reached this unprecedented radiopurity.

With these premises, Borexino was able to identify the fusion reactions of the pp chain emitting neutrinos via the separate measurement of their fluxes. The problem of this analysis is to disentangle solar neutrinos signals from the residues of radio-contaminants, that survived the radio-purification. In addition, a software strategy had to be developed against the ^{11}C, which cannot be purified because it is continuously produced in the scintillator by the muons which survived the crossing of the Gran Sasso overburden (1.2 μ/m^2h). The results are summarized in the attached table where the measured rates and fluxes are compared with the SSM predictions for high and low metallicity: the comparison shows a good agreement.

The pp chain produces 99% of the entire solar energy; therefore the solar luminosity measured through solar neutrinos can be compared to the luminosity measured via photons: the good agreement found between them demonstrates that the Sun is in thermodynamic equilibrium over 10^4 years scale because, while neutrinos take a few seconds to leave the Sun, photons need more than 100,000 years.

Fig. 1. SSM-HZ and SSM-LZ fluxes: from Aldo Serenelli, F.Villante et al.. Global fit fluxes from J. Bergstroem et al.

The measurement of the various neutrino fluxes emitted by the pp chain nuclear fusions allows to determine the electron-neutrino survival probability in an energy range from a few tens of keV up to about 15 MeV, that is, according to the MSW model, from vacuum regime up to the matter enhanced oscillation. The experimental results are in agreement with the MSW-LMA predictions within the experimental and the Standard Solar Model uncertainties.

In the Sun the pp chain produces a temperature able to avoid its implosion caused by the gravitational forces acting among the solar matter. In massive stars, with a mass at least 30% greater that the Sun, a higher temperature is required to avoid implosion. Already in the '30s of the last century, Bethe and Von Weizsäcker hypothesized the existence of a cycle (CNO) dominating the massive stars where it reaches a core temperature of a few x 10^8 K; this hypothesis before Borexino never has been tested and demonstrated experimentally.

Fortunately, the CNO cycle is present in the Sun and produces 1% of its energy, and then Borexino was able to study the CNO cycle undertaking the analysis of the solar neutrinos produced by this cycle. The faced difficulties are due to the presence of CNO, pep and a residue of ^{210}Bi in the same energy window and to the tagging lack of the CNO energy spectrum. pep is not a problem because its shape and its rate are very well known, while to extract the CNO neutrinos flux, a strong constraint on the ^{210}Bi rate is needed. An important tool to this end is the presence of ^{210}Po in the scintillator and its secular equilibrium with ^{210}Bi.

Two components contribute to the ^{210}Po rate in the scintillator, one in secular equilibrium and one out of equilibrium: the latter decays with a half-life of 138.376 days and then, after a proper time, reaches a plateau corresponding to the ^{210}Po continuous production through the chain: ^{210}Pb- ^{210}Bi-^{210}Po and finally the stable ^{208}Pb. However, this plateau is not stable, but shows minor oscillations, due to convective currents in the scintillator which carry ^{210}Po nuclides, present on the IV walls, in the fiducial volume. Then a temperature stabilization is needed and it has been reached with a precision of 0.07 °C by thermally insulating the water tank and installing heating copper coils under the insulation.

As a result, the ^{210}Po and then the ^{210}Bi rates have been obtained, and, through a multivariate fit, the CNO neutrinos flux results to be:

$7.2^{+0.3}_{-1.7} \cdot 10^8 cm^{-2} s^{-1}$ (the uncertainty includes statistical and systematic errors), with no CNO hypothesis disfavored at 5σ C.L. In this way Borexino provided the direct experimental proof of the CNO cycle existence.

Borexino also observed with 5σ statistical significance the geoneutrinos, antineutrinos from the Earth interior. Unlike the solar neutrinos, Borexino is not the only experiment capable of making this measurement, because even the Japanese Kamland has studied geoneutrinos, with greater statistics and with greater background. This study allowed to investigate the presence of radioactive nuclides in the Earth's mantle, the contribution of radiogenic origin to the terrestrial heat and to obtain Earth's geo-physical and geo-chemical information.

The internal rotation of low-mass stars from solar and stellar seismology

G. Buldgen* and P. Eggenberger
Astronomy Department, University of Geneva, Versoix, 1290, Switzerland
**E-mail: Gael.Buldgen@unige.ch*

The possibility of measuring the internal rotation of the Sun and stars thanks to helio- and asteroseismology offers tremendous constraints on hydro- and magnetohydrodynamical processes acting in stellar interiors. Understanding the processes responsible for the transport of angular momentum in stellar interiors is crucial as they will also influence the transport of chemicals and thus the evolution of stars. Here we present some of the key results obtained in both fields and how detailed seismic analyses can provide stringent constraints on the physics of angular momentum transport in the interior of low mass stars and potentially rule out some candidates.

Keywords: Stellar physics; Stellar evolution; Helioseismology; Asteroseismology

1. Introduction

Low mass stars ($\approx 1M_{\odot}$) are mostly characterized by the presence in their structure of an outer convective envelope during their main-sequence. As a result, they will exhibit efficient braking through the effect of magnetised winds and they will most often exhibit long rotation periods of a few days. As a result of their low mass, they exhibit long evolutionary timescales of typically a few Gy on the main sequence. This implies that, if a given dynamical process is at work in stellar interiors, it will have time to leave a durable imprint on the evolution of the star, even if its characteristic timescale is relatively long. A good example of such a process is microscopic diffusion, that plays a key role in both solar and stellar modelling.

Another consequence of the existence of an outer convective envelope in low mass stars is that they will exhibit solar-like oscillations. These oscillations are global acoustic modes of the star that have been measured in both the solar case,[1] giving birth to the field of helioseismology, and in the stellar case,[2–4] paving the way for the field of asteroseismology of solar-like oscillators. With the advent of space-based photometry missions, the field of asteroseismology experienced an exponential growth, with the detection of global acoustic oscillations in thousands of stars.

Moreover, the quality of the observations enabled to perform similar analysis to those of the Sun, but on distant stars, increasing the sample of objects for which the internal rotation could be measured. The detection of mixed oscillation modes also gave access to the deep core rotation of evolved stars, providing laboratories for angular momentum transport process at various evolutionary stages.

In addition, the fact that most solar-like oscillators exhibited slow rotation of their surface allowed modellers to use perturbative approaches applied in helioseismology.

These measurements proved to be very challenging to explain using classical self-consistent rotating models including the effects of meridional circulation and shear-induced turbulence. While there exists multiple candidates to explain the internal rotation of low-mass stars on the main-sequence, the internal rotation of post-main sequence stars is still impossible to fully reproduce. Behind these difficulties hide the limitations of stellar models, emphasizing the need to improve our physical representation of stellar interiors.

In this brief review, we will discuss how the internal rotation of low mass stars is measured using a perturbative formalism in the fields of helio- and asteroseismology in Section 2. We will discuss the implications for angular momentum transport of the seismic constraints obtained on the main-sequence and will discuss the link with the transport of chemicals in Section 3. We will focus here on the constraints from acoustic oscillations only. More complete reviews, discussing also the results of massive gravity mode pulsators can also be found in the litterature[5] and classical textbooks also provide a more detailed view and additional references.[6] In Section 4, we will briefly present the main results using the mixed oscillation modes observed in post-main sequence stars and briefly discuss in Section 5 the implications for the main candidates foreseen as the "missing angular momentum transport process".

2. Measuring the internal rotation of low mass stars

The surface rotation of stars is accessible in photometry through the observations of spots on the stellar surface, or in spectroscopy through the determination of the rotational broadening of spectral lines. This allows us to test for example the formalisms used for the magnetic braking of low mass stars or the correlation between the depletion of light elements such as lithium or beryllium and the rotation period of stars in clusters. However, to study the internal rotation of stars, the only method available is by using the constraints derived from global oscillation modes. Indeed, their properties are intimately linked to the internal structure and dynamics of stellar interiors.

In the case of a non-rotating, non-magnetic, isolated star, the global oscillation modes will exhibit spherical symmetry and their angular dependencies can be decomposed on the basis of spherical harmonics. The eigenfunction of an oscillation mode, denoted $\vec{\xi}$, will thus be written in spherical coordinates as

$$\vec{\xi} = a(r) Y_{\ell,m}(\theta,\phi)\vec{e}_r + b(r)\left[\frac{\partial Y_{\ell,m}(\theta,\phi)}{\partial\theta}\vec{e}_\theta + \frac{imY_{\ell,m}(\theta,\phi)}{\sin\theta}\vec{e}_\phi\right], \qquad (1)$$

with r,θ and ϕ the radial and angular coordinates of the system, with their respective unit vectors $\vec{e}_r$, $\vec{e}_\theta$ and $\vec{e}_\phi$, $Y_{\ell,m}$ is the spherical harmonic of degrees ℓ and m, and $a(r)$ and $b(r)$ are the functions expressing the radial dependencies of the radial and angular components of the eigenfunctions.

There exists actually a degeneracy in the quantum numbers describing the eigenvalues, as they are identified by three quantum numbers, ℓ, the spherical degree, n, the radial order and m, the azimuthal degree in the general case, but only two are needed to describe the eigenvalue in the non-rotating case.

In the case of low-mass stars, we can assume that we are studying a slow rotator. Consequently, the effects of rotation will thus be treated as a perturbation of the operator describing the global acoustic modes, in a similar fashion to the treatment of a weak magnetic field in the case of the hydrogen atom in quantum mechanics. Just as the degeneracy in some eigenstates is lifted by the presence of the magnetic field in the hydrogen atom, the addition of rotation to the eigenvalue problem of stellar oscillations lifts the degeneracy of the eigenvalues, namely the oscillation frequencies of the star. They appear now as multiplets in the oscillation spectrum defined by their three quantum numbers, this time with m taking values between $-\ell$ and ℓ. This breaking of symmetry stems from the fact that adding rotation to the problem leads to the definition of an equator to the star and that one can now differentiates between the lines of the eigenfunction crossing the equator and those parallel to the equator, that define the quantum numbers ℓ and m in the base of spherical harmonics.

In other words, the eigenvalues will now be described as

$$\nu_{n,\ell,m} = \nu_{n,\ell,0} + \delta\nu_{n,\ell,m} \tag{2}$$

Mathematically, the perturbative approach applied to the stellar oscillation problem leads to a simple integral relation linking the so-called rotational splittings to the internal rotation as function of the radial position r and the latitude θ[7]

$$\delta\nu_{n,\ell,m} = m \int_0^R \int_0^\pi K_{n,\ell,m}(r,\theta)\Omega(r,\theta) dr d\theta \tag{3}$$

with $\delta\nu_{n,\ell,m}$ the rotational splitting, $\Omega(r,\theta)$ the internal rotation profile and $K_{n,\ell,m}(r,\theta)$ the so-called kernel function, depending on the internal structure and the eigenfunction of the oscillation mode.

This integral relation can be solved for the internal rotation profile, using specific numerical techniques (see e.g.[8]). Given that the linear perturbative approach is valid, the internal rotation profile can be determined independently from the stellar model used to perform the inversion. In other words, a non-rotating stellar model is sufficient to perform an analysis of the internal rotation of the star, if rotation is slow enough to be treated as a perturbation.

Equation 3 gives the general $2D$ form of the perturbative relations, but the ability to carry out $2D$ inversions is limited to a few exceptionnal targets, and was only possible for the Sun until very recently. In most seismic analyses, the hypothesis of spherical symmetry will be made and the rotation profile will be inferred as a function of r only. The rotation kernels are then a function of r only and show no explicit dependency in m, as shown for example in classical textbooks.[9] Moreover, the availability of only low ℓ modes for asteroseismic targets will also limit the

resolution of the inferences. The positions at which the rotational profile can be inferred are intrinsically bound to the physical nature of the observed oscillation modes and the behaviour of their kernel functions.

3. Results on the main sequence

Main-sequence low mass stars are known to exhibit purely acoustic modes called solar-like oscillations. As indicated by their name, these oscillations have been observed for the first time in the Sun. The main feature of these modes is that they have a much higher amplitude in the outer layers, as indicated in Fig 1 by the $1D$ rotational kernels computed here for a standard solar model.

Consequently, most of the inferences we will have for all main-sequence solar-like oscillators will focus on the upper radiative layers and the outer convective envelope. The inner 20% of the star will not be accessible to the pressure modes and thus will not be constrained by the inversion procedure. This statement is also true for the Sun, despite the wealth of seismic data accumulated in the last 30 years and has motivated the search for the elusive solar gravity modes.

3.1. *The solar case*

In the solar case, thousands of oscillation modes with degrees ranging from $\ell = 0$ to $\ell = 1000$ have been observed.[10–12] This tremendous amount of data has allowed a full scan of the internal solar rotation profile, down to $\approx 0.2 R_\odot$ (see e.g[13]).

The obtained rotation profile exhibits three main features. First, approximately solid-body rotation in the inner radiative layers of the Sun. Second, latitudinal differential rotation in the outer convective zone. Third, these two zones are connected by a narrow region, the so-called tachocline,[14,15] where the transition between the two rotation profiles occur.

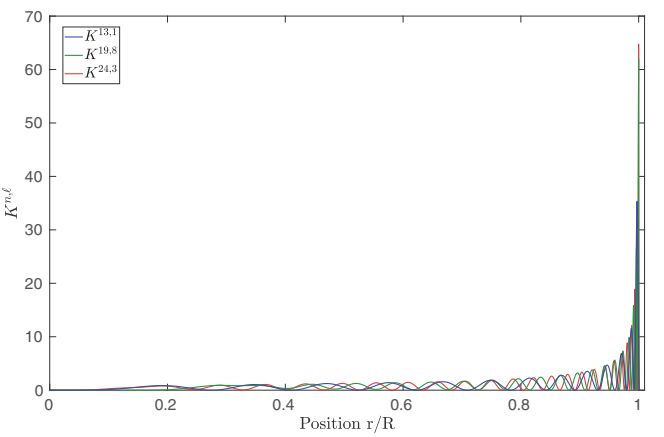

Fig. 1. $1D$ rotational kernels for various acoustic oscillaton modes of a standard solar model.

Here, we will focus mostly on the properties of the rotation profile in the inner solar radiative zone. The observed nearly uniform rotation of the inner solar layers is actually in complete contradiction with rotating models taking into account the effects of meridional circulation and shear-induced turbulence. Despite attempts at revising the prescriptions for these hydrodynamical processes,[16] it appears that their efficiency is too low to prevent the appearence of the characteristic strong differential rotation observed in these models.

Such a strong differential rotation is in disagreement with observations of the internal rotation of low-mass stars and also leads to a transport of chemicals by the shear-instability in disagreement with helioseismic inversions of the structure of the Sun and the depletion of light elements in low-mass stars. Therefore, additional processes have to been invoked to explain the discrepancies between rotating models and observations. The transport process involved should be very efficient at transporting angular momentum, but not chemical elements.

The first candidate is a large scale fossil magnetic field,[17] the second one are magnetic instabilities[18–20] and the third one are internal gravity waves.[21] We will further discuss the properties of these candidates in Section 5. They remain, to this day, the main suspects to explain the efficient angular momentum transport in stellar interiors.

3.2. *Results for Kepler and CoRoT targets*

With the advent of the CoRoT and *Kepler* missions, inferences on the internal rotation of main sequence stars could be carried out for a small sample of the best asteroseismic targets. Various authors[22–24] have shown that in the case of solar-like oscillators, the measurement of the average rotation seen by acoustic modes was consistent with the surface rotation derived from spots or spectroscopic measurements. In other words, no significant degree of differential rotation was found inside solar-like stars. This again accredited the existence of a very efficient transport of angular momentum acting in these stars, allowing to flatten their internal rotation profile.

However, a word of caution is required when stating that solar-like stars rotate as "solid-bodies". The constraints derived from asteroseismic data are not able to fully resolve the internal rotation of distant stars, but rather provide an average measurement of their internal rotation. Just as for the solar case, the purely acoustic oscillations observed for main-sequence solar-like oscillators do not allow to probe the deep core of these objects. As we will see in Section 5, this has important consequences to select one of the three candidates for additional transport mentioned above[a]. Recently, two studies[25,26] have also shown that solar-like oscillators also exhibited latitudinal differential rotation in their convective envelopes.

[a]We note that a similar situation is present also in more massive main-sequence stars such as γ Doradus stars, where the observed gravity modes only constrain the near core region, but not the convective core itself, as they do not propagate in these regions. Getting constraints on this region requires the analysis of inertial modes, recently observed.

3.3. *Link with the transport of chemicals*

An important consequence of the presence of an efficient angular momentum transport mechanism is its potential impact on the transport of chemical elements inside the star. For example, the effects of shear-induced instability in the presence of strong radial differential rotation in the radiative layers will be to erase the effects of microscopic diffusion and inhibit the settling of heavier elements from the convective layers to the deep interior.[27,28] While this effect should be limited as a result of the very low amplitude of rotation gradient in stellar radiative zones, it might not be fully negligible. In addition, a certain degree of additional mixing is required to reproduce the lithium abundance of the Sun[29] and solar-like stars.[30–33]

This is illustrated in Fig. 2 for the solar case and young solar-like stars.[34] The results show that mixing by the shear instability and the effects of magnetic instabilities will lead to a certain degree of mixing at the base of the convective zone thus changing both the helium and lithium abundances.

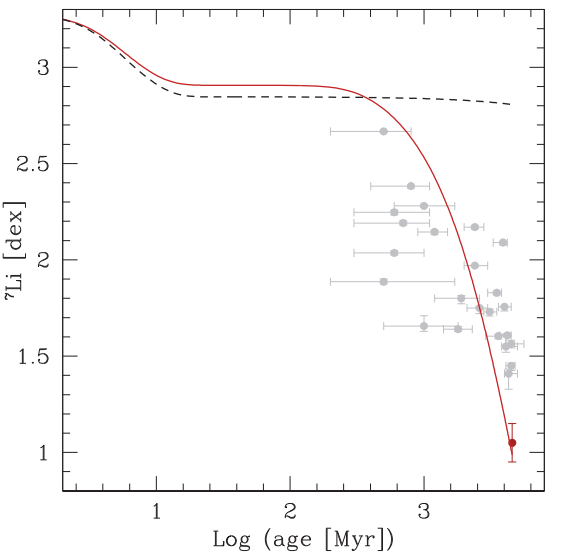

Fig. 2. Lithium abundance evolution as a function of the logarithm of age. The red dot correspond to the solar Lithium abundance[35] and the grey dots correspond to the abundance of solar-like stars.[34]The dashed line indicates the evolution of the surface Li abundance for a standard solar model, while the continuous red line corresponds to a model with hydrodynamic and magnetic instabilities.

Some of the stars observed by the *Kepler* satellite offer excellent testbeds for such effects, as for example the 16Cyg binary system,[36–39] where the binarity also allows to test the effects of planetary formation on the abundances of light elements. Moreover, seismic analyses of the helium abundance in the envelope of other *Kepler*

targets[40] have shown the need for a mecanism reducing the efficiency of microscopic diffusion, that could be due to the effects of small rotation gradients.

4. Results for evolved stars

The determination of the internal rotation of subgiant and red giant stars[41–44] has been one of the main successes of the space-based photometry missions. These results have been achievable thanks to the observation of so-called mixed oscillation modes. The peculiarity of these modes is that they are of double nature and have high amplitudes both in the deep core and in the outer layers of post-main sequence solar-like oscillators. They exhibit a gravity-like character in the core and an acoustic nature in the envelope. Therefore they can be easily detected and carry information on the deepest layers of evolved stars, regions that are even unaccessible in the Sun due to the purely acoustic nature of the observed oscillations, despite the quality of helioseismic data.

From the analysis of these oscillation modes, it has been shown that subgiant and red giant stars exhibited radial differential rotation.[41–44] Namely, that their cores rotated faster than their outer layers. While this was expected, as a result of the contraction of the core and the expansion of the convective envelope undergone as the star leaves the main sequence, the degree of differential rotation observed is far lower than what is predicted by theoretical models.[45–47]

Recent results[48] have also indicated that young subgiant stars seem to exhibit almost solid-body rotation. Later on in the subgiant phase, they show some degree of differential rotation that develops but it appears that on the red giant phase, the stellar core does not spin up with the evolution.[49,50] In later stages of evolution such as the red clump or the secondary clump, similar conclusions are drawn regarding the need for a very efficient transport process.

A crucial point to note here is that to study the efficiency of the missing angular momentum transport process, core rotation is not entirely sufficient, and a measurement of the surface rotation is also required. This is available for a few targets, either from seismology, or from spot modulations. However in the latter case, it seems that the sample is biased towards active, fast rotators, who could perhaps not be quite representative of the bulk of red giants.

The main issue posed by the results obtained for post-main sequence stars is that there is, to this day, no single mechanism capable of explaining all the observations. Analyses of the average efficiency of the missing transport process[51,52] have shown that it should exhibit a drop in efficiency during the subgiant phase but reincrease as the star ascends the red giant branch. This could possibly point at either a change of regime in the transport process or at multiple transport processes acting at different evolutionary stages. For example, it has been shown that mixed modes themselves would lead to an efficient transport of angular momentum on the upper red giant branch and could potentially take over at stages where another process sees its efficiency reducing.[53]

5. Transport mechanism candidates

Apart from the transport by mixed modes, the main suspects under investigation are the processes already invoked to explain the solar rotation profile. Namely, these are large scale fossil magnetic fields, internal gravity waves and magnetic instabilities.

However, all of them needed to be revised to explain the results observed in post-main sequence stars. We will here briefly summarize the main results and remaining issues with each of these processes.

5.1. *Fossil magnetic fields*

The first candidate introduced to explain solar rotation is a large-scale fossil field present in the radiative zone of the Sun.[17] It was demonstrated that the field, if properly confined, could lead to a rigid rotation profile in the interior of the Sun.

The main difficulty for the fossil field solution in the solar case is indeed linked to the confinement of the field, as it should not extent in the solar convective zone where differential rotation in latitude is observed. This requires the field to reach a very specific configuration for which simulations give conflictual results regarding its confinement to the radiative zone.[54–57] In addition, recent work[58] has shown that, in addition to the confinement problem, simulations required a significant increase in the viscosity of the plasma to avoid a dead zone of the field where the profile would not reproduce at all the observed data.

Nevertheless, a second issue with the fossil field configuration used to explain the solar rotation profile is that it enforces a strictly solid-body rotation in radiative zones. As shown before, this is not what is found in later evolutionary stages and thus another configuration, or another physical process, is required to explain asteroseismic data. One possible configuration for red giants is to have a solid-body rotation profile in radiative zones, combined to a profile in the power law of the radius in convective zones,[59,60] of the form $\Omega(r) \propto r^{-\alpha}$, with $\alpha \in [1.0, 1.5]$. These studies[59,60] showed that such a rotation profile could explain the core rotation rate of red giant branch stars inferred from seismic data.[49,50]

However, these results are in contradiction with recent studies[61–63] who seem to indicate that the transition from the slow rotating envelope to the fast rotating core in red giant stars seems to be located in the radiative zone, close to the hydrogen burning shell. A detailed analysis of the case of Kepler 56 was recently performed,[64] including a full dedicated modelling of the internal structure of the star and an MCMC analysis of the rotational splittings using simple parametric profiles, including the power law solution provided by large scale fossil fields. Their results show that such a rotation profile cannot be used to explain the individual rotational splittings unless α is allowed to reach higher values of the order of 3.5, in contradiction with theoretical values.[59] This suggests that fossil magnetic fields are not the explanation for the efficient angular momentum transport process acting in evolved stars, and other processes must also be invoked.

5.2. *Internal gravity waves*

The effect of internal gravity waves has been studied already early on as being of potential interest to the modelling of stellar interiors and applied to the solar case.[21,65]

Later studies[66,67] indicated that the process was not efficient enough to actually flatten the solar rotation profile and pointed that the effect of waves excited by Reynold's stresses would leave a strong imprint of the wavefront on the internal solar rotation profile that is incompatible with observations. When applied to later evolutionary stages, the gravity wave model used on the main-sequence[21] is also found to be not efficient enough to reproduce the internal rotation of subgiants and red giant stars.[68]

However, hydrodynamical simulations[69] underlined the importance of the effects of convective plumes in the generation of gravity waves. These effects were later studied, showing that gravity waves induced by the impact of convective plumes could be much more efficient at transporting angular momentum both in the Sun and subgiant stars.[70,71] They also showed that it would likely not be able to operate efficiently on the red giant branch, where another process would then be needed. It would then be particularly interesting to compute full evolutionary models with plume-induced gravity waves to investigate their effects on the rotation profile of solar-type and subgiant stars.

5.3. *Magnetic instabilities*

The last main candidate to explain the efficient transport of angular momentum in stellar radiatives zone are magnetic instabilities. Work by H. Spruit[72] showed that the first instability likely set in stellar conditions would be the Tayler instability. In the presence of a differentially rotating fluid, the winding up of a seed magnetic field together with the Tayler instability has been shown to lead to an efficient angular momentum transport mechanism, the so-called Tayler-Spruit dynamo.[73] This transport mechanism has been shown to be able to reproduce the internal solar rotation profile.[19,20]

While a promising candidate, numerical simulations have shown contrasting results about the apparition of the Tayler-Spruit dynamo.[74,75] The main difficulty with such conclusions is that such simulations are never in fully realistic stellar conditions.

Nevertheless, in its original form, the Tayler-Spruit dynamo still proves not efficient enough to counteract the spin up of the core at the end of the main-sequence. Models computed taking it into account still predict faster core rotation rates than the seismically inferred values.[76,77]

Recently, a modification of the Tayler-Spruit instability was proposed that led to a more efficient braking of the stellar cores.[78] Further analyses[79] showed however that this variant could not reproduce all the observational constraints. Namely, it was found to be too efficient for subgiants if one wished to reproduce the red giant

cores, or not efficient enough for red giants if the calibration parameter was set to reproduce subgiants, as shown in Fig 3. This calibration parameter, denoted α has to be varied from 0.5 to 1.5 to reproduce respectively the subgiants and the red giants. However, as it is set to the third power in the revised formalism, such a variation is far from anecdotic. A similar issue was found for secondary clump stars and white dwarfs.[80]

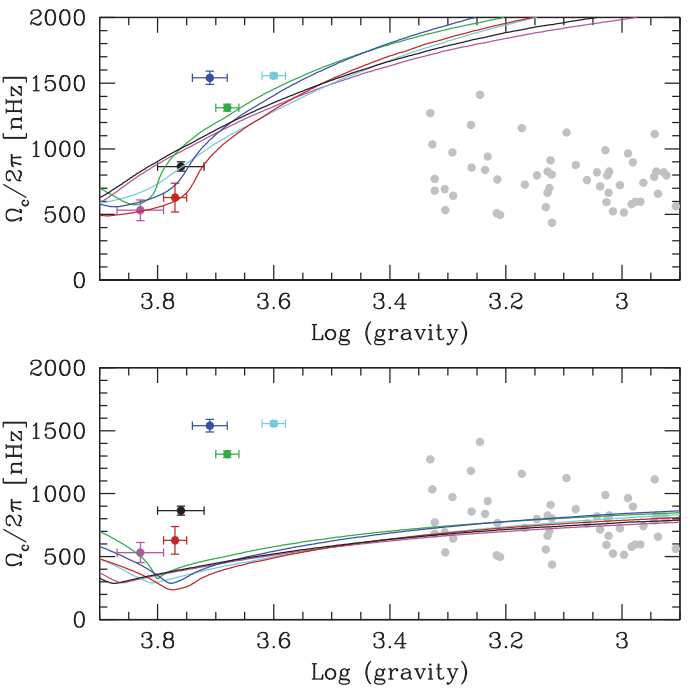

Fig. 3. Core rotation of subgiant and red giant stars as a function of the logarithm of the surface gravity. The colored points correspond to subgiant stars[43] and the grey dots to red giant stars.[49] In the upper and lower panels, the calibration parameter α in the revised version of the Tayler-Spruit dynamo is set to 0.5 and 1.5, respectively.

6. Conclusion

In this brief review, we have described the current state of the vision solar and stellar seismology brought on the internal rotation of low-mass stars in various evolutionary stages. We have focussed on the inferences brought by acoustic and mixed oscillations modes only, trying to provide a complete vision of the current issues at hand regarding the missing angular momentum transport mechanism found to act in stellar radiative zones.

The formalism for seismic inferences within the first-order perturbative formalism has been introduced in Section 2, while results for the main-sequence and post-

main sequence stars have been discussed in Sections 3 and 4. We have also briefly introduced the three main candidates currently under extensive investigations in Section 5.

The main conclusion to be drawn from the current situation is a sort of stalemate between multiple processes, none of them providing a unifying satisfactory solution. In that respect, further investigations on the effiency of the missing transport process are required, analysing its dependencies with stellar properties such as mass and metallicity. To this end, better characterizing the location of rotation gradients inside stars is crucial, as well as providing both surface and core rotation measurements from a consistent seismic inference technique to fully constrain the efficiency of the transport process.

It should also be noted that the potential strong influence of chemical composition gradients in the development and efficiency of instabilities (magnetic or hydrodynamic) also calls for a better depiction of the chemical structure of stars. Therefore, the potential solution to the angular momentum transport problem is also tightly linked to the reliability of our vision of the internal structure of stars, that also relies on improving seismic inference techniques. At stakes is likely the recipe for a new generation of solar and stellar models, which would take into account both the effects of rotation, the depletion of light elements and better reproduce seismic and spectroscopic constraints. Moreover, while a unifying solution is tempting, the variations seen at different evolutionary stages might be pointing at various processes taking over during the evolution. To provide a clearer picture, further efforts must be made in the improvement of seismic inference techniques and in the exploitation of the current and future datasets from the CoRoT,[81] *Kepler*,[82] TESS[83] and Plato[84] missions.

The rotation of supermassive stars

L. Haemmerlé

Département d'Astronomie, Université de Genève, chemin des Maillettes 51, CH-1290 Versoix, Switzerland
E-mail: lionel.haemmerle@unige.ch

Supermassive stars (SMSs), with masses $> 10^5$ $M_\odot$, have been proposed as the possible progenitors of the most extreme supermassive black holes observed at redshifts $z > 6-7$. In this scenario ('direct collapse'), a SMS **accretes** at rates > 0.1 $M_\odot\,yr^{-1}$ until it collapses to a black hole via the general-relativistic (GR) instability. Rotation plays a crucial role in the formation of such supermassive black hole seeds. The centrifugal barrier appears as particularly strong in this extreme case of star formation. Moreover, rotation impacts sensitively the stability of SMSs against GR, as well as the subsequent collapse. In particular, it might allow for gravitational wave emission and ultra-long gamma-ray bursts at black hole formation, which represents currently the main observational signatures proposed in the literature for the existence of such objects. Here, I present the latest models of SMSs accounting for accretion and rotation, and discuss some of the open questions and future prospects in this research line.

Keywords: Stars: massive – stars: rotation – stars: black holes

1. Introduction

Supermassive stars (SMSs), with masses $\gtrsim 10^5$ $M_\odot$, were originally invoked to explain the high luminosity of quasars,[1,2] later understood as a consequence of accretion in the deep potential well of supermassive black holes (SMBHs).[3] The formation of these SMBHs remains, however, one of the main open problems in galaxy formation, and SMSs have been proposed as their possible progenitors.[4,5] In the last decade, a number of quasars powered by SMBHs with masses 10^9-10^{10} $M_\odot$ have been detected at redshifts 6 – 7. The most extreme case known to date is J0313-1806 a quasar at $z = 7.6$ that hosts a SMBH with mass $1-2\times10^9$ $M_\odot$.[6] At redshifts 6 – 7, the age of the Universe is a fraction of a Gyr, so that objects of $10^9 - 10^{10}$ $M_\odot$ that exist at these redshifts must have accumulated their mass at average rates $\dot{M} \gtrsim 10$ $M_\odot\,yr^{-1}$. The direct formation of SMBHs during the process of galaxy formation ('direct collapse' black holes) provides the most rapid pathway to form SMBHs with masses $\gtrsim 10^9$ $M_\odot$.[5,6] In this scenario, the direct progenitor of the SMBH is a SMS undergoing accretion at rates $\dot{M} \gtrsim 0.1$ $M_\odot\,yr^{-1}$, until it collapses due to the general-relativistic (GR) instability.[7,8]

The direct collapse of $\sim 10^9$ $M_\odot$ into a compact object requires special conditions. Fragmentation is inhibited in primordial gas due to the absence of heavy elements, but the cooling by molecular hydrogen remains efficient enough to maintain temperatures 100 – 1000 K, which is thought to result in the formation of a cluster

of stars with individual masses $M \lesssim 100$ M$_\odot$.[9] Black hole seeds formed from the collapse of such primordial clusters remain $\lesssim 1000$ M$_\odot$, and hardly explain the large masses of the earliest quasars.[6,10] Only in the presence of a strong Lyman-Werner flux the molecular hydrogen of primordial gas can be dissociated, which leads to temperatures $\sim 10^4$ K set by atomic cooling.[11] Primordial, atomically cooled halos are found to collapse isothermally with inflows 0.01 – 1 M$_\odot$ yr^{-1} sustained down to sub-parsec scales, allowing for the direct formation of a supermassive compact object in a dynamical time.[12,13] However, this scenario implies tight synchronisation between halo pairs, since only star formation in a neighbouring halo can provide the required Lyman-Werner flux.[14] Another channel of direct collapse is provided by the merger of the most massive galaxies expected to have formed at redshifts 8 – 10, with masses $\sim 10^{12}$ M$_\odot$.[15] The merger is found to trigger inflows of $\sim 10^4 - 10^5$ M$_\odot$ yr^{-1} down to a fraction of a parsec, which allows to accumulate several 10^9 M$_\odot$ in a few tens of kyr. No special chemical composition is required, since the collapse is too rapid for star formation and radiative feedback to start, and metallicities up to solar are expected in these galaxies. However, SMBH formation by direct collapse in metal-rich gas requires a SMS with mass $M \gtrsim 10^6$ M$_\odot$ in order to avoid thermonuclear explosion.[16]

The strong contraction that characterises a gravitationnal collapse leads in general to rapidly rotating structures, by a simple argument of angular momentum conservation. In fact, star formation by accretion requires strong mechanisms to remove angular momentum from the collapsing gas in order to circumvent the centrifugal barrier.[17] This angular momentum problem represents one of the main bottleneck in models of massive star formation[18–20] and plays naturally a critical role in the context of SMS and SMBH formation.[21,22] Here, I review the latest theoretical results concerning SMSs in the context of SMBH formation, focusing on the importance of rotation. In Section 2, I review the main properties of SMSs formed by accretion; I discuss the angular momentum problem in section 3; section 4 focuses on the GR instability and the maximum mass of rotating SMSs; the implication for SMBH formation by direct collapse are discussed in section 5. A summary is given in section 6.

2. Rotation in rapidly accreting SMSs

The evolution of SMSs under rapid accretion has been addressed with analytical and numerical models in the last decade.[23–25] SMSs are always close to the Eddington limit, which implies that their H-burning time is of the order of the Myr, independently of their mass. Thus, forming a SMS of mass $M \gtrsim 10^5$ M$_\odot$ by accretion before fuel exhaustion requires rates $\dot{M} \gtrsim 0.1$ M$_\odot$ yr^{-1}. Under such accretion rates, SMSs are found to evolve as 'red supergiant protostars',[24] following upwards the Hayashi limit in the Hertzsprung-Russel diagram. An example is shown in figure 1, with numerical models of Population III (Pop III) SMSs computed with the stellar evolution code GENEC.[25] The effective temperature on the Hayashi limit remains $\lesssim 10^4$ K,

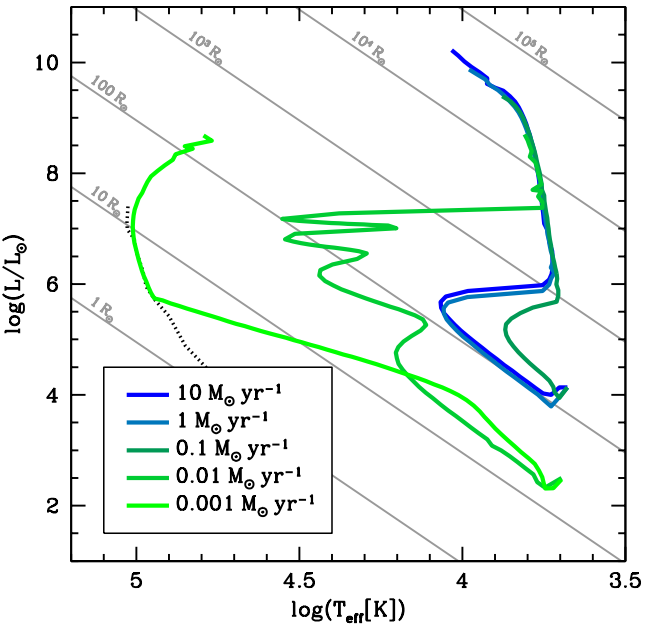

Fig. 1. Hertzsprung-Russel diagram of the GENEC models of Pop III, rapidly accreting SMSs. (Figure from.[25])

which implies negligible ionising feedback and allows for continuous accretion up to at least $M \sim 10^5$ M$_\odot$. As a consequence of the evolution along both the Eddington and the Hayashi limits, the mass-radius relation of rapidly accreting SMSs can be approximated by a simple power-law:

$$R = 260\,\mathrm{R}_\odot \left(\frac{M}{\mathrm{M}_\odot}\right)^{1/2} \tag{1}$$

The increase of the radius with the growing mass results from the fact that, at rates $\gtrsim 0.01$ M$_\odot$ yr^{-1}, the entropy advected by an element of mass ΔM at accretion cannot be radiated efficiently in the corresponding accretion time $\Delta M/\dot{M}$. Thus, the Kelvin-Helmholtz contraction of the stellar interior is too slow compared to the increase in radius that results from the accretion of new mass. As a consequence, most of the stellar interior is not thermally relaxed and maintains an outwards positive entropy gradient that stabilises the gas against convection. This is illustrated in figure 2 with the entropy profiles of the Pop III GENEC models at $\dot{M} = 1 - 100$ M$_\odot$ yr^{-1}, taken at successive stages of the evolution. The highly centralised energy production by H-burning drives convection in a core of $\sim 10\%$ of the stellar mass, that stays isentropic. An **outer** envelope is also convective (non-adiabatic), due to the high opacities at the low temperatures of the Hayashi limit. This **outer** envelope contains negligible mass ($\sim 1\%M$), but represents a significant fraction of the stellar radius. For accretion rates $\dot{M} \gtrsim 10$ M$_\odot$ yr^{-1}, the

evolutionary timescale becomes so short that the radiative envelope contracts adiabatically, compressed by the weight of the layers newly accreted.[26] In this regime, the entropy profile converges towards a simple power-law of the mass-coordinates ('hylotrope'[23]):

$$s \propto M_r^{1/2} \tag{2}$$

This power-law is shown by a grey dotted line in figures 2.

For stars near the Eddington limit, the maximum rotation velocity consistent with hydrostatic equilibrium is given by the ΩΓ-limit, that accounts for the role of radiation pressure:[28]

$$\Omega_\Gamma \simeq \Omega_K \sqrt{1-\Gamma} \tag{3}$$

where Ω_K is the Keplerian angular velocity and Γ the Eddington factor. SMSs have $\Gamma \sim 0.99$, which implies rotation velocities of $\lesssim 10\%\ \Omega_K$; in other words, SMSs must be slow rotators.[22] The maximum rotation velocity set by the ΩΓ-limit is shown in figure 3 as a function of the SMS's mass. The ratio of centrifugal to gravitational forces in the star, which is of the same order as the ratio of rotational to gravitational energies, can be estimated by

$$\frac{\Omega^2}{\Omega_K^2} \sim 1-\Gamma \lesssim 1\% \tag{4}$$

For such slow rotations, the deformation of the star by the anisotropic centrifugal force remains negligible. Moreover, due to the short evolutionary timescales, meridional currents and shear diffusion have no significant impact on the angular momentum distribution. Thus, the radiative layers contract with local angular momentum conservation, which translates into highly differential rotation, with a rotation frequency several orders of magnitude larger in the core than at the surface.[22] The break-up velocity is not reached in the core, thanks to the large Keplerian velocity in the densest regions.

3. The angular momentum problem

Because of the slow rotations imposed by the ΩΓ-limit, SMS formation by accretion implies low angular momentum in the accreted gas. This is illustrated in figure 4, that shows the evolution of a Pop III SMS accreting at $\dot{M} = 1\ \mathrm{M_\odot\,yr^{-1}}$ under the assumption of maximal rotation. Rotation is post-processed from the non-rotating GENEC structures shown in the upper panel. Angular momentum is advected at accretion in order to satisfy the constraint from the ΩΓ-limit (third panel) at each time-step, and the resulting angular momentum accretion history is shown in the fifth panel as a blue line. It remains 2 – 3 orders of magnitude below the Keplerian angular momentum (grey line), which means that, for the ΩΓ-limit to be satisfied all along the accretion phase, the angular momentum advected at accretion cannot exceed a fraction $f \sim 0.1 - 1\%$ of the Keplerian angular momentum. In other

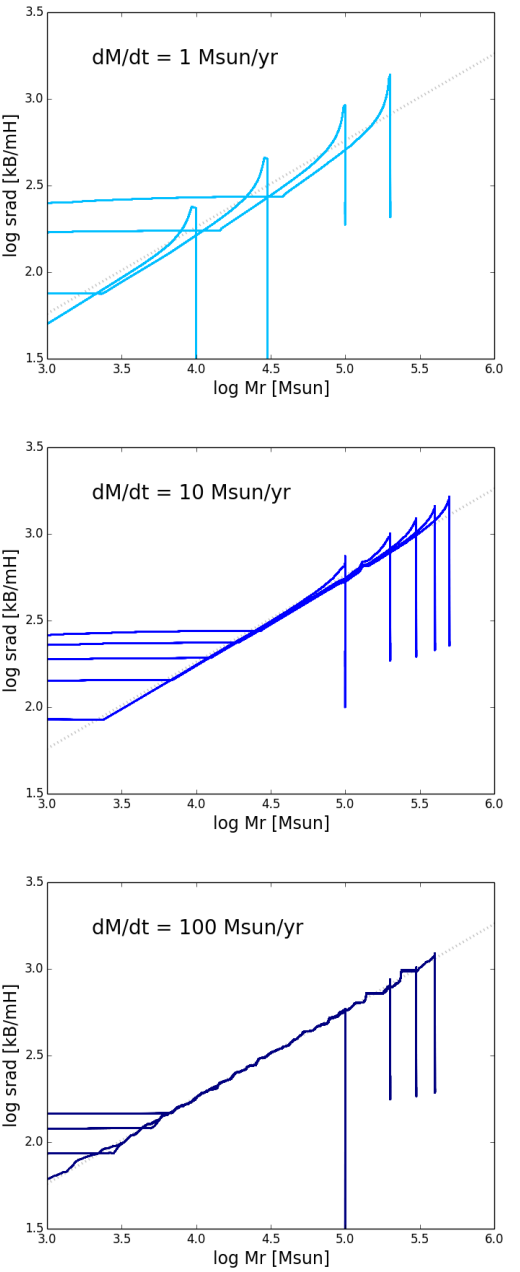

Fig. 2. Entropy profiles of the GENEC models of Pop III SMSs accreting at $\dot{M} = 1{-}100\ \mathrm{M}_{\odot}\ \mathrm{yr}^{-1}$. The grey dotted line indicates the power-law (2). (Figure from.[27])

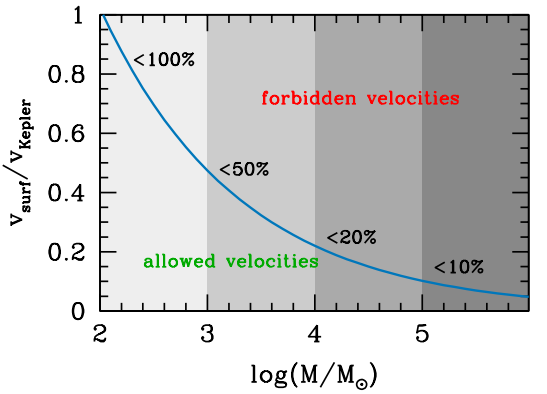

Fig. 3. Maximum rotation velocity of SMSs as a function of their mass (figure from[22]).

words, SMS formation by accretion from a Keplerian disc requires mechanisms efficient enough to remove more than 99% of the angular momentum from the disc. Notice that the fraction f is $1-2$ orders of magnitude smaller than the ratio Ω/Ω_K imposed by the $\Omega\Gamma$-limit, which reflects the instantaneous redistribution of angular momentum in the **outer** convective envelope visible in the upper panel of figure 4. **Indeed, without convection, the ratio Ω/Ω_K in the surface layer would be simply given by the fraction f of angular momentum advected by this layer. But here, the surface velocity is given by the angular momentum accreted plus that received by convection from the deeper layers of the envelope. Thus, a given constraint on the ratio Ω/Ω_K (e.g. $\lesssim 10\%$) translates into a tighter constraint on the ratio f (e.g. $\lesssim 0.1-1\%$).**

The angular momentum problem is general to star formation.[17] For low-mass stars, the problem is easily solved by the magnetic coupling of the star with its disc and winds, thanks to the convective dynamo in the stellar envelope. But the problem becomes more difficult for massive stars, since these stars have no convective envelope, and only a few percent of them have detected magnetic fields, thought to be fossil fields.[30] The most efficient processes to extract angular momentum in the context of massive star formation rely on the gravitationnal instabilities that develop in massive accretion discs.[31] Since these gravitationnal instabilities are enhanced by high densities, their efficiency increases when the centrifugal barrier is reached, as gas accumulates in the vicinity of the star. Thus, these processes allow for a self-regulated, efficient angular momentum transport all along the collapse.

In the case of rapidly accreting, maximally rotating SMSs, the surface magnetic field required to remove the angular momentum excess at accretion from a Keplerian disc by star-winds coupling is of the order of 10 kG, as shown in the bottom panel of figure 4. The corresponding Alfvén radius is shown as a red dashed line in the top panel. According to estimates based on the Rossby number, a convective dynamo in the envelope of the SMS cannot produce a field larger than 1 G. Only fossil

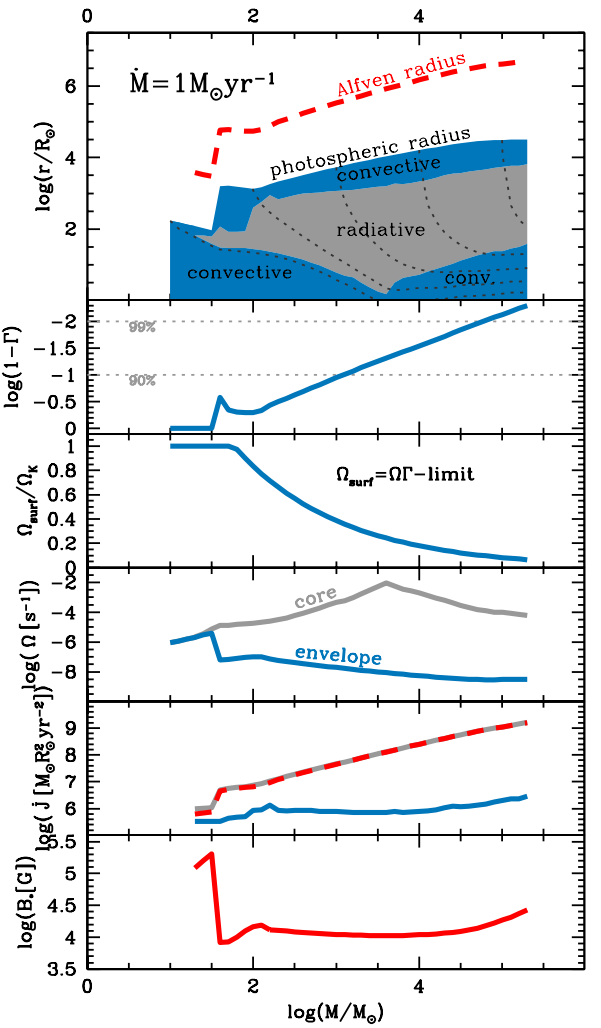

Fig. 4. GENEC model of a maximally rotating Pop III SMS accreting at $\dot{M} = 1\ \mathrm{M}_{\odot}\,\mathrm{yr}^{-1}$. The horizontal axis represents the stellar mass, which is a time coordinate in case of constant accretion. The first four panels show the stellar structure in radial coordinates, the Eddington factor, the ratio of the surface velocity to the Keplerian velocity, and the angular velocity in the core and the envelope. The fifth panel shows the accreted angular momentum (in blue), compared to the Keplerian angular momentun (in grey). The difference is shown by the red dashed curve. The bottom panel shows the surface magnetic field required to remove this difference of angular momentum by star-wind coupling. (Figure from.[29])

fields from primordial origin could reach the required values. On the other hand, gravitational instabilities are particularly strong in the massive accretion discs of SMSs, and are thought to be efficient enough to circumvent the centrifugal barrier in the context of SMBH formation.[21,32]

4. GR instability

The formation of a SMBH by direct collapse occurs when the progenitor SMS becomes dynamically unstable. SMSs are expected to collapse via the GR instability,[33] which is a pulsation instability that arises from the GR corrections to the equation of radial momentum. For a non-rotating post-Newtonian SMS, the eigenfrequency ω of adiabatic pulsations can be obtained with[34]

$$\omega^2 I = \int \beta P \mathrm{d}V - \int \left(\frac{2GM_r}{rc^2} + \frac{8}{3}\frac{P}{\rho c^2} \right) \frac{GM_r}{r} \mathrm{d}M_r \tag{5}$$

where r is the radial distance from the stellar centre, M_r the mass-coordinates (i.e. the mass contained in all the layers below r), ρ the mass density, P the pressure, β the ratio of gas pressure to total pressure, I the moment of inertia, V the volume of the sphere r, G the gravitational constant and c the speed of light. Notice that in the post-Newtonian approximation, distinctions between rest-mass and relativistic-mass are irrelevant.

The GR instability is reached when ω becomes imaginary, which implies that exponentials are solutions to the equations of motion. Equation (5) expresses this condition in terms of the two integrals at the right-hand side. The first one is Newtonian and positive, and scales with β, that is with the departures from the Eddington limit, at which all the pressure support is provided by radiation. As the SMS grows in mass, it approaches the Eddington limit asymptotically with $\beta \to 0$, but $\beta > 0$. Thus, without any additional term, equation (5) would imply that the star remains always stable. However, the second term, that scales with the GR corrections $2GM_r/rc^2$ and $P/\rho c^2$, is negative. As the SMS grows in mass, these corrections grow until the sum of the integrals become negative. At this point, the star is dynamically unstable, which leads in general to the direct formation of a SMBH in a dynamical time.[35,36]

The exact mass at which the SMS reaches the GR instability depends on its structure, in particular on the mass of its convective core. The maximum masses of non-rotating Pop III SMSs as a function of the mass of their convective core are shown in figure 5. The black-blue-cyan tracks are the evolutionary models of Pop III SMSs computed with GENEC under accretion at the indicated rates.[25,26] These models were computed under the assumption of hydrostatic equilibrium, which makes them insensitive to dynamical instabilities, and the ends of the runs are arbitrary, imposed by the numerical stability of the models. The onset of the GR instability on these hydrostatic models, determined with equation (5), is indicated by star-like symbols. It is reached before the end of the run only for rates 1 and 10 $\mathrm{M}_\odot\,\mathrm{yr}^{-1}$. The limitations due to the numerical instability of hydrostatic models with rapid accretion can be circumvented with the use of semi-analytical models built on the hylotropic law of equation (2).[23] With these structures, the limit of stability in the (M_{core}, M)-diagram is uniquely given by the central temperature of the star and its chemical composition. The central temperature of SMSs is well constrained

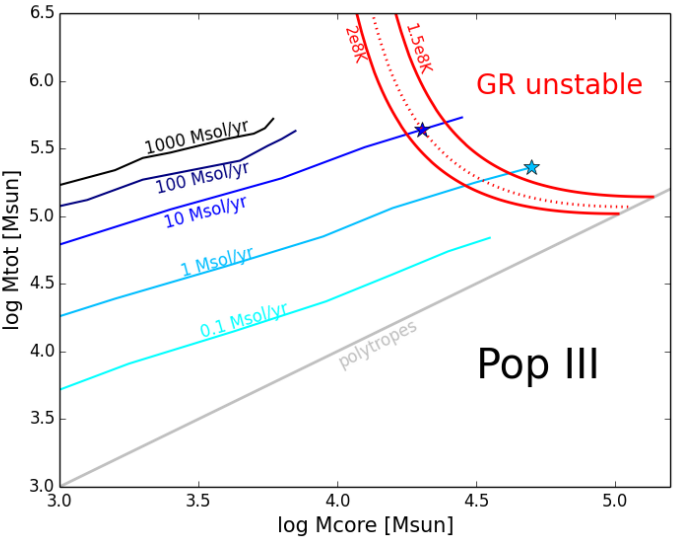

Fig. 5. Maximum masses of non-rotating Pop III SMSs consistent with GR stability, as a function of the mass of their convective core. The red curves show the limit of stability derived from hylotropic structures with the indicated central temperatures. The black-blue-cyan tracks are Pop III GENEC models computed with the indicated accretion rates. The star-like symbols indicate the point of GR instability of these models, when it is reached. (Figure from.[27])

by numerical models, and remains in a narrow range due to the thermostatic effect of H-burning ($T_c = 1.5 - 2 \times 10^8$ K for Pop III SMSs; $T_c = 0.6 - 0.9 \times 10^8$ K for Pop I SMSs). The limits of stability for Pop III SMSs derived from the hylotropic models are shown as red curves in figure 5. The dotted red curve is the stability limit for the exact central temperature of the last stable model of the GENEC track at $\dot{M} = 10$ M$_\odot$ yr^{-1}. We see that the hylotropic limit is already very precise for this rate, in spite of the small departures from the hylotropic profiles visible in figure 2. The entropy profile in the inner part, where the density is high and GR corrections are significant, is already well approximated by the hylotropic law (2) for this rate. Only for rates $\lesssim 1$ M$_\odot$ yr^{-1} the GENEC models departs significantly from the hyloptropic law. But even in this case the discrepancies in the final mass remains of ~ 0.1 dex, that is ~ 20 %. Thus, the limit of stability given by the hylotropic models remains a good approximation for any accretion rate. Moreover, the numerical simplicity of these models allows for a broader view of the parameter space. In particular, we see that for the central temperatures set by H-burning the GR instability cannot be reached if the stellar mass does not exceed $\gtrsim 10^5$ M$_\odot$. Moreover, the GR instability always requires the convective core to contain a mass $\gtrsim 10^4$ M$_\odot$.

Rotation plays a prominent role in the stability of SMSs. Near the GR instability, the dimensionless ratios β, $2GM_r/rc^2$ and $P/\rho c^2$ are all of the order of a percent.

It implies that the positive and negative integrals at the right-hand side of equation (5) represent typically a percent of the total internal and gravitational energies of the star, respectively. Thus, other small effects, that have negligible impact on the hydrostatic structure of SMSs, can play a critical role on the dynamical stability of these structures. This is the case for rotation: the slow rotation velocities ($\sim 0.1\ \Omega_K$) consistent with the $\Omega\Gamma$-limit correspond to rotational energies of the order of $\Omega^2/\Omega_K^2 \sim 1\%$ of the gravitational energy of the star (equation 4). The rotational corrections to equation (5) are thus of the same order as the β- and GR-terms. For these slow rotations and small GR corrections, however, the relativistic rotation terms are expected to be of second order, and can be neglected in the determination of the stability limit. Including the Newtonian rotation term to equation (5), we obtain[34]

$$\omega^2 I = \int \beta P \mathrm{d}V + \frac{4}{9}\int \frac{\Omega^2}{\Omega_K^2}\frac{GM_r}{r}\mathrm{d}M_r - \int\left(\frac{2GM_r}{rc^2} + \frac{8}{3}\frac{P}{\rho c^2}\right)\frac{GM_r}{r}\mathrm{d}M_r \qquad (6)$$

The positive rotation term contributes to the stability of the star, and allows it to increase its mass by orders of magnitude beyond the non-rotating limit.[34,37]

The limits of stability for rotating Pop III and Pop I SMSs are shown in figures 6 and 7, respectively.[34] The limits have been derived from hylotropic structures, on which rotation profiles are defined by local angular momentum conservation in the radiative envelope and solid rotation in the convective core. Each layer of the radiative envelope is assumed to keep the angular momentum it advected at accretion, defined as a faction f of the Keplerian angular momentum at the accretion radius given by equation (1). The angular momentum of the core is then given by that advected from the envelope. We see that the limits start to be shifted by rotation as soon as $f \gtrsim 0.1\%$, while for $f \sim 1\%$ they are already shifted by 3 orders of magnitudes towards larger masses. The lower central temperatures of the Pop I models allows for slightly larger masses when $f \sim 0.1\%$, but when $f \sim 1\%$ the limits do not depend anymore on the thermal properties of the star, and are uniquely given by f. In this regime, indicated by the red areas on the diagrams, the gas term in equation (6) becomes negligible compared to the rotation and GR terms, which means that rotation becomes the main stabilising agent against the destabilising GR corrections. An interesting consequence is that the profile of the spin parameter at the onset of the instability, which is key regarding black hole formation, becomes 'universal', that is, uniquely given by the mass-fraction of the convective core.

For typical conditions of atomically cooled halos (Pop III, $\dot{M} \lesssim 1\ \mathrm{M_\odot\,yr^{-1}}$), the $\Omega\Gamma$-limit imposes $f \lesssim 0.1 - 0.2\%$ (figure 4). In this case, rotation can increase the final stellar mass by up to a factor ~ 2, which does not allow to exceed $10^6\ \mathrm{M_\odot}$. As mentioned in section 3, this low value of f results from the instantaneous angular momentum transport in the deep convective envelope. Interestingly, the depth of the envelope decreases significantly for larger rates, and values $f \sim 1\%$ appear consistent with the conditions of merger-driven direct collapse. In this formation channel, masses up to $10^8 - 10^9\ \mathrm{M_\odot}$ could be reached before the GR instability.

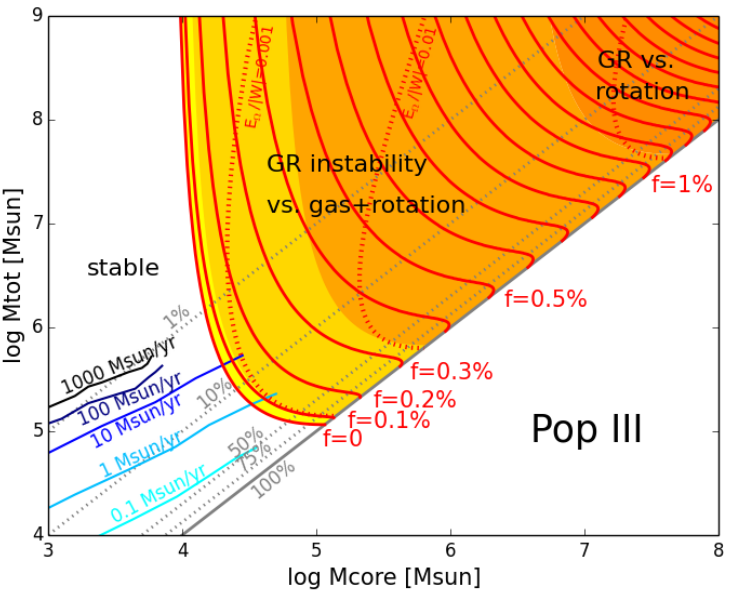

Fig. 6. Limits of GR stability for rotating Pop III SMSs, derived from the hylotropic models with $T_c = 1.8 \times 10^8$ K. The diagram represents the mass of the SMS as a function of the mass of its convective core. The various limits are obtained with the indicated values of the fraction f of accreted angular momentum over the Keplerian angular momentum (solid red lines). The limits are also shown for constant ratios of rotational to gravitational energies (dotted red lines). The coloured areas denote the relative importance of the β term (gas term) and the rotation term in the stability of the star (equation 6). The black-blue-cyan tracks are the same GENEC models as in figure 5. (Figure from.[34])

Since masses $> 10^6$ $M_\odot$ are required for SMBH formation in the Pop I case, the black hole seeds in merger-driven direct collapse must have masses $10^6 - 10^9$ $M_\odot$, which implies that the different channels of direct collapse lead to distinct ranges of seed's mass.

5. SMBH formation and observational signatures of direct collapse

The final collapse of SMSs has been followed with a large number of GR magneto-hydrodynamical simulations.[16,35,36] In the Pop III case, the collapse is found to lead to the direct formation of a SMBH, that contains $\gtrsim 90\%$ of the total stellar mass. A fraction $\sim 1 - 10$ % of the mass can remain in orbit outside the horizon at the formation of the black hole, provided rapid enough rotation. This gas further collapses through the horizon, with possible gravitational wave emission detectable by future space-based observatories. Moreover, in the presence of magnetic fields, relativistic jets could be launched and trigger ultra-long gamma-ray bursts. Thus, the final collapse of SMSs provides the most promising possibilities for observational signatures of direct collapse and the existence of SMSs.

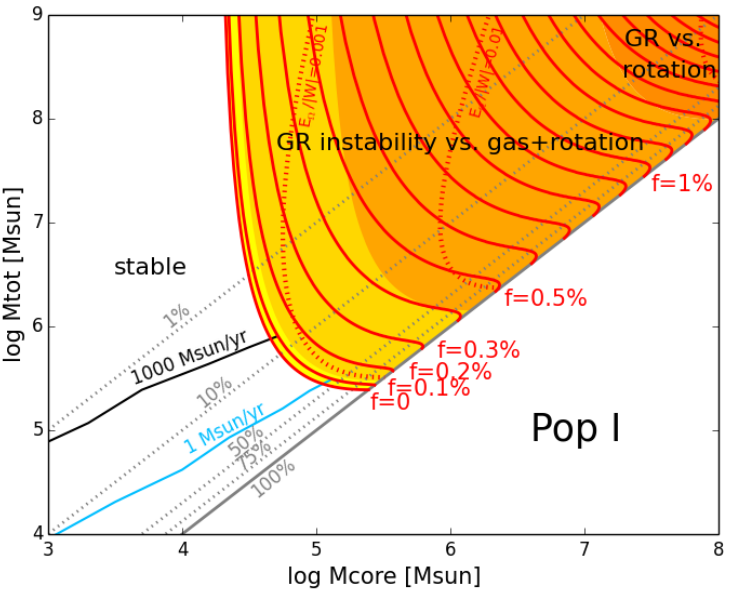

Fig. 7. Same as figure 6 for the Pop I case ($T_c = 0.85 \times 10^8$ K). (Figure from.[34])

Rotation is key since only the centrifugal barrier allows for the survival of a slowly decaying torus, and prevents the direct engulfment of the whole stellar mass by the black hole in a dynamical time. Figures 8 and 9 show the profiles of the spin parameter cJ_r/GM_r^2 (where J_r is the angular momentum of the mass M_r) for the hylotropic models of figures 6 and 7, taken at the onset of the instability. They correspond to typical conditions of atomically cooled halos and merger-driven direct collapse, respectively. In each case, the profiles are shown for three different core mass. The convective core is recognisable as the only region where the profiles departs from each other, as a result of the angular momentum transport by convection. In contrast, the profiles match each other in the radiative envelope, reflecting the angular momentum accretion law. We see that the solid rotation of the core maintains the angular momentum distribution decentralised. Notice that the profiles of figure 9 correspond to the 'universal' profiles obtained when rotation becomes the dominant stabilising agent.

From these rotation profiles, the fraction of the **outer** mass that has enough angular momentum to remain in orbit at the formation of the black hole can be estimated analytically by comparison with the angular momentum of the innermost stable circular orbits (ISCOs).[38] It is found to be significant only for the conditions of merger-driven direct collapse, and for fully convective SMSs, as indicated by the red squares in figures 8 and 9. The low angular momentum ($f \sim 0.2\%$) required in the context of atomically cooled halos prevents the formation of an orbiting structure, and even for $f \sim 1\%$ convection is required in the whole stellar interior for the

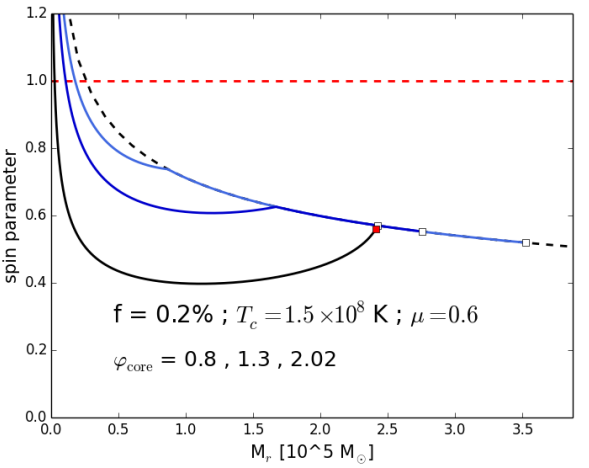

Fig. 8. Profiles of the spin parameter cJ_r/GM_r^2 at the onset of GR instability, for typical conditions of atomically cooled halos. The profiles (solid lines) are shown for three hylotropes with different **core mass-fraction $M_{\rm core}/M$: the black profile corresponds to a fully convective star $M_{\rm core} = M$ (polytrope), the dark blue profile corresponds to $M_{\rm core}/M = 60\%$ and the light blue profile to $M_{\rm core}/M = 25\%$.** The white squares indicate the surface **(i.e. the total mass)** of the three models **(the polytrope has the lowest mass, $M_{\rm core}/M = 25\%$ the highest)**. Only for the fully convective model a comparison with ISCO angular momentum suggests that a tiny fraction of the **outer** mass ($\sim 1\%M$) remains in orbit outside the horizon at black hole formation, which is indicated by the red square. The black dashed line shows the angular momentum accretion law. The red dashed line indicates the maximum value of the spin parameter consistent with Kerr black holes. (Figure from.[34])

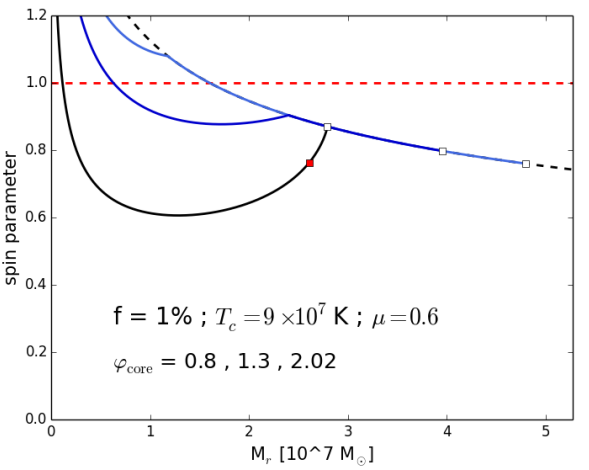

Fig. 9. Same as figure 8 for typical conditions of merger-driven direct collapse. Here, the **outer** mass fraction of the fully convective model that remains in orbit at black hole formation represents $\sim 10\%$ of the stellar mass (red square). (Figure from.[34])

angular momentum to be sufficiently decentralised. Overall, these models suggest that gravitational wave emission and ultra-long gamma-ray bursts at black hole formation are consistent with the conditions of galaxy mergers, but not with those of atomically cooled halos. In both scenarios, the centrifugal barrier is inefficient to prevent the direct formation of a massive black hole seed at the collapse of the supermassive stellar progenitor.

6. Summary and conclusions

SMSs represent promising candidates for the progenitors of the SMBHs that power the most massive quasars detected at redshifts $6-7$, since direct collapse appears as the most efficient scenario to form SMBHs in short timescales. This scenario faces several bottlenecks, however, but solutions have been proposed to all of them. The angular momentum problem represents certainly one of the strongest, as discussed in section 3.

In spite of the low spins imposed by the $\Omega\Gamma$-limit (section 2, figure 3), rotation impacts critically the life and death of SMSs. As an outstanding effect, it allows rapidly accreting SMSs to increase their final masses by several orders of magnitude compared to the non-rotating case, before they reach the GR instability and collapse into a SMBH (section 4, figures 6-7). According to hylotropic models, the masses of the black hole seeds belong to distinct ranges depending on the direct collapse channel:

- $10^5\ \mathrm{M}_\odot \lesssim M \lesssim 10^6\ \mathrm{M}_\odot$ for atomically cooled halos;
- $10^6\ \mathrm{M}_\odot \lesssim M \lesssim 10^9\ \mathrm{M}_\odot$ for merger-driven direct collapse.

Moreover, the conditions of merger-driven direct collapse are expected to be more favourable than those of atomically cooled halos for gravitational wave emission and ultra-long gamma-ray bursts at the collapse of the SMS (section 5, figures 8-9).

Many uncertainties remain, however, in these scenarios, most of them relying on the lack of consistency of the models for the formation of the black hole seed itself. Due to their hypothetical nature, SMSs have been much less studied than other classes of stars, and the picture given here deserves to be refined by additional models accounting for full stellar evolution up to the largest masses and accretion rates, including a self-consistent treatment rotation, multiplicity and radiative feedback. In particular, reliable theoretical predictions for the observational signatures of SMBH formation by direct collapse require precise determination of the properties of the stellar progenitor. In that respect, the future generation of space-based telescopes and gravitational wave observatories could unveil the most massive stars ever formed in Universe's history. Interestingly, according to the models described here, the maximum mass of these stars is set by **the interplay between general relativity and** rotation.

Cosmology with high-redshift FRBs

The quest for high redshift Fast Radio Bursts (FRBs) is ongoing with telescopes such as the Five-hundred-meter Aperture Telescope (FAST) and the Green Bank Telescope (GBT) looking for highly dispersed events. If FRB-producing systems exist at early times, such sources would provide new unique ways to probe cosmic dawn and Reionization. On one hand, FRB dispersion would allow us to probe the history and topology of Reionization. On the other hand, number counts of high redshift FRBs would indirectly probe galaxy formation at high-redshifts. Here we consider prospects of advancing our understanding of the first billion years of cosmic history with high-redshift FRBs.

Keywords: High redshift Universe, Fast Radio Bursts

1. Introduction

The field of cosmology experienced breathtaking growth in the past several decades. Owing to the measurements of the Cosmic Microwave Background (CMB) by telescopes such as WMAP,[1] Planck[2] and others, which reveal a snapshot of the Universe shortly after the Big Bang, we now know that the Universe is well-described by a rather simple six-parameter model (ΛCDM) in which the total energy balance is share between dark energy (Λ), dark matter (that is usually assumed to be cold), baryons and radiative degrees of freedom.

The CMB is also sensitive to the process of reionization. The Epoch of Reionization (EoR) is often referred to as the last phase transition in the history of the evolution of the Universe.[3,4] During the EoR the ultraviolet light produced by young stars in early populations of galaxies ionized the previously neutral intergalactic medium (IGM) turning it into hot plasma. The EoR imprints faint traces in the CMB via the scattering of CMB photon off the ionized gas. Therefore, although the effect is very weak, the CMB observations can be used to constrain this epoch. The redshift of reionization, as inferred from the CMB data, is $\approx 7.5 \pm 0.82$.[2]

The CMB observations have greatly advanced our understanding of cosmology. Given the richness of information extracted from the CMB and the amount of scientific discoveries stemming from these data, it is surprising to realize that the CMB probes only a thin (nearly 2-dimensional) volume of the Universe located at $z \sim 1100$ when the Universe was only 0.4 million years old (for comparison it is 13.8 billion years old today). However, the CMB observations are only weakly sensitive to the processes at later times. Located between the CMB last scattering

surface and us are multiple layers of cosmic history harbouring events such as the formation of first dark matter halos massive enough to accret and cool gas, formation of the first stars and galaxies, and other processes, which cannot be probed by the CMB.

By probing the late-time Universe, large scale structure and galaxy surveys provide complimentary information to what is found in the CMB. These measurements are of the evolved cosmic web and mature populations of galaxies (for example, the Dark Energy Survey measured ~ 300 million galaxies[5]). Much like the CMB these data helped to advance our understanding of the Universe. We now know that the expansion of the Universe is accelerated, low-redshift observations provide ample opportunities to test General Relativity across a wide range of regimes, and we can test galaxy formation theories with data.

However, despite this impressive effort, we do not have the whole picture of how the Universe transitioned from the pristine primordial state observed in the CMB to the evolved state in which it is found today. Even the state-of-the-art observations are limited and can only probe a small part of cosmic history. Large surveys mostly cover our cosmic neighbourhood (out to $z \sim 3$) with only the brightest objects observed at higher redshifts (although using clusters of galaxies as gravitational lenses can help to grasp a more representative picture of the high-redshift Universe[6]). In addition, some of the low redshift observations are inconsistent with the CMB data (e.g. the H_0 discrepancy[7]), and so the true state of the Universe remains ambiguous. Moreover, the elegant and simple ΛCDM theory itself suffers from several shortcomings. To name a few: the nature of dark matter and dark energy, which together compose $\sim 95\%$ of the total energy density in the Universe, is undetermined; not all baryons that are measured from the CMB are accounted for at lower redshifts (*the missing baryon problem*); we have already mentioned the infamous H_0 tension; galaxy formation is not fully understood as well as the structure and composition of the IGM. Finally, the first billion years of cosmic history remain poorly explored.

FRBs, transient radio signals of yet unestablished nature, might result to be unique probes of the EoR, thus advancing our understanding of the first billion years of cosmic history. High-redshift FRBs, if exist, would probe the EoR in a unique way compared to the established tracers such as the high-redshift quasars, galaxies and the CMB. Thus, if a sample of high-redshift FRBs is collected, they will offer new ways to probe cosmology.

FRBs are significantly dispersed by the ionized medium distributed along the path between the sources and the observer. For most of the detected FRBs, the observed dispersion of FRB pulses, quantified in terms of dispersion measure (DM) is much larger than the contribution of our local environment. Therefore, it is now known that the overwhelming majority of FRBs are of extra-Galactic origin. For a typical FRB the largest contribution to the dispersion is from the ionized intergalactic medium, $DM^{\rm IGM}$, which depends on the number density of free electrons along the line of sight. For FRBs coming from redshift z, the mean IGM contribution is

given by

$$\overline{DM}^{\rm IGM}(z) = \int_0^z \frac{n_e(z')}{1+z'} dl = \int_0^z \frac{c n_e(z')}{H(z')(1+z')^2} dz', \quad (1)$$

where the first integral is along the line of sight with dl being the line element. $n_e(z')$ is the mean number density of free electrons at redshift z', c the speed of light and $H(z')$ is the Hubble expansion rate. The electron density directly depends on the ionized fraction of hydrogen $x_i(z)$, which at high redashifts traces the EoR. We will refer to the redshift dependence of the ionized fraction, $x_i(z)$, as the *EoR history*. Dependence of $DM^{\rm IGM}$ on redshift is illustrated in Figure 1 (image credit: A. Tocher).

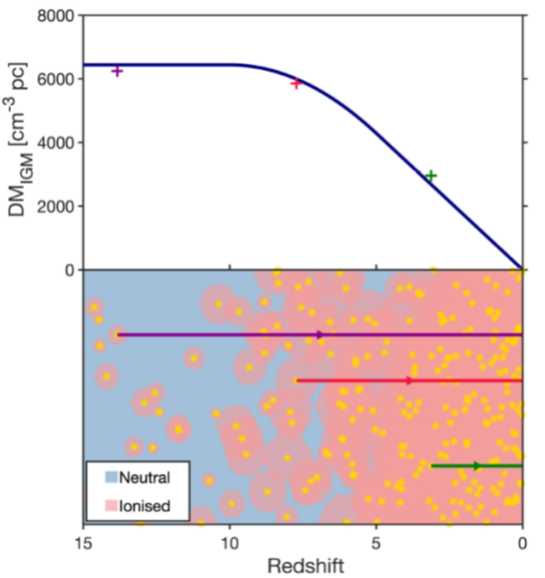

Fig. 1. Dependence of $DM^{\rm IGM}$ on redshift (top) and cartoon of the corresponding EoR history (bottom). Blue regions are the neutral patches, red regions are ionized, yellow markers represent star forming regions. Coloured crosses (top) correspond to three randomly generated FRBs and coloured lines (bottom) are the corresponding lines of sight through the EoR. Illustration credit: A. Tocher.

At low redshifts FRBs have already proven to be valuable cosmological probes. Dependence of $DM^{\rm IGM}$ on the cosmological redshift, z, of the FRB hosts (e.g., see Figure 1) could pin down properties of the IGM[9,11,12] and probe cosmological parameters.[10,11,13,15–21] To give an example, with a sample of localized low-redshift FRBs (host redshifts of $z \lesssim 0.66$), Macquart et al. (2020)[11] showed that the dispersion measure of these transients depends on the baryonic content of the Universe (along the line of sight) and, thus, can help identifying the missing baryons in the IGM by counting the total number of baryons along the line of sight. For

higher redshift FRBs, theoretical predictions show that a population of FRBs at $z \sim 3-4$ could be used to constrain helium reionization occurring around redshift $z \sim 3.5$,[22–26] while signals from $z > 5$ would primarily trace the evolution of the hydrogen ionization state, and, thus, probe the EoR.[10]

Constraining the high-redshift Universe with FRBs might be observationally plausible as the existing telescopes such as the Five-hundred-meter Aperture Telescope (FAST) and the Green Bank Telescope (GBT) can in principle detect bright signals out to $z \sim 10$, i.e. deep into the EoR.[8,14] The future Square Kilometre Array (SKA) will be capable to map the FRB sky detecting thousands of sources from early times.[10,33]

2. Tracing reionization with FRBs

If found, high redshifts FRBs could be used as probes of the EoR owing to the dependence of $DM^{\rm IGM}$ on $n_e(z')$ and, through it, on the EoR history, $x_i(z)$.

Existing constraints on the EoR are very weak. The CMB optical depth, defined as

$$\tau = \int \sigma n_e dl, \tag{2}$$

where σ is the scattering cross-section, is measured from the CMB data (e.g. state-of-the-art constraints from *Planck*[2]) with the relative error being at the level of $6-10\%$. This large uncertainty in τ degrades precision with which other cosmological parameters are measured (e.g. see the discussion by Liu et al. (2015)[27]). For example, the effect of the EoR on the CMB is degenerate with the amplitude of primordial fluctuations from inflation A_s. Additional constraints on the EoR come from quasar observations. For instance, using the dark fraction of Lyman α and β forest observations in tandem with Planck measurements Greig & Mesinger (2017)[28] constrain the redshift of the midpoint of reionization to $\sim 12\%$ (at 68% confidence level). Observations of the hydrogen 21-cm line are predicted to eventually provide precise measurement of τ as well as map the entire history of reionization. However, currently, the EoR constraints derived from the first upper limits on the 21-cm signal are very weak and only rule out the most extreme scenarios.[29,30]

Prospects of mapping the EoR with high-redshift FRBs has been discussed in literature.[10,31–34] Both $DM^{\rm IGM}$ and τ depend on the same physical quantity, namely the mean number density of free electrons weighted differently with redshift (compare between Eqs. 1 and 2). Therefore, it should be plausible to extract reionization history from the dispersion measure of high-redshift FRBs if a large enough sample with host localizations is obtained. Existing works on this topic (apart from the recent publication by Heimersheim et al. (2021)[35] which we highlight here), make assumptions about the reionization history that either lead to biases in the results or limit the constraining power of the data. In an earlier work we[10] were the first to realize that FRBs could be used as tracers of the reionization history EoR, and

might allow us to significantly tighten the constraints on τ. We performed a simplified estimation of the relative error in τ showing that the expected accuracy is much better than the current state-of-the-art, e.g. from *Planck*. This work stimulated further studies (a similar analysis was later carried out by Beniamini et al. (2020)[31]). Other examples of EoR constraints include the works by Beniamini et al. (2020)[31] and Hashimoto et al. (2021)[33] who proposed probing the EoR history by grouping FRBs into redshift bins and considering the difference between mean $DM^{\rm IGM}$ in adjacent bins. Due to the binning procedure, information on each individual FRB is lost and with it the possibility to smoothly trace the reionization history. In addition, in the absence of a defined $x_i(z)$ relation, this approach does not allow us making use of dependences (such as the monotonic growth of $x_i(z)$ with time) across cosmic time.

Details of reionization history $x_i(z)$ affect the dependence of FRB dispersion measure on redshift,[10] i.e. the functional form of $DM^{\rm IGM}$ (example shown in Figure 1). This dependence can, therefore, be used to extract the EoR history if a sample of high redshift FRBs (from before the end of the EoR at $z \sim 5$) is observed and localized. When extracting the EoR history from a sample of high-redshift FRBs it is important to keep a model-independent approach and stay agnostic about the true history of reionization. In Heimersheim et al. (2021)[35] we showed that assuming specific shape of $x_i(z)$ leads to biases in the derived EoR parameters. For example, we find that fixing the reionization history to the symmetric tanh function, parameterized by the duration and midpoint of the EoR, underestimates the value of τ by $\sim 10\%$.

2.1. *Bias-free constraints on Reionization*

Inspired by the model-independent approach adopted in the CMB community, in Heimersheim et al. (2021)[35] we have investigated the possibility of deriving the EoR history from the mock data without assuming a-priory knowledge of its redshift dependence. We constructed a mock catalogue of $DM^{\rm IGM}$, host redshifts and associated uncertainties (see details in Heimersheim et al. (2021)[35]). An illustration of our mock FRB catalogue is shown in Figure 2 (illustration credit: S. Heimersheim).

In the base of our analysis pipeline is the free-form "FlexKnot" method[36] where the entire EoR history is defined by a series of free-moving knots (rather than by a specific functional form). For each such FlexKnot parameterization we model the expected dispersion measure relation, $DM^{\rm IGM}$, and calculate its likelihood given the mock data (e.g. Figure 2). Finally, we employ Bayesian inference to derive constraints on the parameter space (including input cosmological parameters as well as the reionization history specified in terms of the positions and number of knots). This method allows us to extract the reionization history as well as cosmological parameters from the mock data. Importantly, the FexKnot parametrization allows

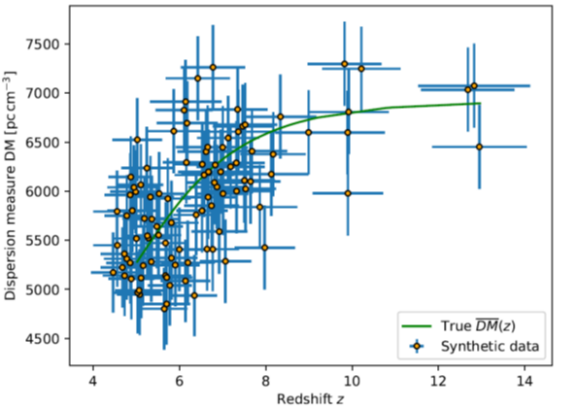

Fig. 2. Illustration of our mock FRB catalogue. Illustration credit: S. Heimersheim.

us to go over the entire space of plausible $x_i(z)$s without making assumptions about their functional shapes. Thus our results are bias-free.

In Heimersheim et al. (2021),[35] we apply the described method to our synthetic FRB catalogue and find that strong constraints on reionization history can be obtained. Figure 3 (Fig. 1 of Heimersheim et al. (2021)) shows the constraints on the reionization history marginalized over individual knot locations and cosmological parameters (only the parameters that have effect on DM^{IGM} were varied). In addition, we include the CMB polarization constraint on the high-redshift portion of the total optical depth τ from $z = 15 - 30$ (based on Planck measurements[37]).

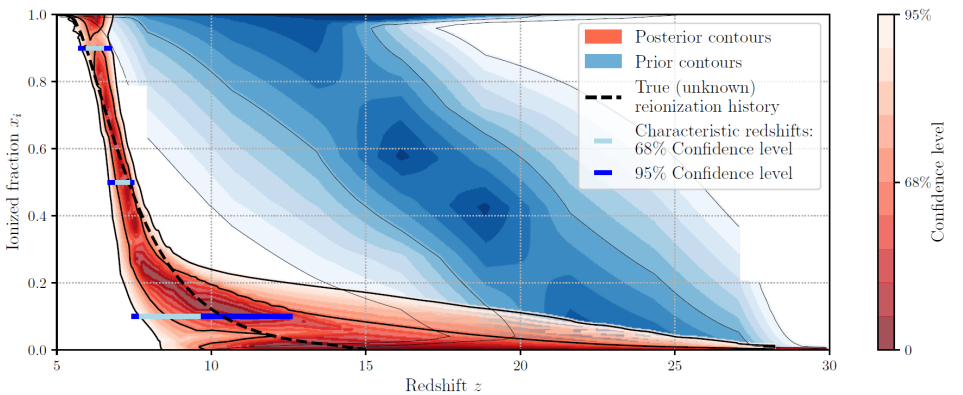

Fig. 3. Illustration of the prior (purple) and extracted (orange) reionization histories. Blue error bars show the constraints on the milestones of the EoR history, namely the start ($x_i = 0.1$), midpoint ($x_i = 0.5$) and end ($x_i = 0.9$) of reionization. Illustration credit: S. Heimersheim. Based on Figure 1 from Heimersheim et al., (2021).

In Figure 3 we demonstrate how the method works by showing the posterior and prior distributions of $x_i(z)$ (indicated by the orange and purple contours respectively, with 68% and 95% confidence intervals marked by the solid lines). We see that the posterior provides tight constraint on the reionization history, and encompasses the true reionization history used to generate the mock data (dashed cyan). Note that the analysis pipeline was not informed about this input history.

We find that, owing to the model assumption that FRB number counts trace star formation rate, the FRB data can constrain the reionization history especially well at low redshift ($z < 10$) where the vast majority (97%) of the FRB sources in our synthetic catalogue are located. Because there is only a small number of FRBs at higher redshifts, the EoR constraints at $z = 10 - 30$ are much weaker.

Owing to the flexibility of the FlexKnot method and because we have the full information on the EoR history for every parameter sample, we can directly constrain key points of the EoR history. To demonstrate this capability, we calculate posterior probabilities of the start ($x_i = 0.1$), midpoint ($x_i = 0.5$) and end ($x_i = 0.9$) of reionization. The error bars are shown in Figure 3 indicating 68% and 95% confidence limits in start, midpoint and end of the EoR, and the numerical results can be found in Table 1 of Heimersheim et al. (2021). We find that with 100 FRBs we constrain the end, midpoint and start of reionization to an accuracy of 7%, 6% and 13% respectively at 68% confidence level, achieving a better accuracy of 5%, 3% and 12% respectively for the sample with 1000 FRBs. The FRB constraints on the midpoint of the EoR would be much stronger than the limits from quasars.[28]

Marginalizing over all other parameters, including all the possible parametrizations of reionization histories, in Heimersheim et al. (2021)[35] we also derive posterior probability distributions for τ from the mock samples of 100 and 1000 FRBs (see Figure 2 in Heimersheim et al. (2021)) and quote the detailed 68% and 95% limits in Table 1 of Heimersheim et al. (2021). In summary, we find that 100 and 1000 FRBs can constrain the optical depth to 11% and 9% accuracy respectively (68% confidence). Our results for 100 FRBs are competitive with the *Planck*[2] measurement, while the accuracy for 1000 FRBs surpasses that of *Planck*. Moreover, the FRB constraint on τ is antisymmetric, owing to the sample of FRBs skewed towards the lower redshifts. Therefore, FRBs provide a much tighter lower limit on τ compared to that from the CMB. We also show the constraints on the amplitude of the primordial power spectrum.

Further details of the method and scientific results can be found in Heimersheim et al. (2021).[35]

Finally, we note that, in addition to serving as cosmological probes, high-redshift FRBs could result to be very useful probes of high-redshift stellar populations (Population III and Population II). The ambiguity regarding the sources of FRBs and the nature of their hosts remains with magnetars being one of the most popular candidates.[38,39] It is also possible that either magnetars or FRBs themselves, are produced as a result of stellar mergers (see discussion in Heimersheim et al. 2021).

In this case, the anticipated number of FRBs would strongly depend on the unknown initial mass function of the early populations of stars. Therefore, mapping the population of FRBs from the first billion years of cosmic history could shed light on the properties of high-redshift stars.

3. Summary

With this work we would like to encourage observational search for FRBs from the first billion years of cosmic history. Observational capability is nearly there with existing telescopes such as FAST and GBT sensitive enough to detect bright FRBs out to redshift of ~ 10, ASKAP excelling in localizing the FRBs and CHIME detecting large numbers of FRBs (although still at relatively low redshifts). If a sample of $100 - 1000$ FRBs from the first billion years of cosmic history can be measured and localized, these events will advance our understanding of the evolution of the Universe in this poorly constrained regime. As we showed in Heimersheim et al. (2021), high redshift FRBs could offer precision constraints on the EoR history and optical depth as well as tightening constraints on the primordial power spectrum and the sum of neutrino masses. In addition, they could serve as probes of high-redshift astrophysics, Population III and Population II stars and binaries. FRBs would probe the high-redshift Universe in new way independent from all the other known probes (high-redshift quasars, the CMB, and the 21-cm signal of hydrogen) thus providing an unparalleled view of this era.

The redshift drift (also known as the Sandage Test) is a model-independent probe of fundamental cosmology, enabling us to watch the universe expand in real time, and thereby to confirm (or not) the recent acceleration of the universe without any model-dependent assumptions. On the other hand, by choosing a fiducial model one can also use it to constrain the model parameters, thereby providing a consistency test for results obtained with other probes. The drift can be measured by the Extremely Large Telescope and also by the full SKA. Recently two alternative measurement methods have been proposed: the cosmic accelerometer, and the differential redshift drift. Here we summarize a comparative analysis of the various methods and their possible outcomes, using both Fisher Matrix and MCMC techniques. We find that no single method is uniformly better than the others. Instead, their comparative performance depends both on experimental parameters (including the experiment time and redshift at which the measurement is made) and also on the scientific goal (e.g., detecting the drift signal with high statistical

significance, constraining the matter density, or constraining the dark energy properties). In other words, the experiment should be optimized for the preferred scientific goal.

Keywords: Observational cosmology; Redshift drift; Extremely Large Telescope.

1. Introduction

The observational evidence for the acceleration of the universe shows that our canonical theories of cosmology and particle physics are at least incomplete, and possibly incorrect. New physics is out there, waiting to be discovered; we must search for, identify and characterize this new physics. But so far, the interpretation of all our extant cosmological observations is model-dependent, in the sense that it requires a number of assumptions on an underlying cosmological model. Ideally, one would like some fully model-independent observables, enabling consistency tests of these underling assumptions. And indeed there is one conceptually simple, but operationally very challenging, such observable: the redshift drift of objects following the cosmological expansion.

The CosmoESPRESSO team uses the universe as a laboratory to address, with precision spectroscopy and other observational, computational and theoretical tools, grand-challenge questions including the universality of physical laws, the characterization of the large-scale behaviour of gravity (and specifically of the source of the recent acceleration of the universe) and the study of fossil relics or early stages of the universe's evolution, together with contributions to ESO and ESA next-generation facilities and to education and public understanding of science. In what follows we highlight recent contributions of the CosmoESPRESSO team to this fundamental quest, pertaining to the cosmological impact of forthcoming redshift drift measurements. Further details can be found in Ref. 1 and Ref. 2.

2. The redshift drift and its sensitivity

The idea that the redshift of objects following the cosmological expansion changes with time—known as the redshift drift— is many decades old.[3,4] Conceptually, a measurement of the redshift drift is fundamentally different from our other astrophysical observables. In our observations at cosmological distances done so far, we are mapping our present-day past light cone. Instead, the redshift drift allows us to compare different past light cones. More crudely, this corresponds to watching the Universe expand in real time. Other than being a different probe of the universe, its conceptual importance is that it is a model-independent probe of the expansion of the universe, making no assumption on geometry, clustering or the behaviour of gravity, and therefore of crucial importance for fundamental cosmology.

The practical difficulty is that cosmologically relevant timescales are orders of magnitude larger than human ones: a measurement of the redshift drift therefore requires exquisite sensitivity, several orders of magnitude better than currently available: the best currently available bound,[5] is about three orders of magnitude larger

than the signal expected for the standard ΛCDM cosmology with reasonable choices of its model parameters, and contains systematic errors comparable to or larger than the statistical ones. Nevertheless, measuring this drift is a key science and design driver for the development of the Extremely Large Telescope (ELT), and specifically for its high-resolution spectrograph currently known as ELT-HIRES.[6]

A detailed feasibility study of high-redshift measurements by the ELT, on a decade timescale, was done in Ref. 7, who also discussed possible targets. It is important to note that although ELT redshift drift measurements, on their own, lead to cosmological parameter constraints that are not tighter than those available by more classical probes (such as supernovae or the CMB) they do probe regions of parameter space that are different from (and sometimes actually orthogonal to) those of other probes, enabling the breaking of degeneracies and therefore leading to more stringent combined constraints;[1] we will provide an explicit demonstration later in this contribution. More recently, it has also been pointed out that measurements at low redshifts can in principle be made by the full Square Kilometre Array (SKA),[8] while measurements at intermediate redshifts can be done by intensity mapping measurements such as CHIME[9] and HIRAX.[10] Measurements of all three of these will require appropriate hardware configurations.

Redshift drift measurements are a key part of what is commonly called real-time cosmology.[11] Usually they rely on the first derivative of the redshift. Recently the role of second derivatives of the redshift, which should also be within the reach of the full SKA, has been studied by Ref.[12] Fisher Matrix techniques[13,14] are well suited for a comparative study of the cosmological impact of redshift drift measurements by these facilities; such a study is described in detail in Ref. 1.

The redshift drift of an astrophysical object following the cosmological expansion, for an observer looking at it over a time span Δt, is

$$\frac{\Delta z}{\Delta t} = H_0 \left[1 + z - E(z)\right] , \tag{1}$$

where for convenience we have defined the dimensionless Hubble parameter $E(z) = H(z)/H_0$, although the actual astrophysical observable is usually a spectroscopically measured velocity

$$\Delta v = \frac{c\Delta z}{1+z} = (cH_0\Delta t)\left[1 - \frac{E(z)}{1+z}\right] . \tag{2}$$

The dependence on the Hubble parameter naturally leads to a model-dependent redshift dependence of the drift. Broadly speaking, in a universe that is currently accelerating but was deccelerating in the past the drift will be positive at low redshifts and negative for higher redshifts, while in a universe that always deccelerates the redshift drift would always be negative. To give a specific example, for a flat ΛCDM model, apart from trivially vanishing at $z = 0$, the signal will also vanish at

$$z_{zero} = \frac{1 - 3\Omega_m + \sqrt{1 + 2\Omega_m - 3\Omega_m^2}}{2\Omega_m} , \tag{3}$$

while the redshift of maximum spectroscopic velocity is

$$z_{v,max} = \left[\frac{2(1-\Omega_m)}{\Omega_m}\right]^{1/3} - 1 \tag{4}$$

and the maximum of the drift itself is obtained by solving the quartic equation

$$9\Omega_m^2(1+z)^4 = 4\Omega_m(1+z)^3 + 4(1-\Omega_m)\,. \tag{5}$$

More specifically, if we choose $\Omega_m = 0.3$ (in agreement with contemporary cosmological data) we obtain $z_{zero} =\sim 2.09$, $z_{v,max} \sim 0.67$ and $z_{z,max} \sim 0.95$. It is interesting to note that for flat ΛCDM with $\Omega_m = 0.3$, the acceleration phase does start at redshift $z_{v,max}$, while the cosmological constant only starts dominating the Friedmann equation at

$$z_\Lambda = \left[\frac{(1-\Omega_m)}{\Omega_m}\right]^{1/3} - 1\,, \tag{6}$$

which for Ω_m leads to $z_\Lambda \sim 0.33$.

We can analytically explore the sensitivity of the redshift drift to the cosmological parameters, for a fiducial flat CPL model.[15,16] In this case we can write the Friedmann equation as

$$E^2(z) = \Omega_m(1+z)^3 + \Omega_\phi(1+z)^{3(1+w_0+w_a)}\exp\left[-\frac{3w_a z}{1+z}\right]. \tag{7}$$

It is also convenient to define a dimensionless redshift drift

$$S_z = \frac{1}{H_{100}}\frac{\Delta z}{\Delta t} = h\left[1+z-E(z)\right]\,, \tag{8}$$

where we have defined $H_0 = hH_{100}$ with $H_{100} = 100$ km/s/Mpc; the corresponding observable spectroscopic velocity will be denoted

$$S_v = \Delta v = kh\left[1 - \frac{E(z)}{1+z}\right]\,. \tag{9}$$

In these we have introduced $k = cH_{100}\Delta t$, which is a constant parameter for a given observation time, with units of cm/s: for $\Delta t = 1$ year, $k = 3.064$ cm/s. This provides a rough estimate of the magnitude of the signal in the relevant time span, and therefore also an estimate of the required sensitivity of the spectroscopic measurements. Then for each cosmological parameter p_i the sensitivities of S_z and S_v are related via

$$\frac{\partial S_v/\partial p_i}{\partial S_z/\partial p_i} = \frac{k}{1+z}\,. \tag{10}$$

For our fiducial model we can then find the following sensitivities

$$\frac{\partial S_z}{\partial h} = 1 + z - E(z) \tag{11}$$

$$\frac{\partial S_z}{\partial \Omega_m} = -\frac{h(1+z)^3}{2E(z)}\left[1-(1+z)^{3(w_0+w_a)}\exp\left[\frac{-3w_a z}{1+z}\right]\right] \tag{12}$$

$$\frac{\partial S_z}{\partial w_0} = -\frac{3h(1-\Omega_m)}{2E(z)}(1+z)^{3(1+w_0+w_a)}\ln(1+z)\exp\left[\frac{-3w_a z}{1+z}\right] \tag{13}$$

$$\frac{\partial S_z}{\partial w_a} = -\frac{3h(1-\Omega_m)}{2E(z)}(1+z)^{3(1+w_0+w_a)}\left[\ln(1+z) - \frac{z}{1+z}\right]\exp\left[\frac{-3w_a z}{1+z}\right]. \tag{14}$$

Note that the sign of the $\partial S_z/\partial h$ term will depend on redshift, while those of the other derivatives are always negative for observationally reasonable values of the model parameters.

Some sensitivity ratios are also illuminating. Consider that of the two dark energy equation of state parameters

$$\frac{\partial S_z/\partial w_a}{\partial S_z/\partial w_0} = 1 - \frac{z}{(1+z)\ln(1+z)}\,; \tag{15}$$

as one would expect this approaches zero as $z \to 0$ and unity as $z \to \infty$. On the other hand, comparing the sensitivities to the matter density and the present-day dark energy equation of state one finds

$$\frac{\partial S_z/\partial \Omega_m}{\partial S_z/\partial w_0} = \frac{1-(1+z)^{3(w_0+w_a)}\exp\left[\frac{-3w_a z}{1+z}\right]}{3(1-\Omega_m)\ln(1+z)(1+z)^{3(w_0+w_a)}\exp\left[\frac{-3w_a z}{1+z}\right]}\,, \tag{16}$$

which tends to $(-w_0)/(1-\Omega_m)$ as $z \to 0$ and to infinity as $z \to \infty$ (though note that in this we are neglecting the radiation density). Considering the specific case of a fiducial ΛCDM model with $\Omega_m = 0.3$, at $z = 1$, the ratios are respectively

$$\frac{\partial S_z/\partial w_a}{\partial S_z/\partial w_0} = 1 - \frac{1}{2\ln 2} \sim 0.28 \tag{17}$$

$$\frac{\partial S_z/\partial \Omega_m}{\partial S_z/\partial w_0} \sim \frac{7}{2.1\ln 2} \sim 4.8\,. \tag{18}$$

Finally, it is also illuminating to consider the low-redshift limits of the various derivative terms. To obtain them, one uses the fact that as $z \to 0$ we have

$$E(z) = 1 + \frac{3}{2}\left[1 + (1-\Omega_m)w_0\right]z + \mathcal{O}(z^2)\,. \tag{19}$$

For the derivatives with respect to h, Ω_m and w_0 we then find, respectively

$$\frac{\partial S_z}{\partial h} \longrightarrow -\frac{1}{2}\left[1 + 3(1-\Omega_m)w_0\right]z \tag{20}$$

$$\frac{\partial S_z}{\partial \Omega_m} \longrightarrow \frac{3}{2}hw_0 z \tag{21}$$

$$\frac{\partial S_z}{\partial w_0} \longrightarrow -\frac{3}{2}h(1-\Omega_m)z \tag{22}$$

while that with respect to w_a (whose value, interestingly, does not affect any of the other three) is of higher order.

Figure 1 depicts the redshift dependence of the two observational sensitivities, $\partial S_v/\partial p_i$ and $\partial S_z/\partial p_i$, for a flat ΛCDM fiducial model with $\Omega_m = 0.3$ and $h = 0.7$.

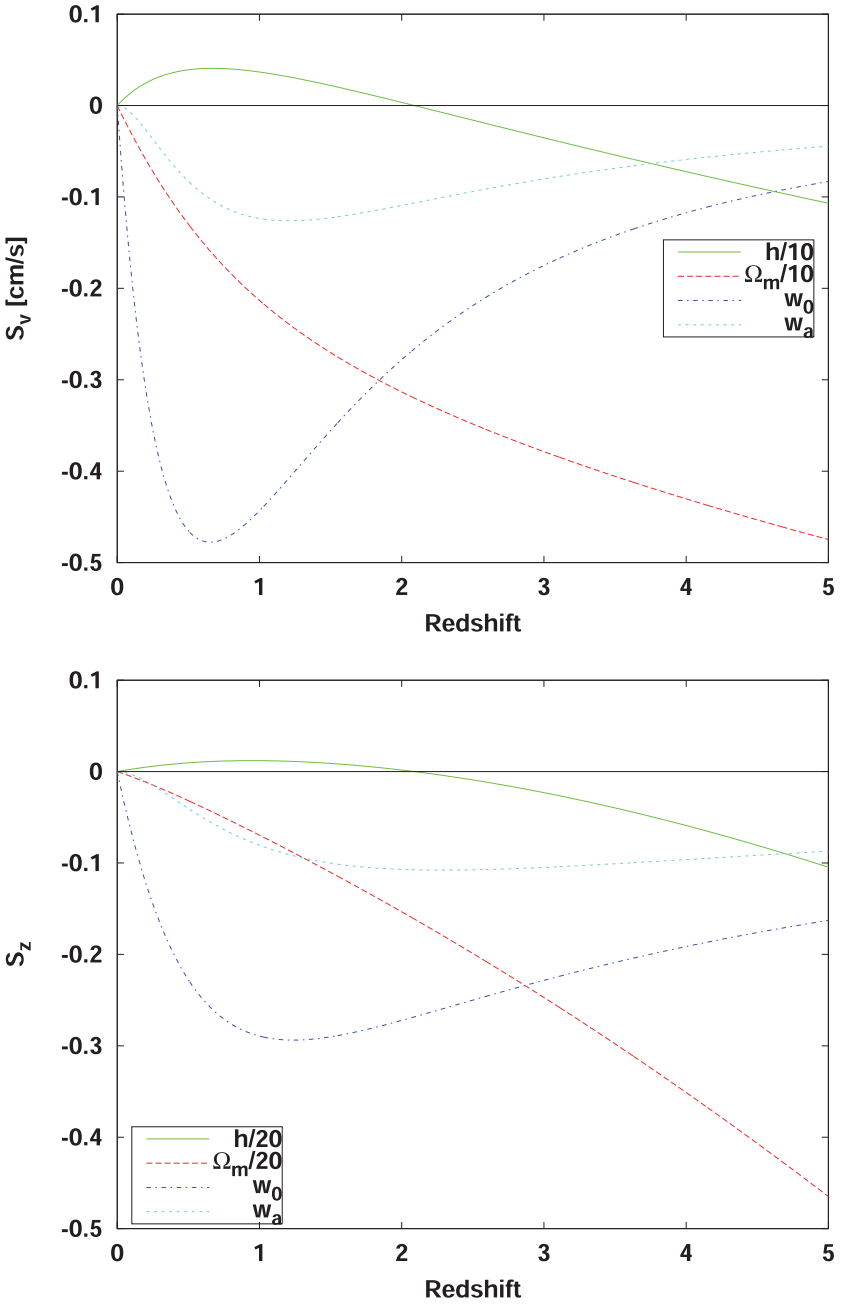

Fig. 1. Sensitivities of the spectroscopic velocity (top panel) and of the redshift drift signal (bottom panel) to the cosmological parameters in the CPL parametrization, for a flat ΛCDM fiducial. For plotting convenience the sensitivities to h and Ω_m have been divided by a factor of 10 in the top panel and by a factor of 20 in the bottom panel. The zero sensitivity line is shown in black. Similar plots can be found in Figure 4 of Ref. 1.

Note that the two are slightly different, being related by a redshift-dependent factor. Also note the different units in the vertical axes of the two panels: $\partial S_z/\partial p_i$ is dimensionless, while $\partial S_v/\partial p_i$ has units of cm/s.

As expected the sensitivity on the dimensionless Hubble constant h (which is proportional to the redshift drift signal itself) is the only one that changes sign; this and the sensitivity on Ω_m are also larger than those on the dark energy equation of state parameters w_0 and w_a. Nevertheless, the most noteworthy point is that the various sensitivity curves have different redshift dependencies. While the matter density sensitivity increases monotonically (in absolute value) with redshift, those of w_0 and w_a are maximal at around the onset of acceleration (just below $z = 1$, with the value being slightly different for S_v and S_z), and the former has a stronger redshift dependence than the latter. This is important because it implies that as long as one is able to do these measurements at sufficiently broad redshift ranges there should not be strong covariances between the parameters.[1]

3. Three experimental strategies

As previously mentioned, redshift drift measurements are unique in comparing different past light cones in a fully model-independent way, rather than mapping our present-day past light cone. Nevertheless, these measurements can complement traditional probes in constraining specific cosmological models. Indeed they have an important role to play here, since they do probe different regions of parameter space, enabling the breaking of key degeneracies upon combination. One may therefore ask how an experimental strategy aimed at maximizing the cosmological constraining power of the redhift drift (on its own or in combination with traditional probes) compares with a strategy aimed at maximizing the statistical significance of the detection of the drift signal itself.

This is a particularly pressing question since two other approaches to detecting the redshift drift have been recently proposed. The Cosmic Accelerometer[17] aims to lower the cost of the experiment, while the Acceleration Programme[18] proposes to measure the differential redshift drift between two non-zero redshifts, rather than measuring the drift with respect to today. In Ref. 2 we again used Fisher Matrix techniques in a comparative study of the cosmological impact of the three approaches. The fiducial model choices were also those described above, to maintain consistency with Ref. 1. Herewith we introduce these alternative strategies and summarize the results of this analysis.

The case study for redshift measurements by the ELT has been done in Ref. 7. The measurement relies on absorption features in the Lyman-α forest, complemented by metal absorption lines redwards of it. The main practical result of this study is that the spectroscopic velocity uncertainty is well described by

$$\sigma_v = \sigma_e \left(\frac{2370}{S/N}\right) \sqrt{\frac{30}{N_{QSO}}} \left(\frac{1+z_{QSO}}{5}\right)^{-\lambda} \; cm/s\,, \tag{23}$$

where the last exponent is $\lambda = 1.7$ up to $z = 4$ and $\lambda = 0.9$ for higher redshifts. Consistently with this and also with the latest top-level requirements for the ELT-HIRES spectrograph,[6] we assume that each measurement has a signal to noise ratio $S/N = 3000$ and uses data from $N_{QSO} = 6$ quasars; as baseline values we take $\sigma_e = 1.35$ and an experiment time $\Delta t = 20$ years, but we also explore different choices for these two parameters. The ELT can measure the redshift drift in the approximate redshift range $2.0 \leq z \leq 4.5$. The main bottleneck, in addition to the spectrograph stability which is thought not to be a bottleneck,[19] is the availability of bright quasars providing the required signal to noise in reasonable amounts of telescope time. The discovery of additional bright quasars will improve the experiment feasibility,[20] so our previously reported ELT analysis[2] might be conservative.

The first alternative, dubbed the Cosmic Accelerometer[17] (henceforth CAC) can be crudely thought of as a low-cost version of the ELT experiment, relying on commercial off the shelf equipment. The proposal is part of the Astro2020 decadal survey, and to our knowledge no detailed feasibility study has been carried out so far. We therefore take at face value the spectroscopic velocity uncertainty given in the proposal white paper

$$\sigma_v = \sigma_c \sqrt{\frac{6}{t_{exp}}}\, cm/s\,, \tag{24}$$

with the baseline value of $\sigma_c = 1.5$ and that of the experiment time $t_{exp} = 6$ years; the authors of the decadal survey proposal state that a further advantage of this approach would be a detection of the redshift drift on a shorter time scale than that of the ELT. In any case, we will again explore the impact of different values of these parameters. The redshift ranges probed are, in principle, similar to those for the ELT.

The second alternative is the Acceleration Programme[18] (henceforth APR), which uses the ELT as described above but proposes to measure the drift between sources at two different non-zero redshifts along the same line of sight. This is to be compared to the standard approach, where one of these redshifts is always $z = 0$. The measured quantity in this case will be a spectroscopic velocity difference, which making use of previously introduced definitions we can write as

$$\Delta v_{ir} = (cH_0\Delta t)\left[\frac{E(z_r)}{1+z_r} - \frac{E(z_i)}{1+z_i}\right], \tag{25}$$

where z_r and z_i are the redshifts of the reference and intervening sources, implying that $z_i < z_r$. The rationale for this proposal is that for some choices of redshifts the absolute value of the detected drift signal (or, more precisely, that of the corresponding spectroscopic velocity) can be significantly larger than in the standard approach. Since the absolute value of the spectroscopic velocity uncertainty of the measurement, σ_v, is determined by the spectrograph's technical specifications, maximizing

the value of the signal to be detected leads to an increased statistical significance of the detection.

4. Cosmological constraints based experimental trade-offs

Our main comparison diagnostic is the derived uncertainty in the cosmological parameters being considered, specifically the matter density fraction and the CPL dark energy equation of state parameters. Our fiducial model for the comparison is flat ΛCDM, with $\Omega_m = 0.3$, $H_0 = 70$ km/s/Mpc, $w_0 = -1$ and $w_a = 0$.

To compare the ELT and CAC it is convenient to assume a single measurement of the redshift drift. Clearly, even for a flat ΛCDM fiducial model a single redshift drift measurement can't simultaneously constrain the Hubble constant and the matter density, so one adopts ample uniform priors for both of these. We can then explore the impact of choices of normalization of the spectroscopic velocity uncertainties (σ_e and σ_c), of the experiment time, and of the redshift at which the measurement is made. Our specific metric in this case be the posterior matter density constraint, σ_m.

The crucial point for this analysis, already discussed and illustrated in Fig. 1 is that the cosmological parameter sensitivities of the redshift drift are redshift-dependent.[1] This sensitivity must therefore be convolved with the spectroscopic velocity uncertainty of each experiment, bearing in mind that the ELT one is redshift dependent (cf. Eq. 23) while the CAC one is not (cf. Eq. 24), at least if one takes the CAC proposal at face value.

In a nutshell, the main result of this comparison is that for identical experiment times the CAC does better, though the difference decreases for larger redshifts. A possible advantage of the CAC (in addition to cost) would be a lower experiment time. The top panel of Figure 2 compares the constraints on σ_m for a 6 year CAC and a 20 year ELT experiment, and one finds that in these circumstances the ELT does clearly better at the redhsifts of interest—up to 62% better. The reason for this is clear. While absolute uncertainties σ_v may be smaller for the CAC, the relative ones will be larger due to smaller experiment times, since a key feature of the redshift drift is that the signal grows linearly in time. The bottom panel of the same figure compares both experiments at 20 years; in this case the CAC is more constraining—by up to a factor of six for measurements around redshift $z \sim 2$.

We therefore see that an experiment optimized to detect the redshift drift signal is not necessarily optimized to constrain particular cosmological models, or indeed specific model parameters. In the example of Figure 2 the constraints on the matter density can be substantially different, but those on the Hubble constant never differ by more than a few percent.[2]

Analogous results ensue when comparing the parameter uncertainties in the canonical redshift drift and the differential redshift drift, for the CPL parameterization. To remain consistent with the work on the canonical redshift drift,[1] in Ref. 2 we used a set of five redshift drift measurements at reference redshifts

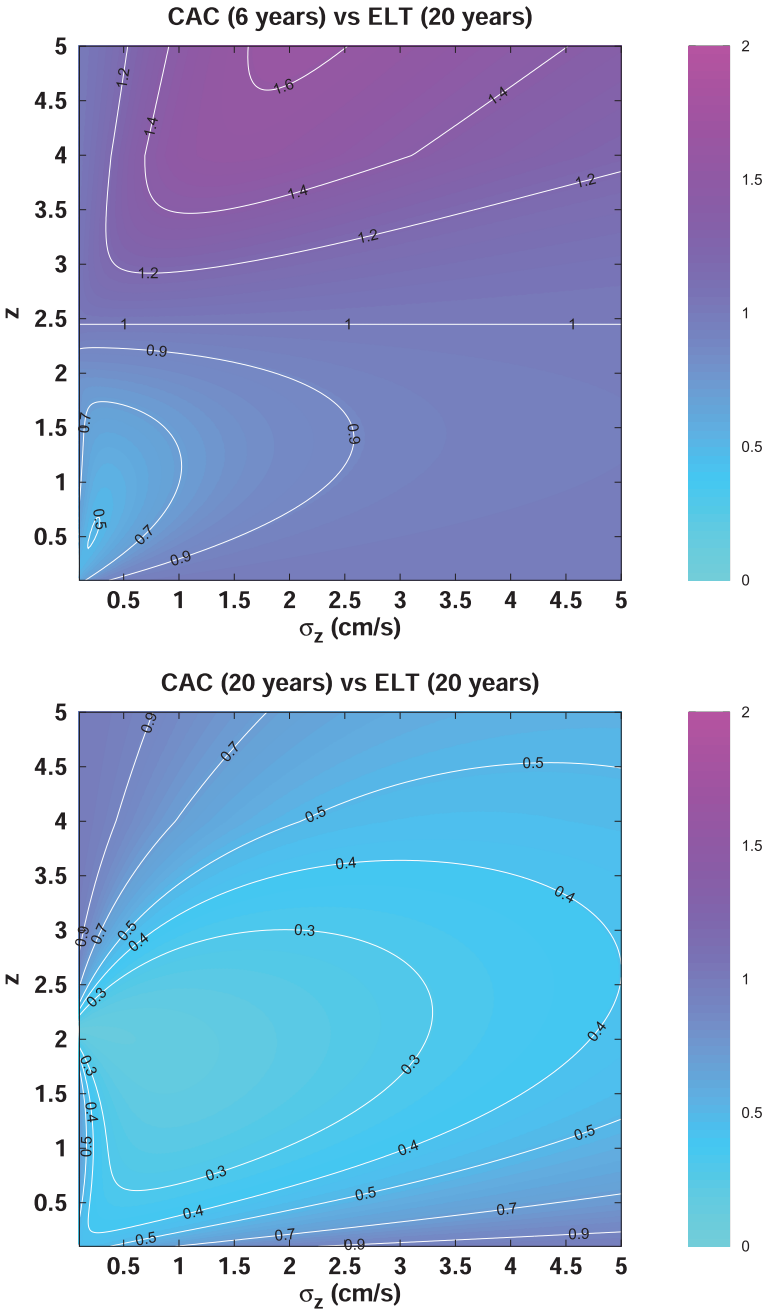

Fig. 2. Ratio of the constraints on the matter density (σ_m) from a single redshift drift measurement by the CAC and ELT, as a function of the redshift of the measurement (z) and the velocity uncertainty (σ_z), with a CAC experiment time of 6 or 20 years (top and bottom panels), and 20 years for ELT in both cases. A ratio larger than unity implies that the ELT measurement is more constraining. An alternative depiction of this comparison can be found in Figure 2 of Ref. 2.

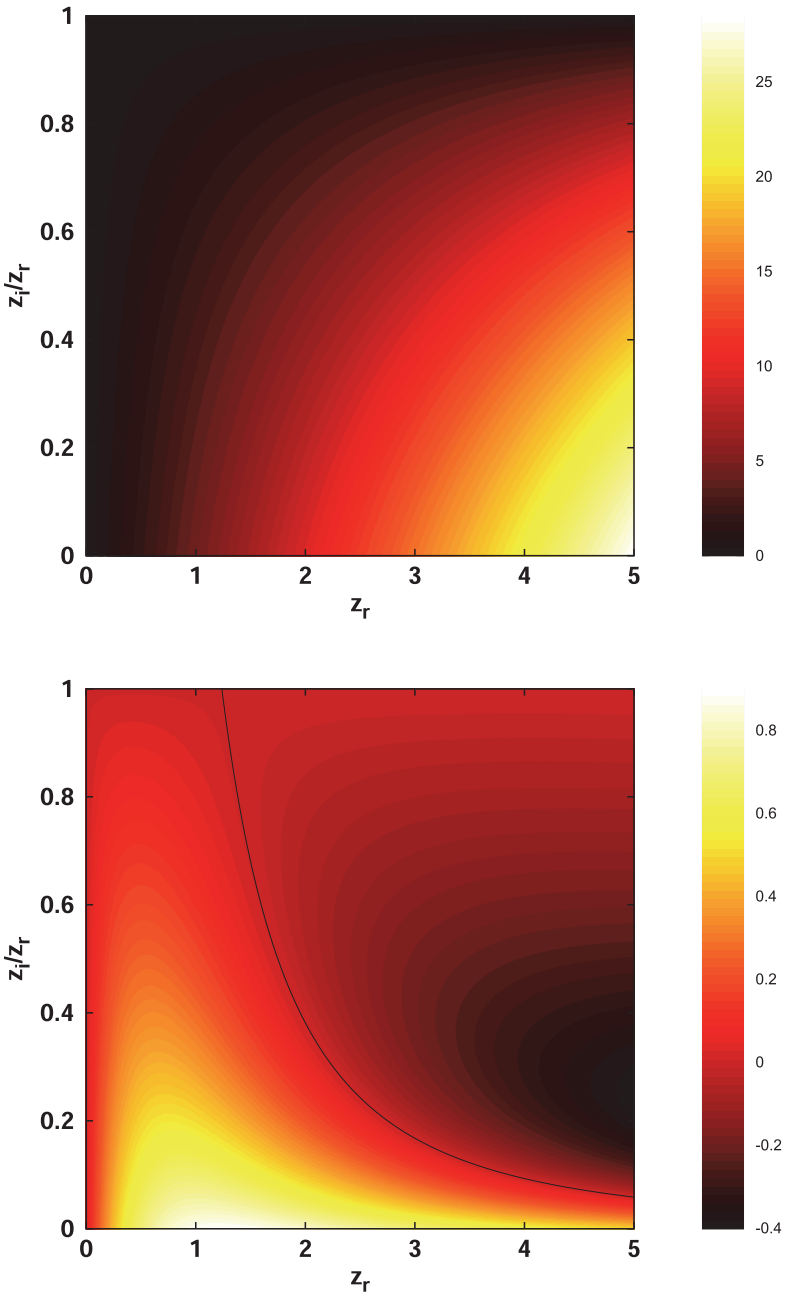

Fig. 3. The sensitivities of the differential redshift drift to the cosmological parameters Ω_m (top) and w_0 (bottom), as a function of the reference redshift z_r and the ratio of intervening and reference redshifts z_i/z_r. The colormaps show the sensitivity in cm/s per year of observation, and the black curves show the locus of zero sensitivity (for Ω_m there is no such non-trivial locus). An alternative depiction of these sensitivities, also for h and w_a, can be found in Figure 3 of Ref. 2.

$z_r = \{2.0, 2.5, 3.0, 3.5, 4.5\}$, and a 20 years experiment. As for the choice of intervening redshifts one may consider two representative choices one with all $z_1 = 0.67$ (this being the redshift with maximum positive spectroscopic velocity for our choice of fiducial model) and another numerically determined with the goal of maximizing the Figure of Merit for the dark energy equation of state parameters, w_0 and w_a, defined as the inverse of the area of the one-sigma confidence contour in the two-dimensional parameter space.

The results, further detailed in Ref. 2, confirm that amplifying the signal for the redshift drift does not necessarily improve the uncertainties of any parameters. However, the numerically determined set of redshifts shows that in ideal circumstances the uncertainties for w_0 and w_a can be improved by one to two orders of magnitude with respect to the canonical redshift drift, while the uncertainties for h and Ω_m were also improved. Nevertheless this advantage is diluted when priors are added, due to relatively high non-diagonal terms in the Fisher matrices. (In particular, we see that constraints on the dark energy equation of state parameters are dominated by the priors, making the ratios of the corresponding uncertainties become unity.) It will be important to validate these results though a MCMC analysis.

These results can be understood by calculating the sensitivity coefficients of the differential redshift drift to our four cosmological parameters, $\partial(\Delta v_{ir})/\partial p$, where p is one of (h, Ω_m, w_0, w_a), These are analogous to the ones shown in Fig. 1 for the standard redshift drift, except that they now depend on both the reference and intervening redshifts. As expected, one finds that the sensitivity to Ω_m is much larger than the others. Crucially, the sensitivity to Ω_m is maximized for $z_i = 0$ and maximal z_r: in other words, if the goal is to constrain Ω_m, the canonical redshift drift measurement is always the optimal strategy. On the other hand, for the other model parameters the differential redshift drift can provide tighter constraints.

5. Synergy with classical cosmological probes

Throughout this analysis, it has become clear that optimal constraints on the background quantities dynamically involved in the redshift-drift require wide redshift intervals to take advantage of the individual parameter sensitivities over the expansion history. This justifies, inter alia, the complementarity of redshift drift experiments, whose main candidates are embodied by the phase-2 SKA for low-redshift spiral galaxies and the ELT for distant quasars. Indeed, as previously pointed out, not only do these experiments complement each other, but there are also hints that they present promising synergies with traditional cosmological probes, potentially allowing to achieve more stringent joint constraints over cosmological parameters of the concordance model and its extensions.[1] Specifically, the fundamentally different nature of the redshift-drift experiment with respect to CMB, SNe, galaxy clustering, or weak lensing experiments, allows for novel correlations within the relevant parameter space, witnessed by degeneracy breaking. As a consistency check and to gain further insights on the degeneracies of the dark energy parameters, it is of

great interest to complement current Fisher forecasts with a more thorough MCMC analysis for accurate sampling of the distributions.

Similarly to the previous section, we account for a possible dynamical behavior of dark energy with two degrees of freedom, w_0 and w_a, through the CPL parametrization. The mock dataset for the ELT is generated according to the prescriptions of the third section for 30 QSOs populating 5 redshift bins between $z = 2$ and $z = 4.5$. As for the total uncertainty over the simulated data, Eq. (23) is used with a somewhat more optimistic value of unity for σ_e, reflecting the fact that redshifts are measured only at two distinct times (the underlying motivation is to compare the full potential of the redshift-drift against tight CMB and SNe constraints). Moreover, random noise is generated from a Gaussian distribution around the theoretical redshift-drift value, with a standard deviation of σ_v to mimic genuine measurements from Lyman-α forests. As for the phase-2 SKA galaxy sample, 5 bins are generated between redshifts 0.2 and 1.0 with redshift-dependent relative uncertainties of 10% following recommendations of previous estimations,[12] to which is added the same artificial Gaussian noise over the theoretical signal.

We implemented the theoretical redshift-drift signal to the dynamical landscape at the background level within the Boltzmann solver CLASS.[21] The theoretical drift is constrained to follow Planck 2018's cosmology[22] not to bias the relative distributions and to ease the comparison. The true posterior is then sampled with the Bayesian sampler MontePython[23] in which we integrated the simulated datasets and the scripts to generate the associated Gaussian likelihoods. The priors over all relevant cosmological parameters are consistent with the ones used in the Planck analysis.

The most noteworthy results from the forecast illustrated in Fig. 4 are first that there is no significant deviation from Gaussianity within the distribution, which further legitimates previous Fisher analyses. More importantly, one can note the remarkable degeneracy breaking of the redshift drift probability density function on most of the parameters with respect to the other probes. In particular, the clear degeneracy within the w_0–w_a space tends to suggest that the joint analysis of classical probes with future redshift drift datasets could further improve the constraints on the first-order term of the CPL parametrization and therefore work toward a better characterization of the possible dynamical behavior of dark energy. Here, the contribution of the low redshift SKA2 sample is important to this endeavor as it probes the dark energy-dominated era and allows to reveal a positive correlation between the two parameters whereas w_0 and w_a are anticorrelated for the other current cosmological observables. Nevertheless, one should keep in mind that such a combination of datasets requires particular attention to the possible correlations between probes and individual systematics.

That being said, in the light of these results, we should expect a consistent gain in the constraints on Ω_m, w_0, and w_a with this type of configuration for SKA and ELT from the joint analysis of the redshift drift measurements with current

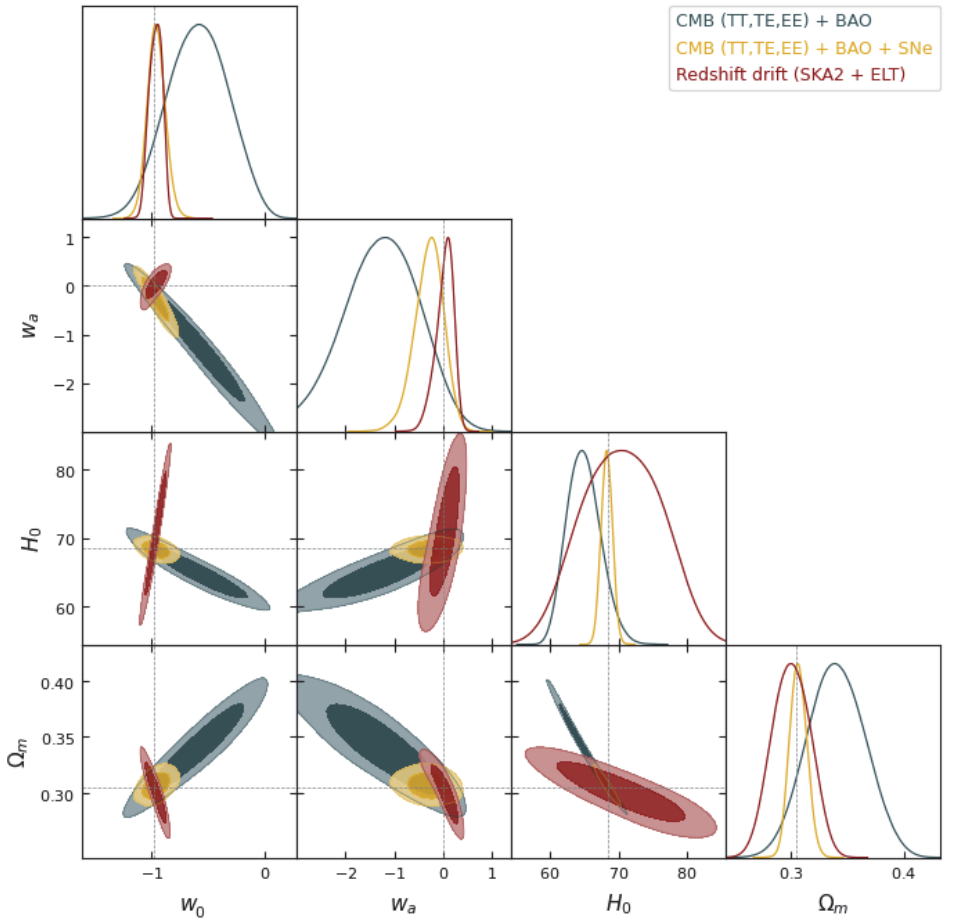

Fig. 4. Marginalized posterior distributions in the space $\{\Omega_m, H_0, w_0, w_a\}$ for the joint contribution of redshift drift experiments (red), CMB experiment with BAO measurement (teal) and CMB + BAO + supernovae (yellow). The data considered for the redshift drift experiments are the mock SKA2 and ELT samples whereas classical probes (CMB, BAO, SNe) are respectively taken from Planck, BOSS DR12, and the Pantheon supernovae samples.

cosmological probes. In the near future, a better instrumental characterization of these facilities is likely to refine the present conservative forecasts, and the CAC program, as well as intensity mapping experiments, will provide more data samples and homogenize the covered redshift range. Furthermore, by the time of the first observations of the redshift drift, next-generation galaxy surveys (Euclid, DESI), supernovae surveys (Vera C. Rubin Observatory) but also CMB experiments (Simons observatory, CMB-S4) will improve individual constraints, although in absence of new observable to present different correlations, these experiments will still highly benefit from the redshift drift degeneracy breaking.

6. Conclusions and outlook

The era of redshift drift measurements (rather than upper limits) is coming. These experiments need to be optimized for a specific purpose, which might be the detection of the drift signal itself, or constraining specific model parameters, such as the matter density or the energy equation of state, or providing a definitive consistency test for the model-dependent analysis of traditional cosmological datasets. Our analysis shows that optimized observational strategies for each of these are significantly different.

We note that an assumption of our analysis is that the measurement redshifts are free parameters, thus ignoring instrumental and observational limitations. In practice one can only do the measurements with the known bright quasars and their absorption systems. The number of astrophysical targets for these measurements remains relatively small despite recent progress.[7, 20] The Phase B of construction of the ELT-HIRES spectrograph, which will likely do the first redshift drift measurements, is about to start, and it will include a detailed feasibility study that will further explore the issues raised herein.

Gamma-Ray Bursts as potential cosmological probes

Gamma-ray bursts are among the most luminous transients in the Universe, a characteristic that permits us to observe them at very high redshifts. For this reason, many efforts have been made to identify a method to use GRBs as cosmological distance indicators through the use of luminosity correlations between their high-energy observable quantities. Some of the most promising methods proposed so far to standardize GRBs and their possible contribution to cosmology are presented and discussed, with a special emphasis on the Combo relation.

Keywords: Cosmology: distance scale; Gamma-ray bursts: general; Cosmology: cosmological parameters.

1. Introduction

Gamma-ray bursts (GRBs) are quick flashes of high-energy radiation initially observed in gamma-rays, where their temporal emission, also called ther "prompt" radiation is quite diversified.[1,2] The energy distribution of the photons emitted during the prompt emission can be successfully modelled with a phenomenological function, the Band model,[3] which can be described by two power-law functions smoothly connected at a given energy value, namely the peak energy of the prompt emission E_{peak}. GRBs can also be classified in two families, the *short* and *long* events, based on the T_{90} duration of the prompt emission.[4] This classification is also reflected in the hardness of the prompt photon energy spectrum, with short bursts having higher E_{peak} values than long events.[5] This classification is not only phenomenological, but it can be related to the physical progenitors of these powerful explosions: short bursts originate in the merger of two compact neutron stars,[6,7] an evidence confirmed by the recent discovery of a double neutron stars merger detected by gravitational wave detectors associated with a short GRB,[8] while long GRBs emitted during the collapse of highly-rotating massive stars.[9,10] The detection of an accompanying supernova few days after nearby long GRBs has given support in the last years to this model.[11,12]

As the time goes on, the bulk of the radiation emitted by GRBs moves to lower energies, such as in the X-rays,[13–15] at optical[16] and radio frequencies.[17] The emission observed in this so-called "afterglow" component looks at this stage more homogeneous, in particular at X-rays where it can be categorized in few subclasses.[18] The associated afterglow optical emission, detected in a good fraction majority of GRBs, has also permitted to identify the cosmological nature of these

explosions, through the identification of the redshift, and then to quantify with good accuracy their energetics and luminosities.[19–21]

2. GRBs luminosity correlations

GRBs are very energetic and luminous events. This property permits to observe them at very far distances: the most distant GRB was observed at a redshift of $z = 9.4$,[22] few hundred millions after the Big Bang and well inside the reionization epoch, when the first galaxies begun to form.[23] Then, it was almost natural to search a method to render GRBs a possible standardizable distance indicator to scrutiny the far Universe, and to search for possible exotic behavior of the dark energy component. The most used method consists in using some correlations between high-energy GRB observables, where at least one of the parameters involved is dependent on the background cosmology while the remaining ones do not. Gamma-ray photons ($\nu > 5keV$) can travel in the empty space without being affected by inter-stellar and inter-galactic absorbers, such as dust extinction, which however affects the use of optical distance indicators such as type-Ia SNe,[24] and this represents one important advantage for using GRBs as distance tools.

One of the most promising and very tested GRB correlation is the E_{peak}-E_{iso} relation, also known as the Amati relation.[25] Here, the intrinsic peak energy of the GRB prompt emission estimated within the T_{90} was found to be related with the isotropic energy emitted in the same time interval. This correlation is satisfied by all long GRBs within a large interval for the energy (almost six orders of magnitude). To illustrate the concept of GRBs as standardizable candles, the E_{peak} is the quantity that represents our cosmology-independent observable while E_{iso} is our "candle": the latter quantity is indeed related to the underlying cosmology through the luminosity distance d_l, and quantified by the bolometric fluence, which is given by the integrated GRB prompt flux in a specific energy range.[26,27] Once we derive the distance for a large sample of GRBs, we can start to build an Hubble diagram and then test the cosmological model.[28] The use of the Amati relation has provided for the first time an interesting estimate of the cosmological parameters with GRBs,[29,30] if compared with other non-standard probes.

Observing these events for more than 20 years with space-based satellites such as *Swift*[31] and *Fermi*,[32] has permitted to build large dataset of GRBs. Moreover, other correlations between GRB observed quantities started to appear frequently in literature.[33] The majority of these correlations have also been used to test cosmological models with some interesting applications. A very promising method that has provided some very interesting results is based on the use of a correlation that connects prompt and afterglow quantities, namely the Combo relation.[34] This relation originates from two existing proposed correlations, the previously-cited Amati relation and its extension to X-rays.[18,35] The core of the Combo relation is represented by a light-curve fitting procedure to model the entire X-ray afterglow emission: the use of a code able to model the X-ray light curve and that permits to get rid of

over-imposed flares by using a very efficient iterative method[35] allows to measure the "candle". From this procedure, the X-ray afterglow observables, namely the luminosity of the afterglow L_0, the time when the late time decay starts t_a and the power-law index of the late light curve decay α are computed and have been found in a tight relation with the GRB prompt peak energy E_{peak}.

The final result is a correlation that is satisfied by all long GRBs, e.g. no outliers,[36] for which there exist a known value for E_{peak} and with a complete observed X-ray afterglow by the X-ray Telescope (XRT) instrument on-board *Swift*. About a physical interpretation of the correlation, the connection between prompt and afterglow properties has been investigated only in recent times[37] but its use to constrain the cosmological models and some exotic variant has provided very interesting results (see also Fig. 1). In recent times, Muccino et al.[36] have found a possible indication of an evolution of the dark energy equation of state parameter w with redshift. However, the standard ΛCDM model with the constant solution $w = -1$ is still consistent with the statistical uncertainties derived by their analysis, which suggests the possibility that unaccounted systematics have a great influence on GRB luminosity correlations.

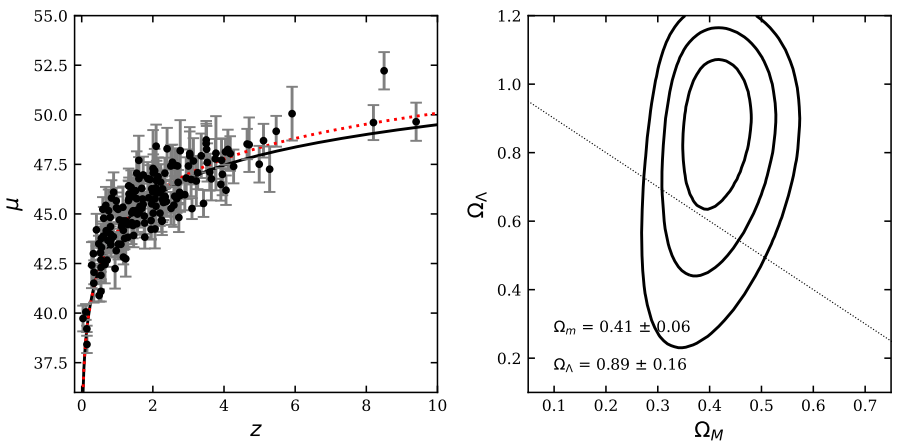

Fig. 1. *(Left panel)* The Hubble diagram built with 174 GRBs satisfying the Combo relation. The black curve corresponds to the best fit model in the context of a non-flat ΛCDM cosmological scenario, while the dotted curve represents a fiducial ΛCDM model with $H_0 = 70$ km/s/Mpc, $\Omega_m = 0.3$ and $\Omega_\Lambda = 0.7$. *Right panel* The best-fit confidence regions obtained by fitting the Combo GRB sample of 174 events within the context of a non-flat ΛCDM cosmological scenario. Here H_0 was fixed to 70 km/s/Mpc. Extra scatter uncertainties and systematics have not been included in the analysis.

3. Drawbacks

So far so good! However, it is mandatory to discuss the main sources of uncertainties that affect the use of GRBs as standardized candles. First, the lack of a considerable

number of GRBs at low redshifts ($z < 0.02$) prevents us to use accurate primary distance indicators to calibrate GRB luminosity correlations. The only GRB event observed at very close distances, GRB 980425,[11] does not have a great coverage in X-rays, given the lack of rapidly-slewing detectors such as *Swift* at the epoch of its discovery. Moreover, its very faint emission and luminosity do not assure that GRB 980425 is really a "cosmological" GRB but it can be originated in other energetic events such as the break-out of the shock wave following the collapse of a massive star.[38]

This problem led several authors to use alternative approaches to calibrate GRB relations, such as 1) the use of an underlying cosmology as explained in the review by Schaefer,[27] a method that includes an intrinsic circularity; 2) the use of alternative techniques that approximate the behavior of the luminosity distance evolution with the use of series expansion for the Hubble-Lemaitre law,[39–41] which however lead to serious problems at high-redshifts, or 3) the use of secondary distance indicators such as type-Ia SNe.[40,42] The latter method is very promising, given the high level of accuracy that type-Ia SN cosmology has reached in the last years.[43] However, in this approach the procedure of calibrating GRB luminosity relation is actually a seven-step method (type-Ia SNe are indeed calibrated using other primary distance indicators and so on). Moreover, given that the most used sample of type-Ia SNe, such as the Pantheon[44] spans a large distance range, any cosmological inference obtained using GRBs calibrated with type-Ia SNe will be strongly biased by the cosmology traced by these SNe, being their luminosity correlations characterised by a great accuracy. In this light, GRBs can only be considered as a mere extension of type-Ia SN Hubble Diagram and not an independent probe.

Selection effects and systematics errors also represent a big source of uncertainty when computing the accuracy (e.g. the scatter) of luminosity relations, but they have been rarely taken into account. In literature, it is common to find GRB samples that have been built using data coming from different detectors, mostly at high-energies (hard X-rays), which are characterised by different energy sensitivities, and then sensitive to specific GRB events. Finally, Malmquist bias also has a strong impact on the detection of the brightest events, and then on the final construction of the sample considered. This also affects the GRB redshift identification, which then becomes possible only for the brightest events. Correcting for the Malmquist bias is not easy, given that the distribution of GRB properties (luminosity function, physical characteristics of their progenitors, etc.) can vary with redshift, and then the use of incomplete GRB samples can lead to ambiguous results.[45]

4. Perspectives

Apart from getting more GRBs at high redshifts, a mission that will be the goal of future space missions, attempting to solve the above issues represents a mandatory step to render more reliable the use of GRBs as distance indicators. The scatter of all GRB luminosity correlations is also not competitive if compared with type-Ia

SNe. However, incoming surveys are currently discovering SNe at redshift comparable to the low end of the GRB distance distribution, and with the Rubin Legacy Survey of Space and Time (LSST) project, starting in few years, we can easily arrive to discover several type-Ia SNe at redshift $z \sim 2$. This will permit to compare GRBs and SNe correlations in a wide redshift range, allowing us to refine the calibration of GRB correlations. An important support on this line comes from the use of machine learning algorithms to reconstruct the distance luminosity function with the redshift , independently on the underlying cosmology. Similar approaches have been already developed, e.g.,[46,47] with very promising results. However, also this approach includes some hidden uncertainties that depend on the model used to train the calibrating sample and the sample itself: uncertainties affecting the training sample[48] will propagate on the calibration of GRB correlations, leading to a completely wrong posterior distributions when using GRBs as cosmological tools. Finally, without a correct treatment of the systematics affecting all GRB correlations, all the results should be treated with large caution.

5. Conclusions

GRB luminosity correlations represent a powerful tool to investigate the high redshift Universe, but their use is still affected by several issues that their application as accurate distance indicators is still far to come. The lack of a complete treatment of uncertainties, in particular of the systematics affecting their observables, and of an unbiased calibration technique represents the main barrier to overcome in order to take advantage of the information that these powerful explosions can give us on the early Universe.

Surface brightness fluctuations: The method and future applications

Michele Cantiello

INAF – Astronomical Observatory of Abruzzo,
Via Maggini, 64100, Teramo, Italy
E-mail: michele.cantiello@inaf.it

The surface brightness fluctuations method is one of the most robust extragalactic distance indicators: with an accuracy comparable to type Ia supernovae Ia and Cepheids ($\sim 5\%$ per galaxy) it is used in a wide range of distances: from very local, up to values relevant for measuring H_0.

In these proceedings, I present an overview of the technique and of the main results it allowed to obtain, further discussing the great potential with future applications based on forthcoming ground and space-based facilities.

Keywords: Cosmological Parameters; Hubble-Lemaitre Constant; Galaxy Distances

1. Introduction

The idea of using stellar counts to study the distance or the star content of a stellar population dates back to the first half of the previous century.[1,2] With the advent of CCDs, Ref. 3 introduced the surface brightness fluctuations (SBF hereafter) method as a modern formalism to obtain distances to stellar systems relying on the discrete nature of star counts. The SBF definition by Ref. 3 uses the Poisson statistics of star counts to measure a quantity that is closely linked to the mean brightness of red giant branch (RGB) stars in the target galaxy or, more in general, in the observed stellar system.

To date, the SBF method is one of the most robust extragalactic distance indicators: with an accuracy comparable to type Ia supernovae (SNe Ia) or Cepheids ($\sim 5\%$ per galaxy) without the limitations of the serendipitousness intrinsic to SNe, or the long observing campaigns needed for Cepheids. Moreover, it is used in a wide range of distances: from the Local Group, up to values relevant for measuring H_0.

Qualitatively, the idea behind the SBF is relatively simple: the stars which appear as resolved sources at relatively small distances, gradually "blend" in a smooth brightness profile when the stellar system moves to larger and larger distances (Figure 1).

Quantitatively, *SBFs are defined as the ratio of the second to the first moment of the stellar luminosity function in a population of stars.* From this basic definition some of the most relevant characteristics of the method follow: how SBF can be measured and what are the inherent complexities, what are the preferred targets, the opportunity of calibrating SBF magnitudes using empirical methods or stellar population synthesis techniques, etc.

In what follows, I will overview the technique, providing a detailed description of the method and on how measurements are carried out, what are the main limitations and sources of uncertainty, and present its great potential with applications based on forthcoming ground and space-based telescopes.

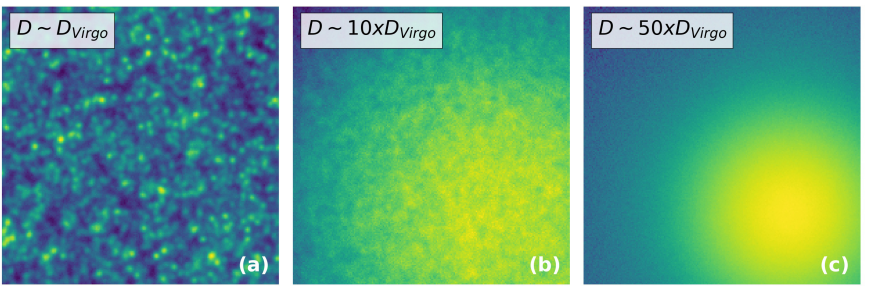

Fig. 1. Qualitative illustration of SBF signal. Panel (a): Simulation of the stellar population in a spheroidal galaxy at the distance of the Virgo cluster ($d \simeq 16.5$ Mpc, Ref. 4) as will be observed with the E-ELT in ∼1 hour exposure time (Cantiello et al., 2022, in prep.). (b) Same as in panel (a), but for a galaxy ten times more distant. Panel (c): Same as in panel (a), but for a galaxy fifty times more distant. Stars, which appear marginally resolved in panel (a), blend into a smooth brightness profile at larger distances.

2. From SBF analysis to galaxy distances

The SBF signal is not easy visualize as it might be for various other classical standard rulers (variable stars, parallaxes, SNe Ia etc.) and, consequently, it does not appear trivial how star-counts fluctuations can be translated into a distance estimate. For this reason, below I provide a concise and detailed description on how the SBF magnitudes $\overline{m}$ are measured, what are the preferred targets, how distances are then derived, and what are the dominant sources of errors.

2.1. *Measurements*

2.1.1. *Determining SBF magnitudes*

The SBF signal, in the absence of instrumental blurring and of other sources of fluctuations but the stellar counts, would simply be the Poisson variance between pixels due to the varying number of stars per pixel, normalized to the galaxy local mean flux. The instrumental point spread function (PSF) blurring forces a correlation between adjacent resolution elements, thus the SBF signal results to be convolved with the PSF, and its measure needs to be carried out in the Fourier domain.

A further complication is that there are sources of *spurious* non-stellar fluctuations. The presence of globular clusters (GCs) in the galaxy, of background galaxies in the observed field, of morphological irregularities due to dust contamination, or

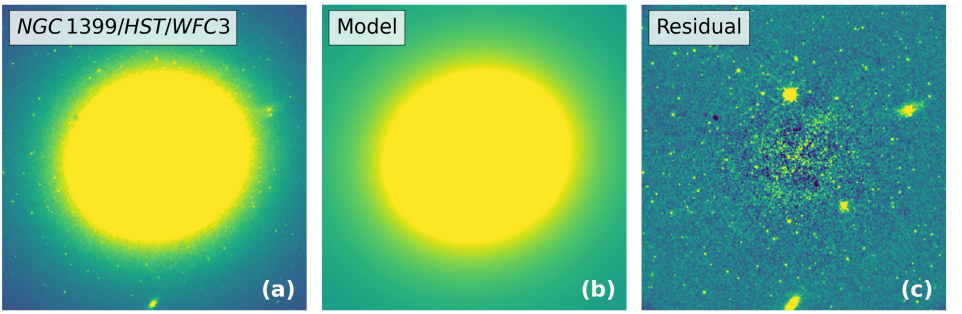

Fig. 2. Illustration of the SBF measurements. (*a*) Near-infrared image of NGC 1399 from the HST WFC3 camera. (*b*) Model of NGC 1399's surface brightness distribution derived from the WFC3/IR image. (*c*) Residual frame, obtained from the galaxy image (*a*) minus the model (*b*).

of obvious regions with markedly different stellar populations (e.g. star forming regions, overlapping regions of companion bright galaxies, etc.), affect the Poisson stellar fluctuation counts. Hence, to estimate fluctuation magnitude $\overline{m}$ all these possible sources of contamination need to be taken into account and removed.

The details of the procedures adopted for measuring SBFs are described in details in a number of papers.[5–12] Here, we summarize the main steps of the procedure, which consists of deriving the:

i) *average galaxy surface brightness profile*: this corresponds to the first moment of the host stellar luminosity function (model frame in Fig. 2 (*b*));

ii) *residual frame*: the galaxy subtracted frame. This image basically corresponds to the second moment of the luminosity function (Fig. 2 Panel (*c*));

iii) *mask frame*: all sources of non-stellar variance (dust, GCs, background galaxies, etc.) are identified and masked out;

iv) *residual, masked frame normalized to the model frame*: this image contains the bumpiness from the stellar fluctuations, plus the fluctuations of un-excised sources;

iv) *power spectrum of the total fluctuations frame*. The fluctuations are convolved with the instrumental PSF, thus in the Fourier domain they are multiplied to the Fourier transform of the PSF. Once derived the PSF and its power spectrum, the SBF amplitude is obtained as the constant term P_0 giving the best match between the power spectrum of the total fluctuations frame, $P(K)$, to the power spectrum of the PSF, $E(k)$, plus a white noise P_1 component: $P(k) = P_0 \times E(k) + P_1$. Figure 3 (left panel) shows a schematic example of the fitting procedure;

v) *correction for spurious residual fluctuations*. The masking process is effective down to a given magnitude limit: the deeper the magnitude limit the higher the detection limit of contaminating sources. However, the spurious fluctuations arising from GCs and background galaxies fainter than the detection limit need to be evaluated and subtracted out. A fit of the combined luminosity functions (LF hereafter)

of GCs and background galaxies above the limiting magnitude is used to obtain by extrapolation the extra-fluctuations term, P_r, due to sources fainter than the detection limit. An example of the total LF fit, derived as the sum of the Gaussian LF for GCs in the galaxy (GCLF) and a power law LF for background galaxies, is shown in Fig. 3 (right panel).

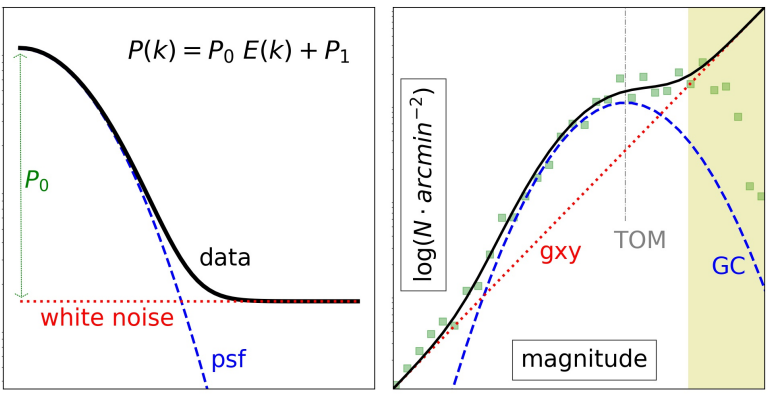

Fig. 3. Left: A schematic illustration of the SBF power spectrum analysis. Right panel: Typical luminosity function analysis for estimating the residual variance P_r due to contaminating sources: green squares show the data, the blue curve and red line show the fits to the GCs and background galaxies LFs, respectively, and the solid black line is the combined model luminosity function (data and fits are from Ref. 13). The vertical grey dashed line indicates the GCLF turnover magnitude, TOM, and the shaded area shows the magnitude interval where the detection is incomplete.

The residual variance is then evaluated from the integral of the second moment of the total luminosity function in the flux interval $[0, f_{lim}]$:

$$\sigma_r^2 = \int_0^{f_{lim}} n_{obj}(f) \times f^2 df \tag{1}$$

where f_{lim} is the flux corresponding to the limiting magnitude, m_{lim}, and $n_{obj}(f)$ is the GC and background galaxies combined LF (Fig. 3, right panel). The residual variance P_r is then derived from σ_r^2 normalized by the galaxy surface brightness;

vi) *SBF magnitudes*: once measured the total fluctuation amplitude, P_0, and estimated the spurious fluctuations term P_r, the stellar fluctuations follows as $P_f = P_0 - P_r$, and then the SBF magnitude as $\bar{m} = -2.5 \log(P_f) + mag_{z.p.}$, where the $mag_{z.p.}$ term is the instrumental zero point magnitude.

Finally, to convert $\overline{m}$ into a distance, the characteristic absolute SBF magnitude of the population, $\bar{M}$, needs to be known. By combining the absolute and apparent SBF magnitudes, the distance modulus μ_0 follows as usual: $\mu_0 = \bar{m} - \bar{M}$ and, then, the distance d is derived by inverting relation $\mu_0 = 5 \log(d/Mpc) + 25$.

2.1.2. *Calibrating SBF magnitudes*

To obtain a calibration of $\bar{M}$, to be used for deriving μ_0, two different approaches are typically adopted: empirical calibrations or population synthesis models.

$\bar{M}$ can be described as a one-parameter family, with the integrated color of the galaxy (or, more in general, of the stellar population) used as main correlation parameter, i.e. $\overline{M}=\alpha + \beta \times color$; at fixed pass-band $\bar{M}$ is a universal function of the color, with residual intrinsic dispersion which can be as ~ 0.05 mag depending on the pass-band.[4,9]

Using theoretical calibrations the SBF method is a primary distance indicator: it does not carry over the systematic uncertainty from the first steps of the calibration. Despite the generally good match between predictions from independent stellar population synthesis models, this is mostly limited to the optical bands. The matching of SBF magnitudes from different models in the blue passbands (more sensitive to stellar population properties), or in the near-IR (where the stellar models are yet not as robust is in the optical bands), is of the order of ~ 0.2 mag. The difference between models is then significantly larger than the estimated SBF cosmic scatter derived empirically.

Finally, although there are obvious advantages from using calibrations based on stellar population models, to date most of the available SBF distances rely on empirical calibrations.[4,11,14,15]

2.1.3. *Caveats in measuring SBF*

One of the major problems in measuring SBF is the contamination from GCs. As the distance of the galaxy increases, the detection of GCs gets more complicated by the combination of GCs crowding and flux limit, consequently the contamination from GCs increases.

Since the estimate of the contamination from unidentified GCs is made by extrapolating the observed GCLF at magnitude levels fainter than the limiting magnitude (Fig. 3, right panel), the brighter the limiting magnitude is, the greater the uncertainty due to the extrapolation is, and the larger is the P_r correction. The relative error on P_r is typically assumed to be of the order of 20-25%,[5,16] hence a reliable SBF measurement requires $P_f >> P_r$. A P_r correction less than 10% P_f, or lower, is an essential condition for obtaining reasonably robust estimates of SBF and, therefore, reliable distances. In optical bands, this condition is typically satisfied when the limiting magnitude is at least one magnitude fainter than the GCLF peak magnitude (TOM in Fig. 3, right). In near-infrared bands this condition is less stringent, as the contrast between M_{TOM} and $\bar{M}$ is more favourable to SBF than in optical bands. Even a limiting magnitude m_{lim} close to the TOM, or one magnitude brighter then that, can be enough for accurate measurements.

The present distance limit for SBF is then due to GCs crowding confusion and detection limit. The level of such limit improves with space-based data, where the PSF is typically sharper ($\sim 0''.1$ for HST observations).

The contamination due to background galaxies is normally a negligible problem compared to GCs. GCs have a spatial distribution strongly concentrated on the galaxy, while the density of background galaxies per angular unit is roughly constant over the observed field, and substantially smaller than GCs in the bright galaxy regions where the SBF signal is measured.

2.2. *Preferred targets and pass-bands*

Currently, the bands considered for SBF analysis range from the $\sim I$ (central wavelength $\sim 7.5 - 8.0\mu m$) to $\sim K$ (at $\sim 2.2\mu m$). SBF at shorter wavelengths are not of great interest, due to the non-negligible dependence on the properties of stellar populations in these bands,[7,16] combined with the more dramatic effect of the contamination of GCs and dust.

The small intrinsic scatter of $\overline{m}$, empirically constrained to ~ 0.05 mag, comes from optical studies in the I and z bands for massive ellipticals. To date, the intrinsic dispersion of $\overline{m}$ in the near-IR bands is much less constrained, but it appears to be a factor of two larger than in the optical bands, likely because of the larger scatter arising from bright giant branch stars.[17] Hence, the preference would seem to be for bands like I or z due to the advantages from the smaller irreducible intrinsic scatter, there are undeniable advantages in near-IR bands. At longer wavelengths SBFs are intrinsically brighter, there is a larger and more favourable contrast with respect to GCs –hence the contamination from these sources is less dramatic–, and the presence of residual dust contamination is typically negligible.

In addition to such advantages, it is worth recalling that some of the key facilities of the next decade will have their highest efficiency at near-IR wavelengths (Sect. 3).

Given the peculiarities of SBF, the ideal target for the measurements is any elliptical galaxy free of dust, with a well identifiable GC system and with a relatively homogeneous population of stars: in other words a passively evolving, red and dead galaxy.

Empirical calibrations show that for bright red galaxies, the linear correlations between $\overline{M}$ and colors have a markedly lower scatter then in the fainter blue galaxies regime. In fact, SBF distances for massive galaxies reach very small statistical uncertainty, 5% or lower.[4,9,10,12] The analysis of integrated colors and SBF for intermediate-mass galaxies, shows that they host a more complex stellar population, consequently the intrinsic scatter of the $\bar{M}$-vs-color relations is larger than for red massive galaxies. Finally, bluer dwarf ellipticals can host stars with low metallicities and/or young ages, or a combination of both. This results in an observed scatter $\gtrsim 0.2$ mag, and statistical uncertainties on distances $\gtrsim 10\%$ due to the calibration effects alone.[12]

In conclusion, red massive galaxies are the ideal target for SBF, yet red bulges of spiral galaxies, or low mass dwarf ellipticals, or any other non-ideal SBF target, represent a plausible object for SBF measurements in all cases where there are no reliable methods to estimate distances.

2.3. *Uncertainties*

2.3.1. *Main Statistical Errors*

We can group statistical uncertainties affecting SBF in two main categories: uncertainties from the measurement of the fluctuations and uncertainties related to the calibration.

For the uncertainties directly linked to the SBF measurement, we mention the accuracy of the galaxy model (item i in section 2.1.1), the fit of the external sources (item v), the fit of the spatial power spectrum (item iv), the determination of the correct normalization to the PSF (which is a systematic uncertainty for a given data set), and the presence of undetected dust.

Concerning the calibration, excluding the zero-point, the total uncertainty of $\bar{M}$ stems from the combination of the uncertainty on the integrated color of the galaxy and of the intrinsic dispersion of the calibration equation (irreducible and wavelength dependent) due to the dispersion of the properties of the stellar population in the galaxy.

Although numerous, statistical uncertainties can be individually minimized by means of suitable observing and data analysis strategies. As reported in the various works,[11,18,19] the total statistical uncertainty on $\overline{m}$ can be 0.05 mag or smaller, while that on $\bar{M}$ is limited by cosmic scatter which, in some bands, can reach levels of 0.06 mag.[4]

In summary, statistical uncertainties in well-conceived observations can be kept at levels below 3% on the distance of the single galaxy.

2.3.2. *Systematic Uncertainties*

For data-sets from different instruments, the only systematic source of error on SBF arises from the calibration zero-point.

Most of the empirical calibrations reported in the literature are based on the zero-point from the SBF ground-based survey by Tonry and collaborators,[14] which obtained SBF for bulges of spiral galaxies with known distance estimates from the Cepheids P-L relations.

In Ref. 11 a total systematic uncertainty of 0.10 mag on SBF distance moduli is cited. This includes a contribution of ~ 0.08 mag from the tie between SBF and Cepheids,[20] and a contribution of ~ 0.06 mag for the Cepheid zero-point, dominated by uncertainty in the distance of the LMC.[21]

Ref. 22 have recently revised the LMC distance using a sample of 20 detached eclipsing binaries, the new distance is $\sim$1% lower than the one used Tonry & coll. and, more important than that, the LMC distance is obtained to 1% precision. The increased accuracy of the LMC distance brings the overall Cepheid zero-point error to 0.028 mag.[23] Consequently, besides a minor effect on the absolute calibration of $\bar{M}$, this revision lowers the systematic error on $\bar{M}$ to ~ 0.085 mag, slightly more than $\sim 4\%$ on the distance.

An alternative to further lower the systematic error derives from the consideration that the ideal target for SBF are elliptical or lenticular galaxies (Sect. 2.2), which have no distance estimates via Cepheid P-L relations. Classical Cepheid stars are high-mass young stars, preferentially found in the dust rich environments of irregular and spiral galaxies, namely the type of target of no interest for SBF. As an alternative to Cepheids, the RGB Tip method (TRGB[24]) is the ideal candidate for measuring distances of early-type galaxies and obtaining an independent calibration of SBF.

A first attempt to calibrate SBF with TRGB, by Ref. 25, used a sample of 16 galaxies within 10 Mpc dominated by relatively blue objects. The authors found negligible changes on distances. However, obtaining a significant sample of SBF and TRGB distances for massive red elliptical galaxies requires reaching the Virgo cluster, and there are few TRGB distances to early-type galaxies at this distance.

Ref. 19 ([B21] hereafter) analyzed the few galaxies for which these measures exist: the massive bright ellipticals M 60 and M 87 in Virgo, and the dusty merger remnant NGC 1316 in Fornax. Excluding the problematic calibrator NGC 1316, the authors find that the mean offset between the SBF and TRGB distances of the two galaxies in Virgo is approximately -0.01 mag. Although preliminary, this result shows no significant difference between Cepheid- and TRGB-based SBF zero-points.

3. Results and future applications

3.1. *Recent results*

The SBF method has been in use for more than three decades. By counting the survey works with more than ~ 50 targets measured, the ~ 600 distances in the range from Local Group to 130 Mpc[a] have proven to be a valuable resource for numerous studies. The reliability and precision of these surveys is quite heterogeneous, with errors on the derived distances typically of 4-5% from HST observations, and of $\sim$10% or more for ground-based SBF (ignoring systematic zero-point uncertainty).

These studies covered, or allowed to cover, a wide range of scientific topics in which the measurement of the distance plays a key role. Among the others, we cite *i*) the measurement of distances for massive galaxies to obtain robust relationship between the mass of the black hole and the bulk dynamics of the galaxy;[18] *ii*) the distance to the first observed dark-matter deficient ultra-diffuse galaxy;[26] *iii*) the detailed structure of the Virgo cluster and the measure of the relative Fornax to Virgo cluster distance with exquisite and still unpaired precision;[4] *iv*) the most precise distance to the host galaxy of the binary neutron star merger event GW170817, i.e. the only GW event also observed in the EM spectrum.

[a]Without checking for duplicates, we included 300 galaxies from Ref. 14, 130 from Ref. 15 and Ref. 18, 140 from Ref. 4 from the ACSFCS and ACSVCS (see also Ref. 9), 80 from Ref. 11 based on the NGVS survey soon to be complemented with 200 more (Cantiello et al., 2022, in prep.).

The study of the Hubble-Lemaitre parameter H_0 deserves a more detailed discussion. Various estimates of this key cosmological parameter have been obtained,[14,27–29] where SBF are either used to calibrate other distance indicators, like SNe Ia, or directly adopted to estimate the local H_0 value. Here, we focus on two recent studies from Ref. 30 and B21.

Ref. 30 presented a re-calibration of the peak magnitude for a sample of 24 local SNe Ia in galaxies based on SBF distances. The authors adopted a rather heterogeneous sample of SBF-based distances, collected from sets of observations spanning over twenty years –combined with a similarly heterogeneous sample of SNeIa. In spite of the difficulties of renormalizing the SBF-distances to a common reference, the heterogeneity of the sample brings with it some advantages, like the possibility to dramatically lower the impact of any instrument- or data-analysis driven systematic effect (e.g. linked to the PSF templates used). Adopting a hierarchical Bayesian approach, the authors extended the calibration to a sample of SNe Ia at redshift $0.02 < z < 0.08$, thus obtaining $H_0 = 71.25 \pm 2.37(\text{stat.}) \pm 3.38(\text{sys.})\text{km s}^{-1}\text{ Mpc}^{-1}$[b]. Such estimate lies in between the value by Ref. 23 based on SNe Ia and Cepheids ($H_0 = 74.03 \pm 1.42$ km s^{-1} Mpc^{-1}including systematics), and the value by Ref. 31 ($H_0 = 67.4 \pm 0.5$ km s^{-1} Mpc^{-1}obtained assuming the standard Λ CDM Cosmology). Hence, the estimate by Ref. 30 lies at $\sim 1\sigma$ from the H_0 estimates which started the debate on the "tension" in the Hubble-Lemaitre constant.[23,31]

B21, using a catalog of SBF distances for 63 early-type galaxies out to 100 Mpc obtained from WFC3/IR HST data,[18] revised the Hubble-Lemaitre parameter to $H_0 = 73.3 \pm 0.7(\text{stat.}) \pm 2.4(\text{sys.})$ km s^{-1} Mpc^{-1}. An estimate that agrees within $\sim 0.5\sigma$ with the value from SNe Ia, and a discrepancy larger than $\sim 5\sigma$ with respect to the estimates from Cosmological models and CMB anisotropy measurements (we ignored the systematic uncertainties on SBF). The H_0 by B21 is from SBF distance estimates for galaxies in the range of 15 and 100 Mpc: a distance where peculiar velocities can have a significant impact on the recessional velocities of the galaxies. Hence a regime where accurate velocities are equally important as accurate distances. In their analysis, B21 included as a test the analysis of four different treatments of the galaxy velocities: group velocities, individual velocities, and two flow-corrected model velocities to verify the robustness of their result within the reported errors. It is also worth noting that, as mentioned in Sect. 2.3, B21 adopts a joint calibration averaging the results for the Cepheid and TRGB which reduced uncertainty on H_0.

The work by B21 demonstrates that, in the next future, using a richer sample of massive galaxies with near-IR SBF within 100 Mpc and with improved constraints on the calibrations and on the cosmic-flow model, it will be possible to obtain SBF-based H_0 estimates at 1% or lower statistical uncertainty. Lowering

[b]The final value adopted by Ref. 30, $H_0 = 70.50$km s^{-1} Mpc^{-1}uses the old LMC zero-point; using the revised LMC distance, reported in the references cited in section 2.3, there is a solid 0.023 mag shift toward fainter distance moduli, which leads to an H_0 value of 71.25 km s^{-1} Mpc^{-1}.

the residual 3-4% systematic uncertainty, requires improving zero-point calibration effort as described in section 2.3 and in the next section.

It should be noted that the estimates of Ref. 30 & B21 agree within $\sim 1\sigma$ the respective statistical errors, also due to the relatively large uncertainty of the former estimate because of the heterogeneity of the sample and to the fact that Ref. 30 has an extra calibration step (SNe Ia calibration with SBF) compared to B21.

3.2. *Future applications*

The perspectives of this method can be divided into two three categories: "going wide" with the next generation survey telescopes, "going deep" with the JWST and AO-assisted facilities at 30-40m class telescopes, and "going precise" with programs aimed at lowering systematic errors and with new stellar population models.

3.2.1. *Large and deep sky surveys*

The forthcoming large sky surveys, including the LSST by the Vera Rubin Observatory and the Euclid wide survey, will produce a breakthrough in many fields of Astronomy. The expectations for SBF measurements, hence for mapping the 3D distribution of galaxies in the low-redshift Universe, are rather high.

At the time of writing, the LSST is expected to produce multi-band optical *ugrizy* observations, with typical seeing of 0.7", and 5σ point source depth of $i \sim 26.8$ mag for stationary sources after the 10 years of the main survey. Adopting the i as reference pass-band, we predict LSST will allow reaching bright massive galaxies at ~ 70 Mpc, that is the distance where the TOM+1 mag is reached at $\sim 5\sigma$ point source depth[c].

The Euclid satellite has about one fourth the collecting area of HST, but compared to LSST it has the advantage of the near-IR observations[d] and the sharp PSF (~ 0.2") allowed by space-based observations. Taking as reference the Euclid/NISP H-band, which is predicted reaching 5σ point source depth of $H \sim 24$ mag, and adopting $H_{TOM} \sim -8.3$ mag,[33] the TOM+1 magnitude will be reached for all bright galaxies at a distance of ~ 30 Mpc. However, in the H-band, the TOM+1 depth rule can be relaxed and a depth at 5σ the TOM could be sufficient in this band for reliable SBF measurement (Sect. 2.1.1), corresponding to a distance limit of ~ 70 Mpc.

Tests on the feasibility of SBF measurements with either Euclid instruments and with LSST precursor data are being carried out. If both instruments will be successful for SBF applications, we will have ~ 18.000 deg^2 of the LSST covering the

[c]Assuming an $i_{TOM} \sim -8.5$ mag,[32] we obtain a limiting distance modulus of $(m-M)_{limit} \sim 34.3$, or $D \sim 72.5$ Mpc.

[d]The wide passband of the optical instrument, VIS, basically covers the entire optical spectrum, thus we expect that the intrinsic scatter of SBF due to stellar population effects will be too large for precise distances from this instrument.

southern skies and $\sim 15.000\ deg^2$ of Euclid in the North, that will potentially allow obtaining the most accurate and complete 3-D map of massive red galaxies in the sky out to ~ 70 Mpc. Certainly a large number of lower mass, bluer galaxies at lower distances will also be mapped. The combination of these two data sets will provide exquisitely accurate cosmic flow models to be used for peculiar-velocity corrected flows, and an incredibly large sample of galaxies with SBF distances, useful for H_0 and for the needs of any near-field Cosmology study.

A further instrument of great impact will be the Roman telescope: with the same aperture of HST, similar PSF sharpness, ~ 100 times the HST field of view, near-IR coverage, and 5σ point-source depth in 1 hr of 28 mag in J and H band, this telescope will combine survey to depth capabilities, allowing to measure SBF for galaxies in clusters or groups at distances out to 100 Mpc and more.

3.2.2. *JWST and 40m ground-based telescopes*

The JWST and the 30-40m class telescopes –like the E-ELT– will have near-IR imaging capabilities at a resolution like HST or better, combined with substantially larger collecting areas, a field of view of the order of one to a few arcminutes, more modern and efficient detectors: all these characteristics combined make it plausible to predict that these telescopes will allow to overcome the 150 Mpc limit, currently "held" by SBF with the HST.[28, 29]

JWST is the natural heir of HST: with a similarly sharp (FWHM$\sim$ 0.1") and stable PSF, it has $\sim 7.5\times$ the HST aperture, possibly sufficient to enable us measuring SBF distances for galaxies at 300 Mpc limit or beyond. The limiting factors at such large distances will be, in this case, the contaminating GCs and obtaining reliable estimates for k-corrections.

The perspectives for ground-based 30-40m telescopes are at the same time exciting and challenging. The next-generation adaptive-optic (AO) modules at near-IR imagers will provide PSF reaching the limit of FWHM$\sim$0.01", thus one order of magnitude better than the best resolution presently available (even better than the JWST), combined with a collecting area at least 150 times larger than HST, and increased detector efficiency. Would this mean that the potential of the SBF with AO assisted imaging data is to reach distances even one order of magnitude farther than present limits, breaking the 1 Gpc limit (z$\sim$0.2)? To date, no answer can be given to the question, because of the lack of studies on the measurement of fluctuations from data taken with AO modules. Although some studies have been made of this topic,[34] quantitative demonstrations are lacking, because of the complexity of combining AO observations for extended objects with the issues of deriving reliable SBF amplitudes from AO supported imaging data. Let us take as example the complexities with the PSF: AO observations are characterized by a PSF variable in space and time, the lack of good PSF candidates within the galaxy field of view because of the small field of the present generation of AO systems, and by the unknown effect on SBF from the large spread of the PSF in diffraction-limited

conditions. In spite of such non-trivial issues, the forthcoming generation of 30-40m ground-based telescopes can be expected to produce breakthroughs in this field. Currently, cosmological studies based on direct distance indicators mostly rely on SNe Ia, which, although calibrated with high precision, are serendipitous events that present a zoo of peculiarities. Furthermore, SNe Ia distances rely on purely empirical information: we still lack a detailed modeling of the phenomena involved in SNe Ia explosion, useful for numerical calibrations of distances. On the other hand, the SBF measurement requires only data of suitable quality (no surreptitiousness), and relies on a signal whose origin is well known (star counts). In other words, though extremely more challenging than with the ideal JWST or Roman telescopes, SBF with 30-40m ground-based AO-assisted telescopes, could lead to SBF estimates out to redshift $z > 0.1$. At such distances, cosmological effects are predicted producing variations measurable with a distance indicator characterized by an accuracy of $\sim$5%. Hence, a dozen of well selected targets could be used to back up the SNe Ia on an independent route to precise cosmological parameters.

3.2.3. *Stellar population models and calibrations*

Possible refinements on the accuracy and precision of SBF distances will depend on the availability of new stellar population models and on improved $\overline{M}$calibrations.

At large distances, i.e. $d > 100$ Mpc, magnitudes (both "standard" and SBF magnitudes) and colors require k-corrections, which can only be derived from stellar population models. The most recent estimates for k-corrections on SBF magnitudes, date back to the 2000,[35] and predict a correction of ~ 0.1 mag for the HST/NICMOS $F160W$ filter ($\sim H$ band) at 200 Mpc. The correction changes significantly with wavelength (as an example it is significantly smaller in the J band, ~ 0.012 mag) and needs to be accounted for also in the colors, which are used for estimating $\bar{M}$.

Hence, any detailed study of cosmological parameters from SBF magnitudes for galaxies at distances where the peculiar velocities are negligible with respect to the Hubble-flow, cannot ignore using reliable k-corrections which, to date, are still poorly constrained or completely unavailable for some filters or distances.

Concerning the SBF calibration, there are here too opportunities for improvements. At present, the dominant systematic error comes from the $\sim$0.08 mag tie between SBF and Cepheids (Sec. 2.3). The results from Gaia will certainly have a positive impact on that: both because of the direct detection of Cepheids in M 31 (one of the SBF calibrators), and thanks to the more accurate and precise results on P-L relations from the data of thousands Galactic and Local Group Cepheids with measured parallaxes.[36]

A further opportunity could be deriving new SBF measurements for the same six calibrators used by Tonry & coIs. (based on imaging data taken prior to 1997) or from new calibrators.

Finally, as also pointed out in B21, the complete independence the Cepheid and the TRGB-based calibrations could also be used as a further factor to reduce the

systematic uncertainty on a joint Cepheid/TRGB calibration, leading to a combined zero-point uncertainty of $\lesssim 2$ % in distance (assuming the uncertainty on the TRGB zero-point TRGB is similar to that of Cepheids).

The upcoming launch of the James Webb Space Telescope (JWST) will allow for more numerous TRGB distances to the Virgo early-type galaxies in only modest observation times. Ultimately, we hope to anchor the SBF method using a much larger sample of giant ellipticals with TRGB distances calibrated using Gaia's parallaxes.

4. Conclusions

The SBF technique, with direct distances on single galaxies reaching an accuracy of $\sim 5\%$, is at present one of the most accurate extragalactic distance indicator in the distance regime between a few Mpc to ~ 150 Mpc.

In this contribution, I have described the basic characteristics of the method, how SBFs are measured, calibrated and used to estimate distances. I also provided a summary of the main scientific results obtained.

The next-generation of ground- and space-based telescopes will provide a variety of data that will generate thrilling results in many fields of Astronomy, not least the study of Cosmology based on direct distances from SBF. The extensive use of near-IR observations with high-resolution cameras –from JWST or E-ELT–, the deep surveys that will cover a large fraction of the sky –from the Vera Rubin Observatory or the Euclid satellite–, the improvements on SBF calibrations –from Gaia and from new stellar population models– will push forward this technique. By combining accuracy with depths and sky coverage, new data will allow using SBF distances for constraining cosmological models using a new path, independent from other direct distance methods, like SNe Ia.

The shape of redshift distribution for uniform sources set in our Metagalaxy defined by cosmological parameters and properties of space. The suggestion that type Ia supernovae might be used as standard candles for cosmological measurements allow considered these objects as homogeneous subsample. This mention occurs since the earliest studies of supernovae in 1938. Firstly the parameters of our Metagalaxy Ω and Λ were determine due sample of Ia supernovae from the Supernova Cosmology Project analysis in 1998. It was found due SN1a characteristics analysis that space in our Metagalaxy is Euclidean at small redshifts and de-Sitter at high ones. Now several tens of thousands supernovae' characteristics analyzed in various catalogues.

The preliminary results of the redshift distribution analysis for SNIa from the Asiago Supernova and Open Supernova Catalogues are discussed in this work. Firstly it was shown that several peculiarities are presented in Ia supernovae redshift distribution. The deviation in the band $0.015 < z < 0.13$ accordingly Open Supernova Catalogue (OSC) data contain more faint supernovae. Two peculiarities also were found in the region $0.25 < z < 0.45$ on data of this catalogue. One of it's contain more faint events, other contain more bright supernovae.

Also faint_m and bright_m supernovae areas could be separated by $m_{fb} \sim 20$ in distribution of object amount on apparent magnitude on both catalogues data. Furthermore, the distribution of SNIa on apparent magnitudes and angular distance to host centre on OSC data also reveal two areas (faint_{dist} and bright_{dist} objects) and ratio between these regions populations is different for different subsamples in OSC (Pan-STARRS1 (PS1) Medium Deep Survey, ASASSN and so on).

Moreover, SNIa apparent magnitudes could differ for $\Delta m_{onehost} \sim 2.5$ within one host galaxy (for example, in UGC03432) and this difference bigger that systematic uncertainties of SN1a characteristics observations. Also there are no specific absorption lines in the energy spectra of these SNIa which exclude influence of surrounding media.

The separated peculiarities and areas could not be explained due 2 groups of type Ia SNe explosions scenarios and dimming of flux due interaction of surrounding media. But it could affect at power in dependence of distance modulus μ on redshift, and, correspondingly, the H_0 tension between various subsamples of SN1a data. May be such tension was caused by different ratio of two SNIa classes objects in analysed catalogues and value of H_0 defined from supernovae subsets analysis became lower after correction for results of dependence of apparent magnitude on distance to host centre.

Thus such peculiarities presence could be caused by several unknown aspects of SNIa explosions scenarios or really changing of the parameters of our Metagalaxy. Further conclusions required subsequent OSC database treatment in combination with high redshift datasets, for example, addition of Dark Energy Survey Supernova Program catalogue into data analysis.

Keywords: SNIa redshift distribution

1. Introduction

The homogeneous subsample characteristics understanding is necessary for the investigation of any astrophysical objects redshift distribution, for example, gamma-ray bursts. The shape of redshift distribution for uniform sources set in our Metagalaxy defined by cosmological parameters and properties of spacetime. Type Ia supernovae considered as such standatd candels since 1995.[1] The effect of a cosmological constant leads to dimming of observed brightnesses of highredshift supernovae than would have been the case with $\Omega_\Lambda = 0$ and allowed to estimate cosmological parameters due analysis of Hubble diagram contain dependence of on redshift — see, for example, Ref. 2.

The interest of the scientific community on supernovae (SNe) has increased in the recent years for several reasons. Mostly they are the advances in the understanding of the SN phenomena obtained with the intensive study of nearby SNe, first of all SN 1987A, which have raised new more fundamental questions with regard to progenitor evolution, explosion mechanism and nucleosynthesis — see, for instance, Refs. 3, 4. In addition, the at least two facts have renewed the interest for the using of SNIa as distance indicators up to cosmological distances. The first one was the calibration of the absolute magnitudes of a few SNIa obtained using the Cepheid variables found in their parent galaxies.[5] The second fact was the discovery of empirical relations between the absolute magnitudes at maximum and the shape of the light curves of SN Is.[6] Other exciting advances are expected for the association of some SNe with the other interest objects, for example, GRBs. Another reason is the necessaries of homogeneous subsample characteristics understanding for the investigation of any astrophysical objects redshift distribution, for instance, also GRB — see Ref. 7. Such wide interest has activate new deep SNe searches and creation or revision of catalogues based of its results. Now the amount of SNe listed in various catalogues is about one hundred thousands which mentioned in several tens of catalogues — see, for instance, Refs. 8–11. SN1a are approximately 25% of this subset volume — see, for instance, Refs. 9, 10, 12.

Firstly the parameters of our Metagalaxy Ω and Λ were determine due sample of Ia supernovae from the Supernova Cosmology Project analysis in 1997 — see Refs. 2, 13. Figure 1 represents the results of tis investigation. The combination of Hubble diagrams for 42 high-redshift type Ia supernovae from the Supernova Cosmology Project and and 18 low-redshift ones from the Supernova Calalan/Tololo Survey was approximated by power law fit. It was found that this fit corresponds to following composition of our Metagalaxy: 70% of dark energy, 25% of dark matter and only 5% of ordinary baryonic matter.[2,13] Later it was found that several objects from this sample are not SNIa, but a valid asymptotic estimations still remain.[14]

2. Asiago Supernova Catalogue

The history of the Asiago SN catalogue began in 1984 with the publication of data for 568 objects.[15] This was compiled starting from the Palomar Supernova Master

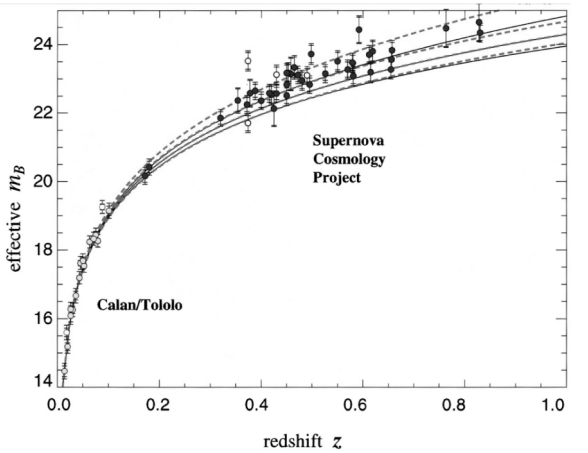

Fig. 1. Hubble diagram for 42 high-redshift type Ia supernovae from the Supernova Cosmology Project and 18 low-redshift type Ia supernovae from the Supernova Calalan/Tololo Survey. Adopted from Ref. 13.

List which since 1958 from time to time appeared in the literature see, for example, Refs. 8, 9, 16. During the same period two other SN listing have been published,[17,18] the Ref. 18 also contains the complete bibliography for each object. The 1984 Asiago SN Catalogue was superseded by a new edition in 1989[19] which listed information for the 661 supernovae discovered up to December 31, 1988.

More recently, van den Bergh at Ref. 20 published a list containing the 203 supernovae discovered between January 1, 1989 and April 3, 1994. Also the Catalogue of extragalactic Supernovae, complete up to 1993, was published in volume V of the General Catalogue of Variable Stars Ref. 21. In the last few years the Asiago Supernova Catalogue was widely used through the literature and available at the Ref. 22. Other supernova listings are available electronically, e.g. the list at the CBAT,[23] and Sternberg Astronomical Institute Supernova Catalogue.[24] The Asiago Supernova Catalogue consists of following datasets contain more than 100 supernovae:

(1) SDSS-II,
(2) LOSS,
(3) LOTOSS,
(4) ESSENCE,
(5) Puckett,
(6) SCP,
(7) HZSST.

Other 27 supernovae datasets included in this catalogue consist of less amount of members. For example, ones BAOSS and CFHT-LSSP contain only 34 and 13 objects correspondingly.

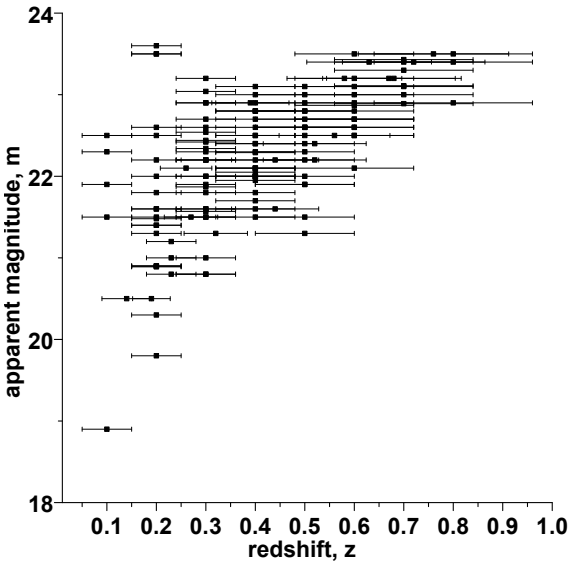

Fig. 2. Plot of SN Ia distribution on apparent magnitude dependence and redshift for ESSENCE experiment data accordingly to Asiago Supernova Catalogue.

Unfortunately the redshift data of several experiments (for example, ESSENCE – see Figure 2) contain big errors. This effect leads to several "lines" looks to areas with z=const occurs in plots of distributions on redshift. Such artefacts makes difficult to process these data and such datasets were excluded from analysis.

The Asiago Supernova Catalogue was last updated on 2 October 2017 and consist of data about 6530 supernovae.[22] The subsample of SN1a contains 3135 objects but redshifts with sufficient for analysis accuracy are known only for 2336 ones.

3. Open Supernova Catalogue

The Open Supernova Catalogue[11,12] is online collection of observations and metadata for presently 92632 supernovae and related candidates. The catalog is freely available on the web.[11] Its main interface having been designed to be a searchable table accessible on desktop and mobile devices due GitHub.[27] It represents an ongoing community driven project to collect and clean supernova metadata and observations spanning X-ray, ultraviolet, optical, infrared, and radio frequencies. At present, ∼14000 events in the catalog include light curves with at least 5 photometric points, and in total the catalogue contains ∼678000 individual photometric detections. Within the catalogue there are ∼4250 supernovae that include spectra, with ∼21000 spectra in total. In addition to the primary catalogue table containing supernova metadata, an individual page is generated for each supernova which displays its available metadata, light curves, and spectra from X-ray to radio frequencies. The information presented in the catalog is automatically rebuilt

on a daily basis and is constructed due parsing several sources, including the data presented in the supernova literature and from secondary sources such as other web-based catalogs — see, for example, Refs. 28–30. The objects included in the catalogue are intended to be entirely supernovae, i.e. the complete destruction of a star by an explosive event that may or may not leave behind a compact remnant, and objects that have been definitively identified as other transient types were actively removed. One difference between Open Supernova Catalogue and some other supernova catalogues is that authors augment the known supernovae with known supernova remnants,[31] which are thought to be supernovae but (currently) with no known associated transient. Absolute magnitudes calculated in the Open Supernova Catalogue take into account luminosity distance and redshift decrements. The Open Supernova Catalogue consists of following lists contain more than 1000 supernovae:

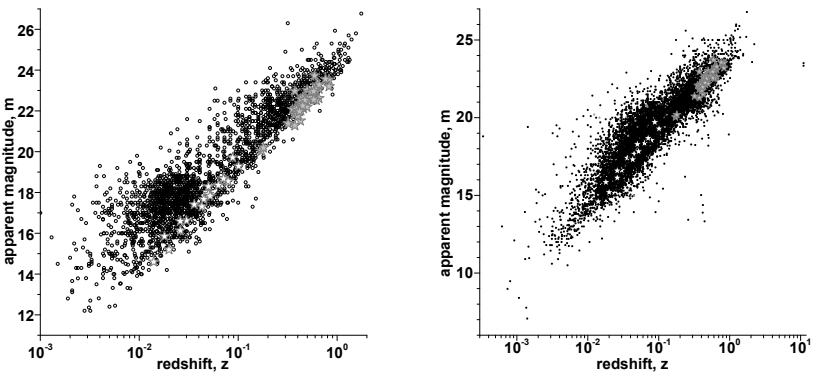
(1) The Open Supernova Catalogue,
(2) Sloan Digital Sky Survey,
(3) Latest Supernovae,
(4) JLA supernovae,
(5) SIMBAD astronomical database,
(6) Transient Name Server,
(7) THE SLOAN DIGITAL SKY SURVEY-II SUPERNOVA SURVEY,
(8) Pan-STARRS 3Pi,
(9) Asiago Supernova Catalogue,
(10) A unified supernova catalogue,
(11) NED-D,
(12) WISeREP—An Interactive Supernova Data Repository,
(13) Catalina Sky Survey,
(14) NASA/IPAC Extragalactic Database,
(15) Sternberg Astronomical Institute Supernova Light Curve Catalogue.

Other 828 supernovae lists included in this catalogue consist of 5 – 919 objects. For example, ones UCB Filippenko Group's Supernova Database (SNDB) and DES Bright Transients contain only 134 and 17 objects correspondingly. Also information about characteristics of individual supernova included in this catalogue due more than 130000 circulars, such as CBET, IAUC, ATel, etc. The Open Supernova Catalogue updated up to now[11] and its subsample of SNIa contains 16428 objects but redshifts are known only for 14607 ones.

4. The preliminary results of data analysis

This section presents the preliminary results of analysis of subsets of Ia type supernovae with known redshifts from the Asiago Supernova (ASC) and the Open Supernova (OSC) catalogues.

The distribution of SNIa on redshift and apparent magnitudes on data of these catalogues are shown on Fig. 3. Both distributions are more wide than mentioned on Fig. 1 and contain several peculiarities. Moreover, the sample OSC has deviation in the band $0.015 < z < 0.13$ contain more faint supernovae and two peculiarities in the region $0.25 < z < 0.45$. One of its contain more dim events, other contain more bright supernovae. But both analysable subsets contain data from several catalogues and at first we should exclude selection effects. These characteristic features appears at distribution on absolute magnitude and redshift too — see Fig. 4.



(a) (b)

Fig. 3. The distribution of SNIa amount on redshift and apparent magnitudes on data of following catalogues: (a) Asiago Supernova and (b) Open Supernova. Gray stars show Supernova Cosmology Project data, open ones represent subsample from the Supernova Calalan/Tololo Survey mentioned on Fig. 1.

The uncertainties in recent SN Ia cosmology analyses usually excluded due following methods[32]: probing relations between luminosity and properties of the host galaxies of the SNe (see Refs. 33, 34) and analyses of the light-curve parameters of SNe and how these parameters relate to luminosity.[35,36] Many of the associated systematic uncertainties of these effects are on the 1% level, and considering a typical SN distance modulus is measured with roughly 15% precision.[32] Also K-corrections should be used to provide a transformation between an observed-frame magnitude and a rest-frame one and account for the SN redshift (see, for example, Refs. 37–40), but object magnitude was maximally shifted for value less then 1.2 and no systematic effects were found for such corrections. Thus all uncertainties could not influence to shapes of observed distributions.

Several peculiarities in the plots of the distributions of SNIa on redshift and apparent magnitudes for HZSST and SCP experiments within Asiago Supernova Catalogue are are presented on Fig. 5. Also some peculiarities in the plots of the distributions of SNIa on redshift and apparent magnitudes for Sternberg Astronomical

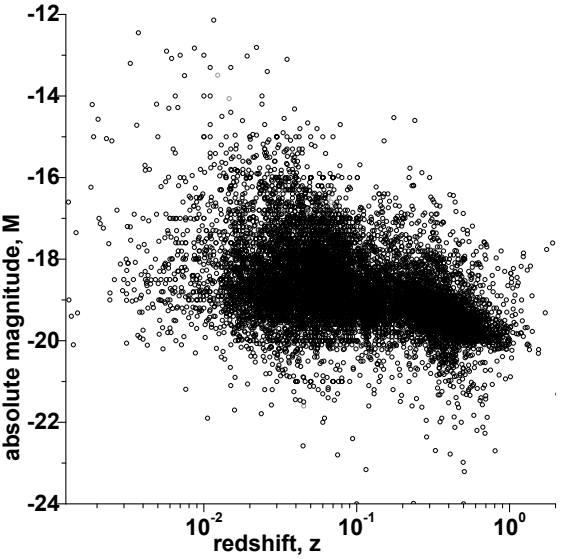


Fig. 4. The distribution of SNIa on absolute magnitudes and redshift on data of Open Supernova catalogue.

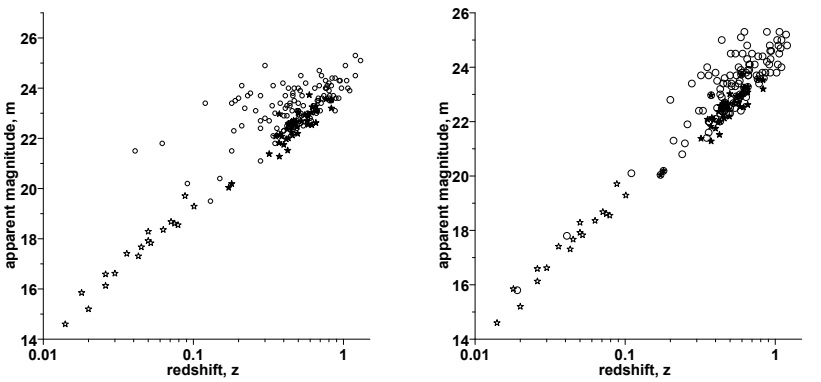

Fig. 5. Several peculiarities in the plots of SNIa apparent magnitude dependence on redshift for HZSST (a) and SCP (b) experiments. Black stars show Supernova Cosmology Project data, open ones represent subsample from the Supernova Calalan/Tololo Survey. Black stars show Supernova Cosmology Project data, open ones represent subsample from the Supernova Calalan/Tololo Survey mentioned on Fig. 1.

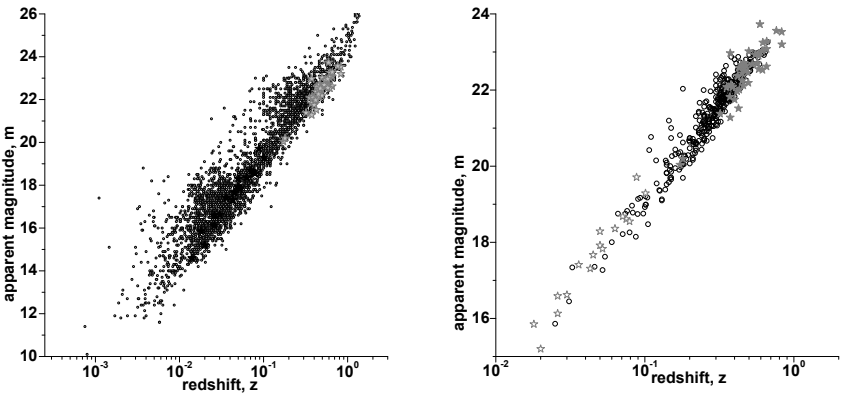
Institute Supernova Light Curve Catalogue[24] and Pan-STARRS1 (PS1) Medium Deep Survey[29,32] within Open Supernova Catalogue are are presented on Fig. 6. The discussed in the previous paragraph uncertainties could not caused such features too.

The distributions of SNIa amount on redshift on data of the Asiago Supernova and the Open Supernova catalogues are shown on Fig. 7. It is seen feature at $z > 0.2$ on Open Supernova dataset possible connected with peculiarities in the region $0.25 < z < 0.45$ on Fig. 3. Than we consider the distributions of these catalogues data on apparent magnitude — see Fig. 8. Preliminary analysis results have shown the presence of two subsets (faint_m and bright_m supernovae) at each distributions separated by $m_{fb} \sim 20$. These dual structure appear in the same distributions of catalogues composing OSC — see, for example, Fig. 9.

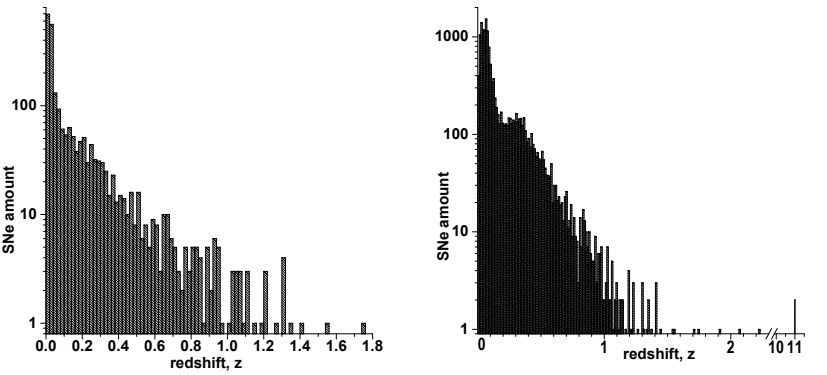


(a) (b)

Fig. 6. Several peculiarities in the plots of the distributions of SNIa on redshift and apparent magnitudes for: (a) Sternberg Astronomical Institute Supernova Light Curve Catalogue, (b) Pan-STARRS1 (PS1) Medium Deep Survey within Open Supernova Catalogue. Stars show data, mentioned on Fig. 1. Grey ones show Supernova Cosmology Project data, open and black stars represent subsample from the Supernova Calalan/Tololo Survey at panels (a) and (b) correspondingly.

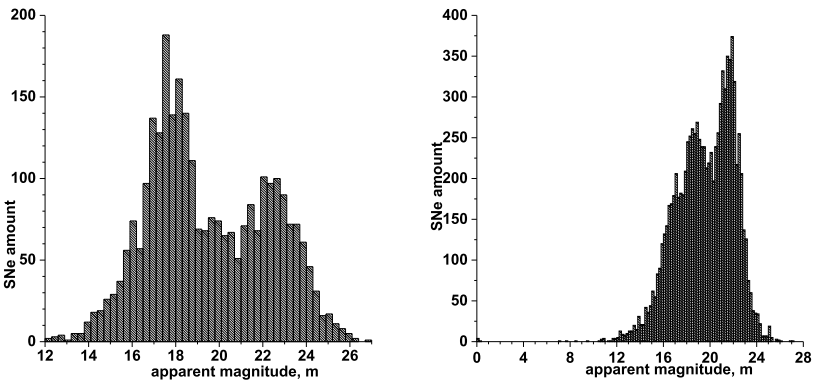
The distribution of SNIa on apparent magnitudes and angular distance to host centre for OSC objects is presented at Fig. 10. Also two areas (faint_{dist} and bright_{dist} SNIa) separated at this distribution. Preliminary analysis results allow conclude several differences between these regions and peculiarities on distributions of SNIa amount on apparent magnitude and redshift also with one on redshift. Moreover, these area not fully correspond to subsets on the distributions of apparent magnitudes from Fig. 8b and Fig. 9.

Let's consider two SNIa at $z_1 = 0.0039$ and $z_2 = 0.0037$: 1998aq and 2004W. The difference in the apparent magnitudes of these objects is ~ 6: $m1_{max} = 12.5$ (bright SNIa at Fig. 10) and $m2_{max} = 18.5$ (faint SNIa at Fig. 10) correspondingly accordingly Ref. 11. Also the same differences observed at various redshifts — see Table 1. Moreover, some hosts contain several supernovae but its apparent magnitudes could differ for $\Delta m_{onehost} \sim 2.5$. For example, galaxy UGC03432 with



(a) (b)

Fig. 7. The distribution of SNIa amount on redshift on data of following catalogues: (a) Asiago Supernova and (b) Open Supernova.

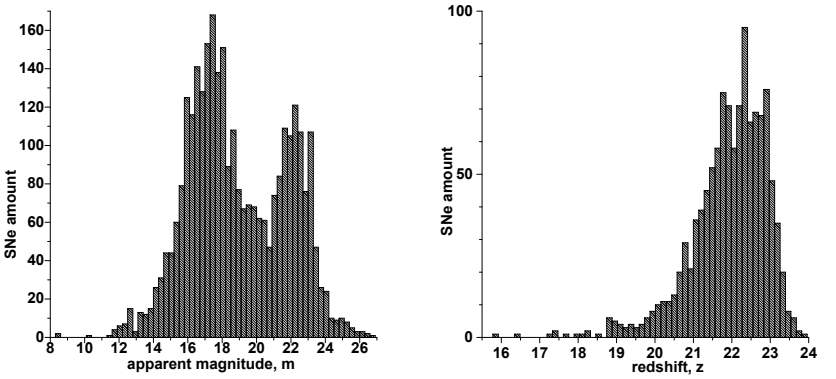


(a) (b)

Fig. 8. The distribution of SNIa amount on apparent magnitudes on data of following catalogues: (a) Asiago Supernova and (b) Open Supernova.

$m_{gal} = 15.51$ at z=0.016667 contain two SNIa 1996bv has $m_1 = 15.5$ and 2003kb has $m_2 = 18$. But usually supernovae has the same characteristics within one host. For instance, two SNIa 2004br and 1994M had m=16.3 within galaxy NGC4493 with $m_{gal} = 14.951$ at z=0.02315.

Up to now there are no evidence for an astrophysical origin of the apparent faintness of SNe Ia has been found (see Refs. 41, 42). Early only SFR (star-formation rate) of the parent galaxies was considered as influence factor for diminution of SN apparent magnitudes. Thus, dependence of distant SN Ia light-curve shapes on star-formation in the host galaxy was studied in Ref. 34, and it was found that passive galaxies without star-formation, preferentially host dimmer SNe Ia with faster-declining light-curves, while brighter events with slower-declining ones only



(a) (b)

Fig. 9. The distribution of SNIa amount on apparent magnitudes on data of: (a) Sternberg Astronomical Institute Supernova Light Curve Catalogue, (b)Pan-STARRS1 (PS1) Medium Deep Survey within Open Supernova Catalogue.

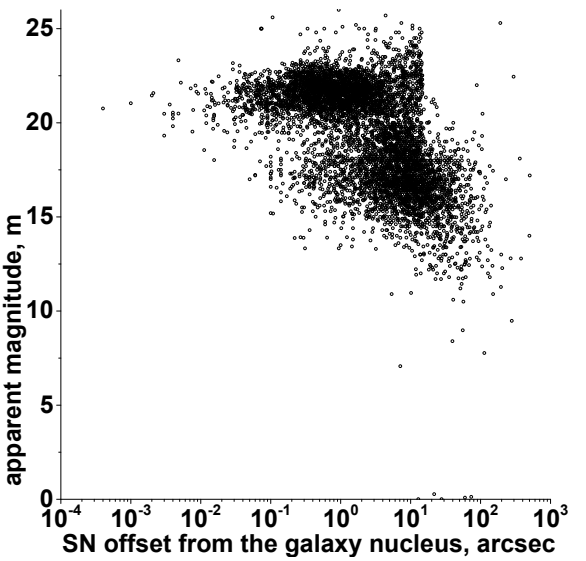


Fig. 10. The distribution of SNIa on apparent magnitudes and SN offset from the galaxy nucleus on data of Open Supernova catalogue.

originated from systems with ongoing star-formation. The mean stretch smaller for 0.08 against the typical precision on the stretch measure is $\pm 0.01 - 0.02$ at 95% confidence, which change distance modulus μ less than for 1% and could not explain the observed difference in the apparent magnitudes of SNIa $\Delta m_{onehost}$. All mentioned objects were observed by LEDA and there are no any evidences

to suppose additional matter presence between observer and SN##1–4 because additional absorption lines are absent in the spectra of these supernovae — see, for example, Refs. 25, 26.

Table 1. The examples of difference in the apparent magnitudes of SNIa at various redshifts.

#	SN	redshift z	m_{max}	Δm_{max}	m_{host}

(a) (b)

Fig. 11. The illustration of different ratio of two classes of SNIa on the distribution of SNIa on apparent magnitudes and offset from the galaxy nucleus on data of Open Supernova catalogues (open circles) in: (a) subsamples of Supernova Cosmology Project (grey stars) and Supernova Calalan/Tololo Survey (open stars) mentioned on Fig. 1 and (b) Pan-STARRS1 (PS1) Medium Deep Survey data (open stars).

Thus we have found several areas on distributions of SNIa from OSC on apparent magnitude and apparent magnitude vs offset from the galaxy nucleus. However the type Ia supernovae models not explain such subtypes. These models can be divided into two broad categories (Single Degenerate and Double Degenerate scenarios of Type Ia SNe explosions), but the authors of these scenarios concluded that both scenarios are able to correctly predict the bulk properties of Type Ia observations.[43–45] One type of progenitors are a $1.4M_{\odot}$ white dwarves that are likely created in an accretion process and self-ignite due to high central pressure/density. Other ones are white dwarves too but of considerably lesser mass ($1M_{\odot}$) can be ignited in shell

detonations or in the merging process that formed them. Both scenarios are able to correctly predict the bulk properties of Type Ia observations and widely discussed difficulties in recognition of models of concrete SNIa.

Such areas presence in various ratio in subsamples contain OSC — see Fig. 11 and could affect at power in dependence of distance modulus μ on redshift, and, correspondingly, the H_0 tension in various subsamples of SN1a data. The H_0 tension[46–48] occurs due comparison of estimation of the current expansion rate of the Netagalaxy H_0 due CMB data[50] and results of observations of astrophysical objects such as SNIa and so on — see, for example, Ref. 51. Now this tension is more than 5σ: accordingly to CMB measurements[50] a value for $H_0 = 67.36 \pm 0.54$ km s^{-1} Mpc^{-1}, but the best-fits of the SNIa data[51,52] gave the values of $H_0 = 73.2 \pm 1.3$ km s^{-1} Mpc^{-1} and $H_0 = 75.4 \pm 1.7$ km s^{-1} Mpc^{-1} correspondingly. May be such discrepancy were caused by different ratio of two SNIa classes objects in analysed catalogues and value of H_0 defined from supernovae subsets analysis became lower.

5. Conclusions

The preliminary results of the redshift distribution analysis for SNIa from the Asiago Supernova and Open Supernova Catalogues are discussed in this work. The Asiago Supernova Catalogue (ASC) was last updated on 2 October 2017 and consist of data about 6530 supernovae.[22] The subsample of SN1a contains 3135 objects but redshifts with sufficient for analysis accuracy are known only for 2336 ones. The Open Supernova Catalogue (OSC) updated up to now[11] and its subsample of SNIa contains 16428 objects but redshifts are known only for 14607 ones. It was concluded that not all experiments from the catalogue could analysed (small statistics or big errors in the determination of z caused difficulties in data representation and analysis), for example, ESSENCE experiment data within Asiago Supernova Catalogue.[22]

The shape of redshift distribution for uniform sources set in our Metagalaxy defined by cosmological parameters and properties of space. The suggestion that type Ia supernovae might be used as standard candles[1] for cosmological measurements allow considered these objects as homogeneous subsample. Firstly the parameters of our Metagalaxy Ω and Λ were determine due sample of Ia supernovae from the Supernova Cosmology Project analysis in 1998.[2] It was found due SN1a characteristics analysis that space in our Metagalaxy is Euclidean at small redshifts and de-Sitter at high ones. Now several tens of thousands supernovae' characteristics analyzed in various catalogues.

The various redshifts distributions of SNIa from ASC and OSC have analysed. Firstly it was shown that several peculiarities are presented in Ia supernovae redshift distribution. The deviation in the band $0.015 < z < 0.13$ accordingly Open Supernova Catalogue (OSC) data contain more faint supernovae. Two peculiarities also were found in the region $0.25 < z < 0.45$ on data of this catalogue. One of it's contain more faint events, other contain more bright supernovae.

Also faint$_m$ and bright$_m$ supernovae areas could be separated by $m_{fb} \sim 20$ in distribution of object amount on apparent magnitude on both catalogues data. Furthermore, the distribution of SNIa on apparent magnitudes and angular distance to host centre on OSC data also reveal two areas (faint$_{dist}$ and bright$_{dist}$ objects) and ratio between these regions populations is different for different subsamples in OSC (Pan-STARRS1 (PS1) Medium Deep Survey, ASASSN and so on).

Moreover, SNIa apparent magnitudes could differ for $\Delta m_{onehost} \sim 2.5$ within one host galaxy (for example, in UGC03432) and this difference bigger that systematic uncertainties of SN1a characteristics observations. Also there are no specific absorption lines in the energy spectra of these SNIa which exclude influence of surrounding media.

The separated peculiarities and areas could not be explained due 2 groups of type Ia SNe explosions scenarios (see, for example, Refs. 43–45) and dimming of flux due interaction of surrounding media. But it could affect at power in dependence of distance modulus μ on redshift, and, correspondingly, the H_0 tension between various subsamples of SN1a data. May be such tension was caused by different ratio of two SNIa classes objects in analysed catalogues and value of H_0 defined from supernovae subsets analysis became lower after correction for results of dependence of apparent magnitude on distance to host centre

Thus such peculiarities presence could be caused by several unknown aspects of SNIa explosions scenarios or really changing of the parameters of our Metagalaxy. Further conclusions required subsequent OSC database treatment in combination with high redshift datasets, for example, addition of Dark Energy Survey Supernova Program catalogue[53] into data analysis.

Understanding prompt emission: Where do we stand?

Asaf Pe'er

In recent years, there is a renewed debate about the origin of the observed prompt emission signal. Some authors found that synchrotron emission can dominate the spectra of several long bursts, and a recent analysis show that it may be possible to overcome the famous 'line of death' argument by a direct fitting procedure. On the other hand, several recent works showed that non-dissipative photosphere is preferred as the dominant emission model in at least 1/4 of long and 1/3 of short GRB population. Here I critically review the arguments given as well as their physical consequences. I present some recent results that show a connection between the prompt spectra and the early afterglow emission, thereby argue for an independent method of discriminating the physical conditions that result in the different dominant radiative processes.

Keywords: Gamma-ray: bursts; Radiative mechanisms: non-thermal; photosphere; polarization

1. Introduction

After more than three decades of an extensive study, there is a broad consensus about many of the observational properties defining gamma-ray bursts (GRBs), yet there is still a strong debate about the correct way of interpreting the data. One of the key problems is that when interpreting the observed data, one may conclude about the leading radiative process that produces the observed signal. However, the radiative process is the last in a long chain of physical processes, that include gravitational energy extraction, relativistic motion, kinetic energy dissipation, particle acceleration and radiative process that eventually result in the observed signal. It is therefore impossible to disentangle the radiative process from the rest of this chain. Furthermore, the underlying physics of most of these processes is still only partially understood, and is the subject of an intensive research. As a result of this complexity, the leading radiative process is still uncertain.

When looking at the data, common to all GRBs are the following. The spectra has a peak in the sub-MeV range; at lower energies (below this peak) the spectral slopes are steep, $F_\nu \propto \nu^\alpha$, with $\alpha \approx 0$, but with considerable variation between bursts, and sensitive to the fitting procedure; In several bursts a higher energy emission, at the GeV-TeV range is seen; and when making spectral fittings for bursts with strong enough signal, multiple components are identified.[1]

The lightcurve of the prompt emission, which lasts for a few- few tens of seconds generally varies at a sub-second level. The prompt phase itself is distinguished from later emission ("afterglow") by a sharp decay in the flux. In a large fraction - 10's of % of GRBs, an X-ray plateau is detected, lasting for a few thousands seconds following the prompt phase. At later phase, a decaying "afterglow" which is well modeled by a self-similar expansion phase (the "Blandford-McKee" solution) is frequently detected. Furthermore, to many nearby long GRBs, evidence for a coinciding supernovae explosion exist. Finally, the connection between GRB170817 and the gravitational wave (GW) event clearly indicates that this particular event is associated with the merger of binary neutron stars.[2]

Following these plethora of data, already in the early 1990's the basic "fireball" picture had emerged,[3–6] according to which the gravitational energy released during the collapse of a massive star (or merger of binaries) is partially converted to kinetic energy in the form of a relativistic jet. At a second stage, part of this kinetic energy is released by internal dissipation (e.g., shock waves). Part of this energy is used in a accelerating particles, which then emit the observed signal. This model could explain both the high energy ($>$ MeV) emission, which is above the threshold for pair production, as well as the high variability detected in the lightcurve. It further obtained the afterglow as a prediction, to be later confirmed after the launch of the Beppo-SAX satellite.

Despite this success, many of the basic questions remain unanswered in the framework of this model. These include: (i) the nature of the progenitor star, and the event that led to its explosion and death; (ii) the nature of the launching mechanism of the relativistic jet[7,8]; (iii) The composition of the jet, and in particular its magnetization; (iv) The structure (geometry), dynamics (velocity field) and evolution of the propagating jet; (v) The nature of the kinetic energy dissipation mechanism - while initially internal shocks were considered, it became evident that they are not very efficient energy converters,[9] and additional mechanisms were proposed, mainly involving strong magnetic fields[10,11]; This directly related to the question of particle acceleration, which is associated with this dissipation. (vi) The nature of the radiative processes involved in producing the observed signal. (vii) Addressing these questions is important in understanding the connection of GRBs to other objects of interest and field of active research, such as stellar evolution, star formation, pop-III stars, supernovae, binary star evolution, cosmic rays, energetic neutrinos, and more. Finally, complete understanding of the nature of GRBs could be useful for addressing fundamental questions in cosmology (e.g., about the expansion of the universe) and Lorentz violation.

The key problem remains that while many theories exist for each of these open questions, in order to test the theoretical ideas one has to rely on the observed signal, which is the result of the long chain of physical processes. Thus, one has to find clever ways of discriminating between the models based on the final outcome, which is not directly related to the processes themselves, and in many cases is very confusing.

2. The leading radiative processes

Very broadly speaking, there are three competing models that are in wide use in explaining the observed prompt emission signal. These are synchrotron as a leading radiative process, hadronic and photospheric model.

The idea that synchrotron emission (possibly accompanied by inverse-Compton [IC] scattering at higher energies) is the leading radiative process during the prompt phase of GRBs was in wide use in the 1990's,[12,13] and regain interest in recent years.[14–16] Synchrotron emission is indeed very ubiquitous in many different astronomical objects, and in many GRBs it provides very good fitting to the lightcurve and spectra seen during the afterglow phase. Indeed, it is a very efficient way of extracting energy from energetic electrons via radiation. Furthermore, the conditions for this process to occur, namely the existence of energetic electrons and a magnetic field are both believed to exist as part of the dissipation process of the relativistic jet's kinetic energy. This is despite the fact that a complete model for the dissipation process still does not exist.

A second possibility that had been discussed is that of a hadronic origin, namely that the observed signal is due to emission from energetic protons, e.g., via synchrotron emission,[17] or possibly photo-meson (pion production) or Bethe-Heitler (pair production) interaction of the protons with the ambient photon field. In order for this process to take place, existence of energetic protons and a magnetic field are required. While synchrotron emission from protons is considerably less efficient than emission from the electrons due to the smaller cross-section, the advantage is that observations of energetic cosmic rays provide a direct evidence that proton acceleration to high energies necessarily exist in astronomical objects, while evidence for acceleration of electrons exist only indirectly. Thus, as long as the theoretical understanding of particle acceleration is incomplete, we do have certainty that this process does exist, though of course it is not clear whether the conditions that exist during GRB prompt emission are sufficient.

The third radiative process discussed is emission from the photosphere.[18] As opposed to the previous alternatives, this can be considered as a more complete model. As part of the GRB "fireball" model, the flow begins its relativistic expansion while being optically thick. Thus, at a certain radius, it must become optically thin - this is the photospheric radius, where photons escape. Thus, a photospheric component naturally exists in expanding, (initially) optically-thick flows, and in particular as part of the GRB "fireball" model. Furthermore, as no additional kinetic energy dissipation is required, this process can be highly efficient, with 10s of % of energy being released as photons at the photosphere.[19–21] On the other hand, in order to gain high efficiency, one requires to avoid adiabatic losses, namely that the photospheric radius r_{ph} is not much above the coasting radius, which marks the end of the acceleration of the jetted material.

3. Confronting synchrotron emission with the data

Already in the 1990's, synchrotron emission was suggested as a leading radiative model to explain the prompt emission from GRBs. This is based on the fact that for relativistic expansion with $\Gamma \gtrsim 100$ and dissipated kinetic energy that is spread roughly equally between accelerating electrons and generating magnetic fields (i.e., equipartition), the observed peak energy, $\nu_m^{ob.} \sim 500$ KeV is in good agreement with the peak observed energy.

However, a closer look reveals that under such a strong magnetic field, the electrons will rapidly cool (namely, will be in the "fast cooling" regime), in which case the expected low energy spectral slope is much shallower than the observed one. This is the famous "synchrotron line of death" problem,[22] which made this model less appealing for many years.

In recent years, as the quality of data increased, several attempts were made to overcome this problem. For example, Refs.[14,15,23] argue that the low energy spectral slope (below the peak) cannot be considered as a single power low, but rather there is an intermediate break at several tens of keV. This break enables to fit the spectra with a smaller than equipartition value of the magnetic field, thereby relaxing the 'line of death' restriction. Recently, Ref.[16] correctly argued that one should not attempt to fit the synchrotron spectra to the already fitted "Band" function, as is commonly the case, but rather directly to the raw data. When doing so, they managed to provide acceptable fits to the data within the framework of the synchrotron emission model.

Despite this success, a close look reveals that in providing these fits, the magnetic field assumed was extremely weak, ~ 1 G, and the emission radius obtained from the fit was $\sim 10^{17}$ cm. These require a ratio of burst energy to ambient density of $E_{53}/n_0 \sim 10^8$, which is 8 orders of magnitude larger than inferred from afterglow data (here and below, $Q_x = Q/10^x$). Thus, while the shape of the spectra can be fitted with such a model, the values of parameters obtained make it physically unacceptable.

Similarly, the idea of synchrotron emission from protons was investigated by several authors.[17,24] The allowed parameter space in this scenario, $B \sim 10^6$ G and emission radius of $R \sim 10^{13}$ cm, are much in line with the parameter estimate from afterglow data. However, due to the much less efficient radiative energy extraction from the protons (as compared to the electrons), this scenario requires that the total amount of energy given to the accelerated protons, E_p exceeds the jet kinetic energy, namely $E_p > E_k$. Thus, this scenario challenges models of particle acceleration.

4. Confronting photospheric emission with the data

The drawbacks of the synchrotron model mentioned above, led several authors to consider photospheric emission as an alternative.[18,19,25] However, this alternative

was less appealing for many years, due to the fact that the observed spectra never appears as a "pure black body" (Planck), but rather is much broader.

This situation changes with the observation of GRB090902B.[26] This was a particularly bright burst, which showed clear evidence for a dominant narrow peak, Planck-like component. Furthermore, its extreme brightness enabled a time-resolved analysis during the onset of the prompt phase. This analysis proved that the spectrum change during the prompt phase: it started as a very narrow peak, close to a black body, and then gradually widened to resemble the common "Band" spectra. This had demonstrated the importance of **time-resolved** analysis, as an essential tool needed to understand the origin of the prompt phase.[27]

Recently, a similar analysis done on a large number of bursts[28] showed that this behavior is in fact common among pulses seen in many bright GRBs: initially, many pulses are narrow (hard spectrum) which become softer in time. This may be interpreted as a change in the leading radiative process with time: an initial thermal (or quasi-thermal) emission decays, and a later synchrotron emission becomes dominate at later times.

Furthermore, theoretical works[29–31] proved that in fact the initial expectation for a "Planck" spectrum was misleading: due to light aberration from the relativistically expanding jet, even a "pure" photospheric emission (so called "non-dissipative photosphere", or NDP) would be detected as a broader spectra, with spectral slope $dN/dE \propto E^{-\alpha}$ and $\alpha \approx 0.4$ below the peak[30] (compare with the Rayleigh-Jeans slope of $\alpha = 1$). Even this, though, is an asymptotic limit: when considering the finite detector's energy range, and the "curvature" of the spectrum near the energy peak, it is found that the expected observed values of the low energy spectral slope are even smaller than this.[32]

After considering these effects, a recent analysis show that in fact more than 1/4 of long GRBs, and 1/3 of short GRBs are consistent with having a pure thermal origin.[33,34] When adding a possible sub-photospheric energy dissipation that can potentially broaden the spectra, these fraction of course becomes much larger.

5. Applications

The realization that a photospheric emission does not appear as a textbook-solution blackbody, but rather is modified, enabled a refined analysis of the GRB properties. For example, Ref.[34] showed that the short GRB population that are consistent with having a pure thermal origin can be divided into two separate populations, clearly divided by their peak energy, E_{pk}, duration (T_{90}) and inferred Lorentz factor. One of these populations forms a continuation of the properties of the long GRB population, while the other one is separated. This result thus suggests that the classical separation of the GRB population to "long" and "short", which is based nearly entirely on the duration (T_{90}) is likely insufficient, and additional criteria are needed. Part of the "short" GRB population is in fact a continuation of the long GRB population.

One of the most puzzling questions is the observed isotropic energy-peak energy ("Amati") or luminosity - peak energy ("Yonetoku") relations reported. One appealing advantage of the photospheric emission model is that it may provide a natural explanation to the observed correlation, as due to viewing angle effect. Observers at different angles see the photons with different Doppler shifts, as $\nu^{ob.} = D\nu'$ (here, $D = [\Gamma(1 - \beta\cos\theta)]^{-1}$ is the Doppler shift, and primed quantities are in the comoving frame). Using the invariance of L'/ν^2, the observed luminosity is related to the peak energy via $L^{ob.} \propto (\nu^{ob.})^2 \sim E_{pk}^2$, providing a natural explanation to the Yonetoku relation.[35]

While this may provide a very elegant explanation to the observed relation, this analysis relies on the underlying assumption that the comoving luminosity and comoving temperature are related via $L' \propto (T')^2$, while one expect the comoving temperature to decay with radius.[36] Thus, an underlying assumption here is that the photospheric radius is roughly similar in many different GRBs, which is unknown. I further discuss this issue in section 7 below.

6. Broadening of the photospheric emission

Numerical simulations of jets propagating inside and outside the collapsing star[21,37–39] clearly demonstrate that part of the jet kinetic energy is dissipated at various radii, in many cases below the photosphere. Such a dissipation can result from recollimation shock with the collapsing stellar material, magnetic energy dissipation or internal collisions. The resulting spectra was studied by various authors, e.g., Refs.[19,25,40–42] to name a few.

In this scenario, the dissipated energy is used to heat the plasma, which is then characterized by 2 temperatures: an electron temperature T_e which is greater than the photon temperature. Under these conditions, the resulting spectrum above the thermal peak is mainly due to inverse Compton (IC) scattering of the photons inside the plasma. It depends mainly on 2 parameters: the number of scattering (namely, the optical depth at the location of the energy dissipation) and the available energy, namely the ratio between the electron and the photon field energies, u_{el}/u_{ph}.

Below the thermal peak, one may expect an additional modification due to synchrtron emission from the (newly) heated electrons. Above the thermal peak, multiple scattering broadens the peak; if the optical depth is high enough, a new thermal peak would emerge, at higher temperatures. But in the intermediate case, $\tau \lesssim 100$, there is no simple analytical solution, and one has to refer to numerical works,[25,30,43–45] which show the plethora of possible spectra.

Another, independent broadening mechanism to be considered is geometrical broadening, which is the relativistic version of the "limb darkening" effect. Even for a spherical explosion, the photospheric radius is a function of the angle to the line of sight, θ, via $r_{ph}(\theta) \propto \left(\Gamma^{-2} + \theta^2/3\right)$, where Γ is the Lorentz factor of the flow.[29] This implies that photons emerging from angles $\theta > \Gamma^{-1}$ escape the expanding plasma at large radii. Furthermore, the photons have a finite probability of

escaping the expanding plasma at different radii, leading to the concept of "vague photosphere".[29,30] This distribution inherently results in broadening of the emerging signal.

The explosion, though is not expected to be spherical, but rather a jet-like, with a finite jet opening angle. The flow properties may best be approximated as $\Gamma(\theta) \propto \Gamma_0/\sqrt{(1+(\theta/\theta_j)^{2p}}$ (see simluation by[38]), where θ_j is the jet opening angle, and p represents the "steepness" of the velocity profile. In this case, the observed signal depends, in addition, on the viewing angle, θ_v.[46] This scenario naturally leads to an enhancement of the limb darkening effect, as the Doppler boost of photons emitted from larger angles and larger radii is considerably smaller than that of photons emitted from the central jet regions. As a result, these photons are observed at much lower energies, and the observed spectrum – purely from the photosphere – is nearly flat for a wide energy range, for different jet parameters and viewing angles.[46]

This scenario naturally results in a polarized signal, for an off-axis observer. The scattered photons are 100% polarized, the photon field is anisotropic near the photosphere, and the rotational symmetry is broken for $\theta_v > 0$ (observer off the jet axis). The resulting polarization can reach 10's of % ($Q/I \lesssim 40\%$ for an off-axis observer, with flux that is still detectable). Another prediction of the theory is $\pi/2$ shift in polarization angle,[47] with spectra that is so smeared it looks very different from a pure "Planck". Indeed, such a polarization angle change was recently detected by the ASTROSAT mission,[48] though its exact origin is still debated.

7. Back scattering photospheric model

An underlying assumption of the discussion above is that the source of photons is the expanding plasma inside the jet: either via acceleration of particles that radiate synchrotron, or that the photons are coupled to the plasma below the photosphere. However, one may envision a different scenario, in which, following an initial expansion of the jet which clears a cavity inside the collapsing star,[39,49] continuous production of pairs via, e.g., neutrino annihilation occurs close to the newly formed black hole. These pairs then annihilate to produce photons. The photons, in turn, propagate inside the empty funnel until being scattered by the expanding stellar "cork" (made of stellar material cleared by the jet and by the surrounding cocoon).

In this scenario, therefore, the photons are back scattered by the relativistically expanding cork ahead of them from behind. Due to the relativistic motion of the cork, in the frame of an observer at infinity these photons are scattered in the forward direction, at some angle to the cork propagation direction. Due to the different Doppler boosts, photons scattered at different angles are seen at different energies. The obtained spectra integrated over different viewing angles, $dN/d\epsilon \propto \epsilon^1$ for energies below the peak, resembles the observed one.[50] For hot cork, multiple scattering inside the cork leads to photon energy gain,and the high energy spectral slope obtained is also similar to the observed.[51]

Perhaps the greatest achievement of this model is its ability to naturally explain the $E_{pk} - E_{iso}$ correlation ("Amati" relation) as a natural outcome of observers located at different angles, without the need to invoke any additional underlying assumptions, as in the "classical" photospheric model discussed above.

8. Summary

Understanding the origin of GRB prompt emission remains one of the big puzzles in the study of gamma-ray bursts. It is of particular importance, due to the fact that understanding it directly enables to probe the key physical ingredients involved in producing the GRB phenomena.

In recent years, there is a healthy debate between different ideas of interpreting the observed signal. As it turned out, different models both seem to produce key parts of the spectra. However, the physical parameters required for the synchrotron radiation to be the dominant mechanism seem at odds with afterglow observations.

Photospheric emission model turned out to be much more complicated than initially thought. Various effects and mechanisms act to modify the observed signal, which does not resemble the textbook "Planck" function. Among them are the finite detector's bandwidth, the jet velocity profile and sub-photospheric energy dissipation. For jet viewed off-axis, as in the vast majority of jets, the observed signal may be highly polarized. Another major advantage is the ability to explain the observed $E_{pk} - E_{iso}$ correlation, which is a natural outcome of a model in which the source of photons is not relativistically moving, but rather the photons are back-scattered from the expanding cork.

Acknowledgments

I wish to thank Damien Begue, Husne Dereli-Begue, Liang Li, Felix Ryde, Vidushi Sharma and Mukesh Vyas for many helpful discussions. This talk is attributed to the memory of Prof. David Eichler, a collaborator and friend, who sadly passed away earlier this year.

Although the observed spectra for gamma-ray burst (GRB) prompt emission is well constrained, the underlying radiation mechanism is still not very well understood. We explore photospheric emission in GRB jets by modelling the Comptonization of fast cooled synchrotron photons whilst the electrons and protons are accelerated to highly relativistic energies by repeated energy dissipation events as well as Coulomb collisions. In contrast to the previous simulations, we implement realistic photon-to-particle number ratios of $N_\gamma/N_e \sim 10^5$ or higher, that are consistent with the observed radiation efficiency of relativistic jets. Using our Monte Carlo radiation transfer (MCRaT) code, we can successfully model the prompt emission spectra when the electrons are momentarily accelerated to highly relativistic energies (Lorentz factor $\sim 50-100$) after getting powered by $\sim 30-50$ episodic dissipation events in addition to their Coulomb coupling with the jet protons, and for baryonic outflows that originate from moderate optical depths $\sim 20-30$. We also show that the resultant shape of the photon spectrum is practically independent of the initial photon energy distribution and the jet baryonic energy content, and hence independent of the emission mechanism.

Keywords: Gamma-ray burst: general; methods: numerical; radiation mechanisms: thermal; radiative transfer; scattering.

1. Introduction

The radiation mechanism responsible for the prompt emission of long-duration GRBs has remained elusive ever since their discovery. The observed photon spectrum has a distinctly non-thermal shape and is generally modelled using the Band function,[1] which is a smoothly connected broken power-law with peak energy $E_{\rm peak} \sim 300\,{\rm keV}$ and the low/high energy dependence[2,3] given by $f_\nu \propto \nu^0/f_\nu \propto \nu^{-1.2}$. A robust radiation mechanism should explain the non-thermal features observed in the prompt emission spectrum in a self-consistent manner. The two most widely explored models to this end are the synchrotron and photospheric models.[4–6]

In the synchrotron model, the electrons accelerated by either internal shocks[4] or magnetic reconnection[7] produce the prompt radiation via synchrotron emission process.[8] Although this model accounts for the non-thermal nature of the photon spectrum, it cannot explain the high observed radiation efficiencies up to few tens of percent.[9] Moreover, the observed hard GRB spectra at low energies cannot be explained with synchrotron emission process.[10,11] Owing to these shortcomings of the synchrotron model, many researchers have considered photospheric emission model

in more detail.[12,13] Unlike the synchrotron model, photospheric model naturally explains the observed high radiation efficiencies and spectral shape is completely determined by photon-matter interactions irrespective of the dissipation mechanism involved. Although there have been many successful attempts to explain the high-energy non-thermal behaviour using sub-photospheric dissipation,[7,14,15] explaining the low-energy non-thermal tails has turned out to be really challenging.[16]

Here we study the sub-photospheric Comptonisation of synchrotron seed photons[5,17] to find the plausible conditions under which both low/high-energy non-thermal behaviour and observed peak energy can be explained self-consistently. The particles in the jet are accelerated to relativistic energies by repeated dissipation events such as internal shocks[4,18] or magnetic reconnection.[7,19] The photons continue to scatter electrons while the outflow is optically thick and gain energy until either the average photon energy matches that of the electrons or the outflow becomes optically thin so that the photons escape the photosphere. We determine a correlation between the number of reheating events and initial optical depth, and perform an exhaustive parametric space search to obtain a Band-like photon spectrum. We also perform analytical calculations to examine the evolution of photon energy spectrum with multiple scatterings and validate the numerical results.

2. Energy requirement for photons and particles

We first estimate the average energy $E_{\gamma,\rm avg}$ that the jet photons need to have to generate a Band-like output spectrum. As most of this energy is transferred by hot electrons through Comptonisation, this also places a threshold energy requirement $\gamma_{e,\rm crit}$ on the electrons. As the electrons are maintained at $\gamma_e \sim \gamma_{e,crit}$ by energy gained from either Coulomb collisions or repeated dissipation events and subsequent cooling due to IC, we further constrain the injected energy and the number of episodic dissipation events required.

2.1. *Analytical estimate for* $E_{\gamma,\rm avg}$ *and* $\gamma_{e,\rm crit}$

The observed photon spectrum has a Band-like shape with a low/high-energy dependence, $f_\nu \propto \nu^0/\nu^{-1.2}$ in the energy range $\sim 10\,\rm keV - 300\,keV/\sim 300\,keV - 10\,MeV$, where f_ν denotes the photon flux per unit frequency. The average observed energy of each photon in the lab frame is then $E'_{\gamma,\rm avg} \sim 300\,\rm eV$, assuming a jet bulk Lorentz factor $\Gamma = 300$. Equating the total energy content of the photons with the maximum energy that the electrons can deposit via Comptonisation gives

$$N_\gamma E'_{\gamma,\rm avg} = N_e(\gamma_{e,\rm crit} - 1)m_e c^2 \left(\tau_{\rm in} t'_{\rm dyn}/t'_{\rm IC}\right), \quad (1)$$

where τ_{in} is the initial optical depth, $t'_{\rm dyn/IC}$ is the dynamical/inverse-Compton (IC) timescale and $\tau_{\rm in} t'_{\rm dyn}/t'_{\rm IC} \sim$ number of times the electrons interact with photons during jet expansion. The characteristic dynamical timescale is $t'_{\rm dyn} = R_{\rm in}/\Gamma c$ while the IC timescale is $t'_{\rm IC} = 3(\gamma_e - 1)m_e c/4U'_\gamma \sigma_T \gamma_e^2 \beta_e^2$. Here, $R_{\rm in}$ is the photon injection

radius, σ_T is the Thomson cross section, γ_e is the electron energy and U'_γ is the radiation energy density. Substituting typical GRB parameters gives $\gamma_{e,crit} = 1.352$.
